Each processor looks at the pointer on the lowest-numbered page it can see. There are three possible states for the pointer. First, if it points to the page itself, the processor has found the communication page and may now proceed to interact with other processors about the common environment. If it points to a higher-numbered page, the processor may just fix the pointer, as the requirement that the communication page be lowest makes this case inconsistent. If it points to a lower-numbered page, the processor must attempt to check if the indicated communication page is active. It must assume that the data might simply be old or invalid and must time it out using a dedicated entry in a special array of timers which is allocated on each page. The processor increments the timer, and, if it ever reaches a certain threshold, unilaterally fixes the communication pointer, and starts to use this page for communication. The processor is prevented from doing this by any other processor which is successfully using the lower-numbered communication page; such a processor will periodically zero all the timers in the array for each memory page in the system before the threshold is reached.

Consider what happens during various possible hardware failures. If the memory bus containing the communication page is lost, all processors will attempt to establish a new communication page on the other bus. Using their timers on the new lowest page (which initially points to the old one after the failure), they await the threshold. No one is holding the timers to zero, so the new page becomes the communication page when some processor's timer first runs out.

A processor blinded to the communication page by a bus or coupler failure will try to establish a higher-numbered page for communication. From the point of view of the failing processor, this case is indistinguishable from the previous case, where the common bus failed. Since the rest of the processors are satisfied with the communication pointer, they will hold all timers to zero, and the failed processor will never be able to change the communication page pointer. If the processor sees a set of pages disjoint from the rest of the system, it behaves as if no other processors are running, but there is no memory where it may interfere and now we have two systems operating independently. In this case it is likely that the two systems will interfere over other resources; since multiple failures are required for this situation to occur in a Pluribus, we choose not to attempt recovery here.

The consensus mechanism

When configuration data must be updated, it is crucial to coordinate the Pluribus processors before making the modification. The mechanism to accomplish this goal we call consensus. Each stage has a consensus which is maintained as part of its environment. The first step in forming a consensus is to determine the set of processors that is executing the corresponding stage. This set has certified the primitives necessary to maintain successfully this stage's portion of the configuration map. In order for the system to respond to failures, the consensus must be kept current—new processors must be able to join it rapidly and processors that may

have halted or ceased to run the stage must be erased from the set.

Each processor, based on its hardware address in the Pluribus, is assigned a bit in three consensus arrays, called "next," "smoothed," and "fix-it". As part of running the corresponding stage, every processor periodically sets its bit in the next consensus array to show that it wishes to participate in the consensus. After enough time has elapsed for each properly running processor to set its bit, this array is copied into the smoothed consensus and cleared. The set of processors in the smoothed array will then be used as a basis for decisions to reconfigure some portion of the resource map.

Any processor which wishes to modify some configuration information sets its bit in the appropriate fix-it array. Processors that agree with the configuration map clear their bits, and bits corresponding to processors not in the smoothed array are also cleared.

In effect, the bits in the fix-it array represent the votes of the individual processors in favor of a potential modification. In most cases, it is desirable that all processors agree before making the change. All processors wait until the fix-it array matches the smoothed array before implementing the fix. Other modifications might require only majority or two-thirds agreement. The choice of policy often depends on some trade-off between resources (e.g., should we use more memory or more processors?). The Pluribus approach allows us to make this choice independently at each stage.

Since each processor in the Pluribus performs each stage of the checking code, the consensus mechanism provides the coordination needed to change the configuration map gracefully. As one of its stages detects a failure, the processor sets the appropriate fix-it bit and disables the following stages. When enough processors detect the failure they implement the fix to the configuration map. Now these processors can complete the later stages, devoting their attention to any further changes required by the failure. A processor which sees a different picture of the resources and cannot reach agreement with the rest of the system hangs forever at the point of detecting the discrepancy. This technique effectively prevents the processor from damaging the system.

Application-dependent checking

In general, it is desirable for the application system to perform its own checks before initiating or resuming normal operation. The last stage provides a mechanism which polls application-oriented processes to perform consensus-driven checks and repairs of their own data structures. This stage uses the results of the hardware (application-independent) discovery stages to certify its own data structures. For example, it could allocate or deallocate device parameter blocks as the devices are discovered or disappear and initialize spare memory pages for use as data buffers as they become available. User-written reliability checks can be performed on any of the application data structures, and the appropriate reinitialization invoked to remedy failures.

Occasionally, it is possible for a processor checking application data structures to implement minor repairs to the data structures unilaterally. For major reconfigurations of the data structures, such as complete application system reinitialization, the checking routines must signal to the stage dispatcher that consensus is needed. The last concurring processor is then permitted to perform the reinitialization routine. Just as the early stages guarantee the hardware map, the application-dependent routines have the consensus mechanism at their disposal to validate the system data structures before entering the system. In addition, the application system data structures are rechecked periodically during normal system operation.

AN EXAMPLE OF APPLICATION RELIABILITY

We use two general techniques to ensure the validity of data structures in the Pluribus. First, redundant information, where it exists, is checked for discrepancies, and appropriate action taken if they exist. Second, since detailed examination of all data for inconsistency is deemed impossible for any system of non-trivial complexity, we use watch-dog timers to ensure the correct operation of the application system at various levels. As an example, we will discuss the buffer management strategy for the Pluribus IMP system.

Buffers in the Pluribus IMP circulate through the system from queue to queue; in some cases, they may be shared between two or more processes. Since a compromised queue structure may, in general, rapidly degrade the performance of the system, elaborate checking methods are built into the IMP program at various levels. In particular, we must be able to detect queues that are crossed or looped and buffers that have been lost (are on no queue at all).

Associated with each buffer in the system is a set of use bits corresponding to various processes that consume buffers. Any process that enqueues a buffer for some other process first sets the use bit for that process. When a process dequeues a buffer, the appropriate use bit must be on or the buffer will not be processed. As a special case, buffers on the system free list must have all their bits turned off. The buffer-freeing routine only returns a buffer to the free list if the last remaining use bit is that of the freeing process.

This technique intentionally generates redundant information and continually validates it as a buffer circulates through the system. In other words, the existence of a buffer on a queue informs the system that some processing is desired for that buffer. In principle, the use bit signals the same thing. Each buffer-processing routine could scan all the buffers in the system for those with its use bit set, but such strategy would clearly be inefficient. The redundancy check gives preference to neither the queue nor the use bit as an indication of need for service, but rather requires agreement between the two indicators. When they disagree, the system assumes that a failure has indeed occurred and attempts to correct it by forcing the queue to be empty, so that the effects of the failure can be contained as much as possible.

The use bits allow the prompt detection of looped and

crossed queues. In addition, an improper buffer pointer will often lead to a failure of the use bit check. We must also consider the case of a buffer which has been lost from all queues. This condition could arise due to a program bug or as a result of a queue being emptied after a use bit failure. We could employ a classical garbage-collection scheme for this purpose; unfortunately, the demand on buffers is often large in a high-speed communication system, and the requisite locking of the buffer resources during such a garbage collection would likely result in lost inputs.

The recovery scheme we have chosen is a watch-dog timer mechanism. Each buffer has associated with it a flag which is set by normal activity of the buffer, which in this case is defined to be the periodic appearance of that buffer on the free list. Whenever a buffer is freed, its flag is set. In addition, flags for all the buffers on the free list are set periodically. In the high-speed communications environment, where data passes through a network node very rapidly, each buffer must appear on the free list at least once every two minutes. Therefore, each buffer flag is checked every two minutes to be sure it is set, and then cleared. A zero flag indicates that the buffer has dropped out of normal activity, and the buffer is unilaterally freed and its use bits cleared. In this way, any lost buffer is detected within at most four minutes and returned to normal usage.

FAILURE DIAGNOSIS IN THE OPERATIONAL SYSTEM

The Pluribus design permits the continuation, after perhaps a brief outage, of normal system operation following the failure of any single component. The component might be a single bit of memory or an entire common memory bus. Much of the responsibility for ensuring recovery from failures lies in the software; very little hardware beyond that necessary to construct a multiprocessor should be required.

The initial Pluribus systems performed their recovery quite well in many cases. Minor problems were often repaired so effectively that the maintainers and users were never aware of the repair being carried out. Even following drastic failures, such as the loss of a common memory bus, normal system operation was restored within seconds. As we gained experience with the operational systems, however, certain deficiencies in our strategies became clear.

In some failure cases, one repair would lead to another, until eventually a fairly major reinitialization would be performed, with obvious effects on the users of the system. Unfortunately, the massive recovery often destroyed the evidence of the original failure, or occurred too late to permit effective diagnosis. While the stated goal of restoring the system to normal operation was achieved, we were left without any idea of why the reinitialization was necessary. This was particularly frustrating when the frequency of the reinitialization was on the order of hours or days.

In other cases, normal operation seemed to continue, while some hardware failure occurred undetected. Either the failure was covered by effective recovery at a fairly low level in the system or it occurred in a redundant portion of the hardware which was not being exercised. A second failure, in conjunction with the first, would remove the last copy of some critical resource, causing the system to fail.

Such experiences have led us to an improved design for the recovery software. Any recovery operation is reported by the system using a system trap (i.e., a supervisor call). Even in those cases where an error might occur occasionally in normal operation, we prefer to report the failure and filter out the non-important occurrences of the report. In this way, an incipient hardware failure is often detected early enough that it can be remedied well before the inevitable second failure brings the system down.

We have also adopted strategies which exercise all the hardware in the machine periodically. Including a spare copy of some resource helps the system recover only if that spare resource is known to be good. Therefore, we force the system to exercise all of its resources from time to time. In some cases we use manual procedures, but the tendency has been to include automatic rotation procedures in the operational system software.

One beneficial side-effect of this policy is that the operational program has become the best diagnostic for the hardware. Traditionally, some of the most subtle hardware failures occur during operation of the application system, though the hardware diagnostic program never detects any errors. By augmenting the operational system with diagnostic capabilities, we are able to isolate hard-to-find or intermittent failures, sometimes even without interrupting normal operation. The system-integration personnel routinely use the operational program as the last step in constructing a new Pluribus machine.

Understanding the nature of a failure in the running system requires fairly accurate knowledge of the state of the machine at the instant of the failure. The initial implementation of the trap mechanism recorded only the code number of the trap, which processor or set of processors had encountered it, and a total occurrence count. More recently, we have augmented the trap mechanism to allow for saving a larger snapshot of the instantaneous state of the processor, including such information as the contents of the general registers, the global system time, map register settings, the last value read from the PID, and other important local data. These snapshots allow us to examine critical information about the failure after the fact, while permitting the recovery code to take effect and normal operation of the system to proceed.

To aid in the development of new software, we have also included a password-protected facility whereby a processor which has detected a serious malfunction may signal all the other processors to stop before obtaining their next task from the PID. This capability allows examination of the failure in the global environment, which might otherwise be repaired by recovery code or cause some other more dramatic failure. These mechanisms combine to provide the programmer with a reasonably tractable debugging environment. In particular, such facilities have greatly aided software development for new Pluribus applications.

SUMMARY

The structure of the Pluribus operating system has been described above, together with some techniques for software reliability and fault diagnosis. We have built Pluribus systems for several applications, and our experience has been favorable on the whole. While the emphasis of our applications has been upon communications, we expect our techniques could be applied to many different uses. Recoverable faults arise in most computer applications, and we feel that non-redundant computer systems would benefit from the incorporation of recovery-oriented operating systems such as that of the Pluribus.

ACKNOWLEDGMENTS

Much of the initial development of the Pluribus computer was supported by the Information Processing Techniques Office of the U.S. Defense Advanced Research Projects Agency, under Contract Numbers DAHC15-69-C-0179, FO8606-73-C-0027, and FO8606-75-C-0032, and by the Defense Communication Agency under contract DCA200-C-616. Additionally, a number of the application systems were developed under contracts from various branches of the U.S. Government.

Many people have contributed to the Pluribus project; Frank Heart has led the effort since its inception. Will Crowther, Mike Kraley, and Bill Mann in particular have contributed many of the ideas incorporated into the Pluribus operating system. Jane Barnett and Bob Brooks provided encouragement and help with the actual writing of the manuscript.

MTR—A tool for displaying the global structure of software systems

by GUY de BALBINE
Caine, Farber & Gordon, Inc.
Pasadena, California

INTRODUCTION

The purpose of this paper is to propose a new computer based method for displaying the global structure of software systems. We are particularly motivated by finding a manageable representation of the directed graph (digraph) of calls within a design or an executable program, each directed edge representing one or more calls from a procedure to another. We expect such a representation to provide a better understanding of the relationships between various components of a software system and to lead to the design of systems that are better organized.

The directed graph of calls within a program is an example of what we call invocation digraphs. Invocation digraphs are a particular class of directed graphs with at most one directed edge from one vertex to another or to itself. These invocation digraphs constantly arise during the design, implementation and maintenance of software systems.

Usually, invocation digraphs are drawn by hand if they are drawn at all. "Structure charts"[14] provide the most familiar example of a graphic representation which is visually informative. However, such a technique is of limited value in practice because of the considerable effort required to draw even a graph of modest size—and large graphs are the most interesting because they are the least understood. One of the major difficulties is deciding where to position adequate size boxes on the page so that the resulting structure becomes visually informative instead of hopelessly confusing. Ofter, a judicious positioning of the boxes becomes apparent only after the first charting is essentially complete. Even if a good layout is obtained, the charts remain cumbersome and expensive to maintain and modify.

One obvious solution is to try mechanizing the whole drafting process. This certainly alleviates the manpower problem but leaves other problems still unsolved—how to dimension and position boxes, draw edges that do not cross over at random, handle the off-page connector problem and cope with the lack of adequate graphic devices at many installations.

As an alternative, we propose an extension of the simple yet powerful indented representation of trees, capitalizing on the observation that most invocation digraphs of interest are loop free or almost loop free. We call this one dimensional, indented representation the Modular Tree Representation (MTR) of the invocation digraph.

In an MTR, the position of each node (procedure, subroutine, . . .) is chosen systematically to reflect its relationship with other nodes in the structure. Although the connections are not explicitly materialized by lines, the specific location of each node in the MTR implies to the reader that certain connections must exist. Thus, the MTR emphasizes the global structural properties of the digraph while relegating specific path connections to a secondary role. We believe this approach to be practical because invocation digraphs are most often used to grasp a morphological "understanding" of the structure of a software system rather than to trace through many individual paths.

DEFINITION OF INVOCATION GRAPHS

We start with a set of components numbered 1 through n. Components is a loosely defined term which will mean subroutines, procedures, design segments,[2] . . . , depending upon the context.

Let us construct the *invocation graph G* as follows:

- create for each component an associated vertex, e.g., v_i corresponds to the ith component;
- for all pairs of vertices (v_i, v_j) draw a directed edge from v_i to v_j if there is at least one invocation of the jth component from the ith one.

In some simple cases, the invocation graph may turn out to be a tree but, in general, we expect a directed graph, some of its vertices having indegrees greater than 1. Invocation graphs are a subset of directed graphs since there can be at most one edge between any pair of vertices, distinct or not. Notice that invocation digraphs have loops if coroutines or recursively callable components are present.

We shall use the $n \times n$ adjacency matrix A whose element A (i,j) has the value

1 if there is a directed edge from v_i to v_j
0 otherwise

The reachability matrix R is an $n \times n$ matrix such that its element R (i,j) has the value

1 if there exists a directed path, i.e., a sequence of directed edges from v_i to v_j
0 otherwise

Invocation digraphs usually have only one begin node v_1, i.e., v_1 is the only vertex in G with indegree 0. But they may have several or even none at all if every component is at least invoked once.

If several vertices with indegree 0 exist and/or the graph is not at least weakly connected with begin node v_1 (i.e., the corresponding undirected graph is not connected), we create another vertex v and draw a directed edge from v_0 to each node with indegree 0. We then determine if all vertices are reachable. If some vertices are still not reachable from v_0, we select any such vertex, connect v_0 to it with a directed edge and compute the reachability again. This process repeats until all vertices are reachable from v_0. Although this algorithm clearly forces the graph to become weakly connected (which is our requirement), it is inadequate in practice. In the appendix, we shall present some refinement to this algorithm guaranteeing that the number of vertices artificially connected to v_0 is minimal. At any rate, we can now renumber the vertices so that v_0 becomes v_1 and so forth. Thus, we have obtained a weakly connected invocation graph with begin node v_1. Without loss of generality, we can, therefore, turn our attention to weakly connected invocation digraphs with begin node v_1 only.

MTR PROPERTIES

The MTR is an extension of the common indented representation of trees. By design, the MTR becomes the preorder representation if applied to a tree. In that case, the tree is traversed from left to right, visiting descendants first. Each vertex traversed is listed on a new line, horizontally indented to show its distance from the root. An example is shown in Figure 1.

The purpose of the square bracket to the left of v_1 is to make the scope of v_1 visible, i.e., to identify the set of vertices that can only be reached by traversing v_1. Since v_1 is the root of the tree, every vertex is enclosed in the outermost and only bracket. The role of brackets will become obvious when we examine more complex MTR examples later.

In practice, invocation digraphs are rarely as simple as trees. As soon as a procedure is called from two distinct procedures, the invocation graph no longer is a tree. Due to the non-recursive nature of most software systems being built, we expect invocation graphs to be acyclic or almost acyclic.

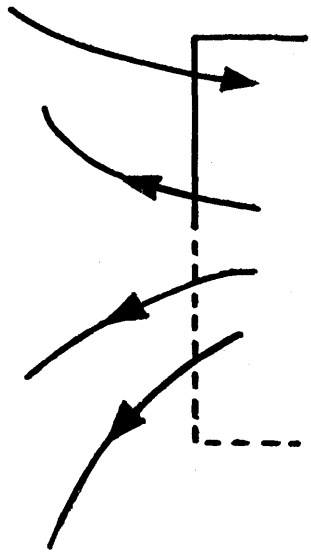
This observation is crucial for the MTR. Notice that it is simply a paraphrase of the fact that most software systems are hierarchical in nature.[3] They have a top and a bottom—high level components and low level ones. Thus, we can expect a representation that displays these hierarchical properties to be useful both at the global and local levels.

To introduce the MTR of a non-trivial digraph, let us informally examine Figure 2. Looking at part 1 of Figure 2 first, we have separated the subgraph into four disjoint trees by breaking the incoming edges to vertices with indegrees greater than 1.

The four subtrees rooted at vertices 1, 6, 9 and 11 each have an associated bracket in the MTR. These brackets allow the following "understanding" of the graph:

—1 calls 2, 3, and 4 which are called by no one else.
  2 calls 5 and 6, but 6 is called elsewhere
  . . .
—the trees rooted at 6 and 9 are referred to by the tree rooted at 1 (because they are in the broken part of the bracket associated with 1)
—the tree rooted at 9 is referred to by the tree rooted at 1 but also by the tree rooted at 6 (since it is in the broken part of the bracket associated with 1 but also indented to the right of 6)
—the tree rooted at 13 is only referred to by the tree rooted at 9 (since it is in the broken part of the bracket associated with 9)

In particular, we can infer from the MTR that the tree rooted at 13 is not known outside the "scope" of 9. Similarly, the trees rooted at 6 and 9 are not known outside the "scope" of 1. This property of not being known outside the "scope" of a particular vertex is fundamental for using the MTR. Each square bracket shields the vertices that are defined within it, except the root, from outside references, i.e., there are no incoming edges except possibly to the root. On the other hand, references from within the square bracket to outside vertices are freely permitted.



In order to arrive at this MTR, we have made use of the dominance concept. It can be summarized as follows: in a weakly connected graph with a begin node of v_1, we say

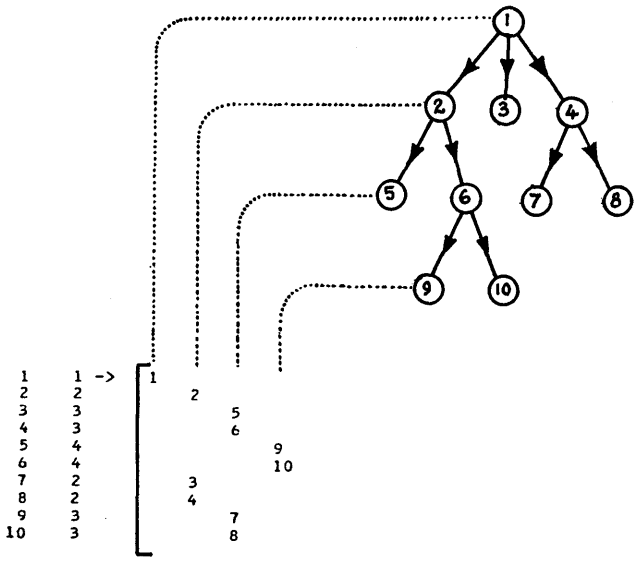


Figure 1—MTR of a tree

that v_i *dominates* v_j if $v_i \neq v_j$ and every path from the begin node v_1 to v_j contains v_i.

We say that v_i *directly dominates* v_j if:

(i) v_i dominates v_j;
(ii) if v_k dominates v_j and $v_k \neq v_i$, then v_k dominates v_i.

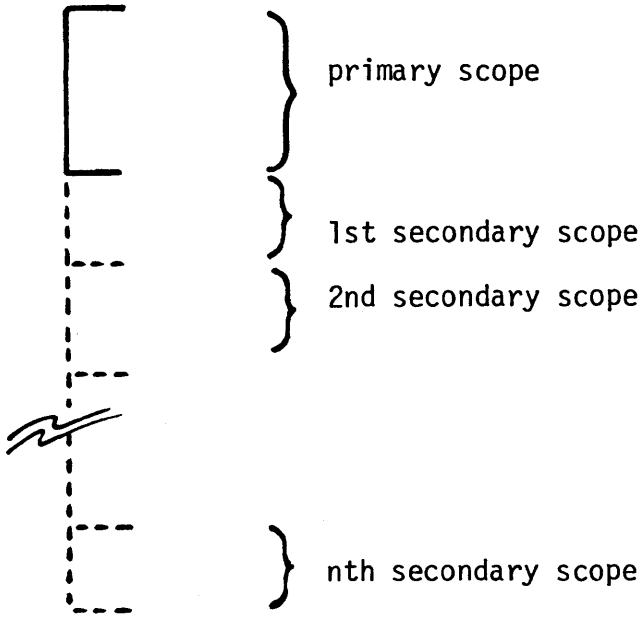
One of the important properties of the dominance relationship is that every node except the begin node (which has no dominators), has a unique direct dominator.

In the example shown in Figure 2, the subtrees rooted at 6 and 9 are located within the scope of 1 because vertices 6 and 9 have 1 as their common direct dominator. Similarly, the subtree rooted at 13 is located within the scope of 9 because 9 is the direct dominator of 11 whereas 1 is only a dominator of 11.

By placing the definition of each subtree within the scope of the direct dominator of its root, we guarantee that each subtree is enclosed within the most restrictive scope possible. This rule provides much of the power obtainable from the MTR.

In Figure 2, we saw examples of square brackets drawn with either a solid or broken line and defining two regions:

—a solid region containing the subtree attached to the root v_i and obtained by only traversing vertices with indegree less than two (i.e., with at most one predecessor). Notice that the vertices enclosed in angle brackets ⟨ ⟩ seem to violate that rule but these are only visited, not traversed. We call the solid region associated with v_i the primary scope of v_i.
—a broken region containing the subgraphs whose roots all have v_i as their direct dominator and indegree at least equal to 2. We call this broken region the secondary scope of v_i. In general, there may be not just one but several secondary scopes of a given vertex. Two subgraphs are in distinct secondary scopes of v_i if they are disconnected within the scope of v_i.



Within one of the secondary scopes of a given vertex, we expect to have p bracketed subgraphs, $p \geq 0$. Let us designate by $s_1, s_2, \ldots, s_p$ the roots of these p subgraphs and let $L(s_i)$ be the indentation level of s_i. By construction, we require that:

$$L(s_i) > L(s_j) \quad \text{if } R(s_i,s_j)=1 \wedge R(s_j,s_i)=0$$
$$L(s_i) = L(s_j) \quad \text{if } R(s_i,s_j)=1 \wedge R(s_j,s_i)=1$$

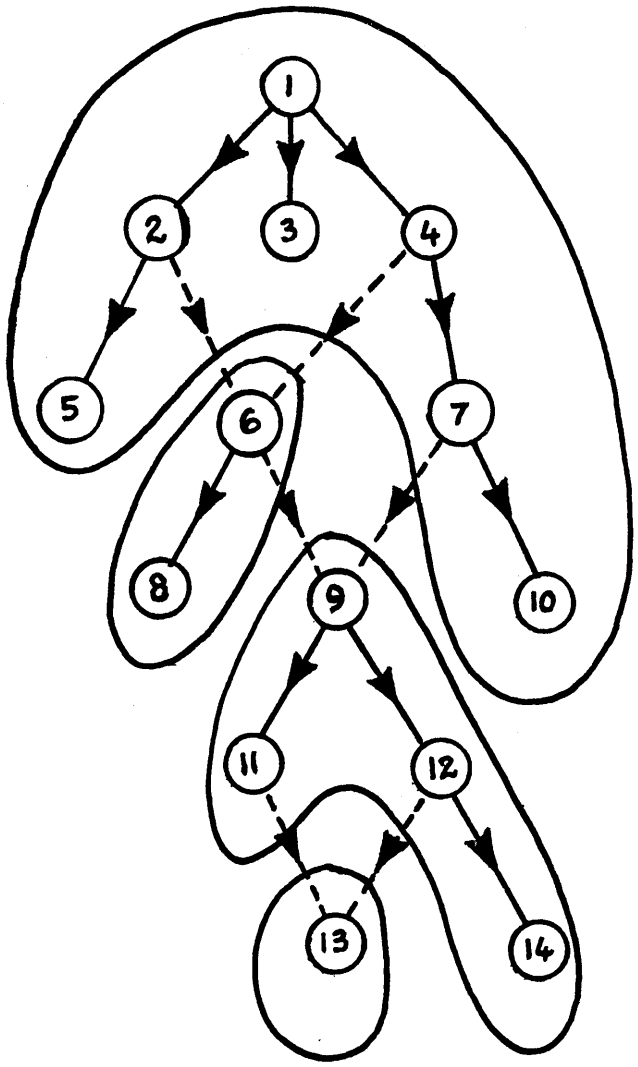
To make the solution practical, we also require that $\max_i(L(s_i))$ be minimum.

This indentation strategy has the advantage that for an acyclic subgraph, the root of each subtree is further indented than the root of any subtree that references it. Notice that if two roots s_i and s_j are at the same indentations level, then

$$(R(s_i,s_j)=0 \wedge R(s_j.s_i)=0) \vee (R(s_i,s_j)=1 \wedge R(s_j,s_i)=1)$$

i.e., either they call each other recursively, possibly via some indirect paths, or neither calls the other. As we mentioned earlier, most invocation digraphs of interest are acyclic or almost acyclic so that we expect most subgraphs that end up at the same indentation level not to reference each other.

Whether or not there are any recursive invocations can be quickly determined by scanning the definition/reference lists in the right hand margin of an MTR. Whenever a vertex with indegree greater than 1 is referenced (i.e., vertices in ⟨ ⟩), we append the MTR line number at which its definition (its subtree of descendants), is located. Conversely, whenever a vertex with indegree greater than 1 is defined, we append the list of MTR lines at which it is referenced. If a vertex with indegree greater than 1 happens to be on a cycle,



```
                +-----
1     1 ->      | 1
2     2         |     2
3     3         |           5
4               |           <6>
5     2         |     3
6     2         |     4
7               |           <6>
8     3         |           7
9               |                 <9>
10    4         |                 10
                |
                +-----
                .
                .   +-----

```

Figure 2—MTR of an acyclic graph

a '*' precedes any MTR line number at which it is either defined or referenced.

Figure 3 shows an example of MTR containing recursive invocations. The reference lists contain '*' to indicate recursive paths and '|' to separate references located within the primary scope from those in the secondary scope. For instance:

REF AT (19| 72,228)

primary scope references	secondary scope references

Finally, each reference line can be supplemented by a left arrow showing which secondary scope contains the corresponding definition. An example is shown on Figure 4.

CONCLUSION

We have introduced the idea of Modular Tree Representation (MTR) of invocation digraphs. The algorithms necessary to build MTR's in practice are presented in Appendix A. The MTR provides a canonical representation for invocation digraphs.

Figure 3—Partial MTR of the FORTRAN 77 syntax

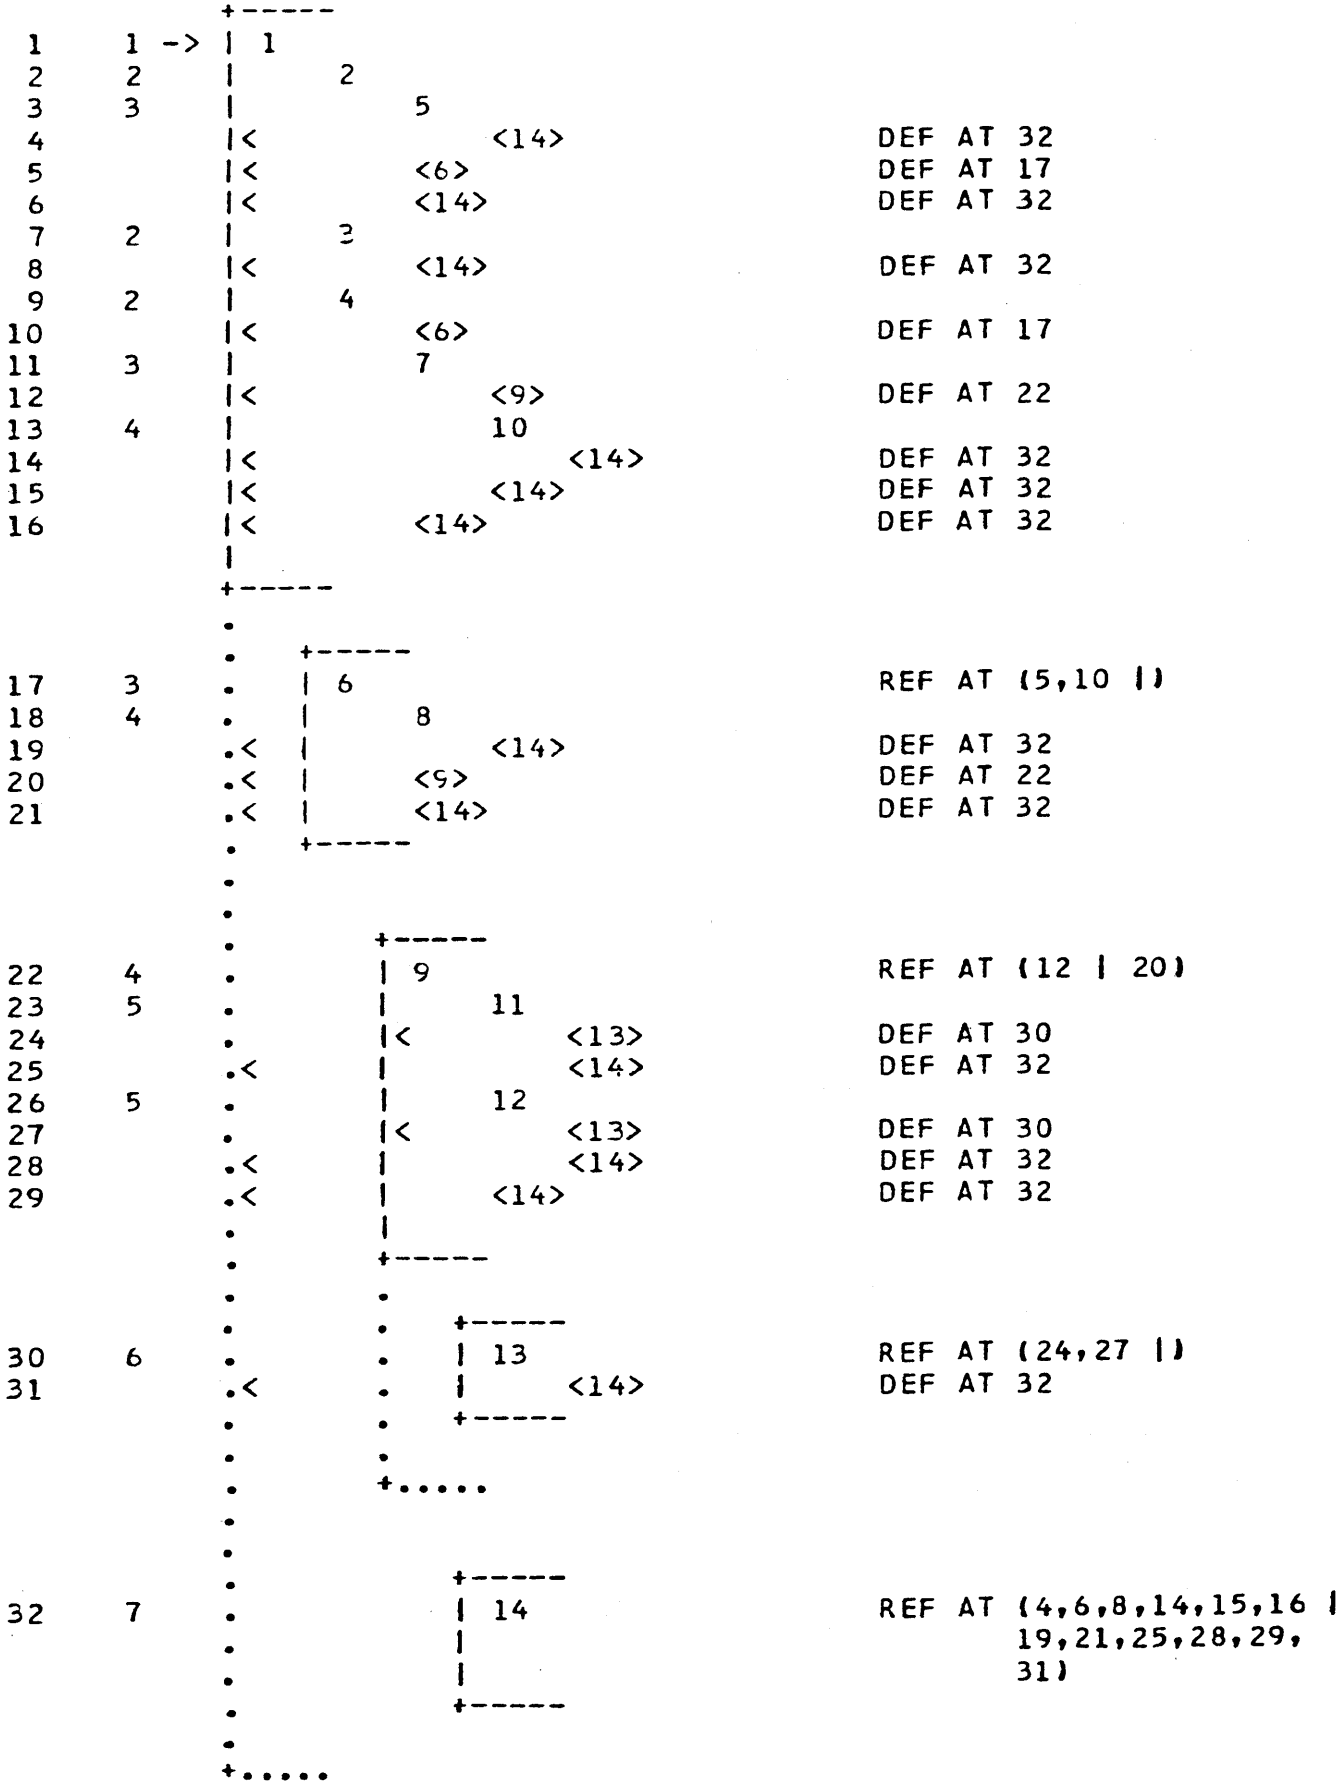

Figure 4—MTR with arrows

In order to experiment with the MTR concept on real projects we have built an omnibus MTR processor. With appropriate input/output interfaces, it can be used to process invocation graphs generated from PDL designs, HOL source code, load modules. . . . We have already used the processor in the following contexts:

—as an extension of the PDL[2] processor to help understand the morphology of a software design. The invocation graph is, in that case, the graph of segment references in a PDL design.
—as an aid in packaging software, particularly when grouping low level design segments into modules. The MTR provides an intrinsic decomposition into modules from which the actual module structure can be selected.
—as an analyzer of existing packages to help understand the hierarchy of calls to procedures, references to external structures. . . . An executable load module can be processed automatically to yield the MTR of all external references.
—as an aid in designing overlay structures by applying the MTR to the nonoverlay load module.

Based on our experiments so far, we can make the following observations:

- MTR's should be used during software development, particularly during the design phase. We have found that even a cursory examination of the computer generated MTR of a design could trigger design changes aimed at making the resulting MTR more "structured" i.e., more simply nested. For instance, realizing that a "GET NEXT CHARACTER" design segment was not nested within "GET TOKEN" simply because of an early initializing reference, suggested making "GET NEXT CHARACTER" a self-initializing module.
- MTR's can be effectively used during maintenance to help assess the impact of a change on an existing package. In that case, the MTR processor is applied to the executable load module directly.
- Practical MTR's can only be computer generated. This is due to the size of practical applications (the load module of the MTR processor itself has 90 vertices and almost 600 edges) and also to the high sensitivity of the MTR to small changes in the input graph.
- MTR's should only be computer maintained. This can be easily achieved because MTR's can be produced cheaply (for instance, the MTR of the MTR processor only takes 8.85 sec of computer time on an IBM 370/158 and a few thousand lines of print). Therefore, a new MTR can be produced every time a design change takes place or a new load module is generated.

There are several questions about the MTR which have not been answered yet. The first important question is to determine user acceptance of such a tool. Admittedly, an MTR is not as intuitively obvious as a graphical structure chart. It takes a little practice to learn how to read an MTR, i.e., to visualize the graph through the MTR and be able to use the MTR to reason about the graph. The second question is to investigate modifications and/or extensions which might make the MTR even more useful in practical situations. These may involve modifications of the display layout or extensions of the MTR capabilities. For instance, one might try visualizing the implicit scope of data items by indicating the direct dominator which controls all references to a given data item. Then, there is the fascinating possibility of applying the MTR to nonconventional areas. For instance, Figure 3 showed the partial MTR of the FORTRAN 77 syntax.

Clearly, further experimentation is needed to answer those questions and assess the full potential of the MTR technique.

APPENDIX

A1 Construction of the MTR representation

This section deals with the algorithms required for generating MTR's. The construction of the MTR of an invocation graph involves primarily:

- finding the direct dominator of every vertex in G;
- performing an extended topological sorting of a digraph, acyclic or not;
- selecting entry points to force the invocation digraph to become weakly connected.

These algorithms are either classical or extension of classical ones.

It is important to notice that there exist several alternative formulations for most of the algorithms described here, depending upon the choice of data structure representation. For the MTR, we have chosen to use bit vectors and bit matrices rather than linked lists for representing the graphs and their ancillary data structures. Consequently, these algorithms are oriented towards parallel bit vector operations. For instance, for inding the descendants of a particular graph node, we rely on a bit vector "fusion" algorithm instead of the more familiar, stack oriented, depth first search algorithm.

A2 Computation of Direct Dominators

The algorithm for the computation of direct dominators can be found in Reference 1, for instance. Using PDL,[2] the algorithm can be informally written as follows:

```
• COMPUTE DIRECT DOMINATORS (DIRECT_DOM( ))
  LET THE VERTICES BE NUMBERED 1,2,. . . ,N WITH 1 THE BEGIN NODE
  INITIALIZE DIRECT_DOM (I)=1, I=1,2,. . . ,N
  DO FOR EACH VERTEX I EXCEPT 1
  :  DELETE TEMPORARILY VERTEX (I)
  :  BUILD LIST OF DESCENDANTS (D( )) REACHABLE FROM VERTEX (1)
  :  DO FOR EVERY VERTEX J IN D( )
  :  :  IF DIRECT_DOM(I)=DIRECT_DOM(J)
  :  :  :  SET DIRECT_DOM(J)=I
  :  :  ENDIF
  :  ENDDO FOR
  :  RESTORE VERTEX (I)
  ENDDO FOR
```

A3 Extended Topological Sorting

We now examine the algorithms required to determine the indentation level of a group of p shared subtrees having the same direct dominator. A directed graph G' with vertices $\{v'_1, v'_2, \ldots, v'_p\}$ is built as an invocation digraph where the p components would be the p shared subtrees. In other words, there is an edge between v'_i and v'_j if and only if the root of the jth subtree is referenced from within the ith subtree. Notice that G' is not in general weakly connected, but this is not required by the algorithm that follows.

The problem is to partition the set of vertices $\{v'_1, v'_2, \ldots, v'_p\}$ into the smallest number of disjoint subsets $s_1, s_2, \ldots, s_k$ such that

(a) if there is a path from v_i to v_j but not from v_j to v_i then

$$v'_i \epsilon s_\nu,\ v'_j \epsilon s_\mu \qquad 1 \leq \nu < \mu \leq k$$

(b) if there is a path both from v_i to v_j and v_j to v_i then

$$v'_i,\ v'_j \epsilon s_\nu \qquad 1 \leq \nu \leq k$$

If $v'_i \epsilon s_\nu$, the rank of the ith vertex is said to be ν. In the acyclic case, this problem is a simple topological sorting and we know[9] that condition (a) above is satisfied after the sort is performed. But if G' contains cycles, the classical topological sorting algorithm cannot be applied. We shall, therefore, extend it to handle cyclic graphs as well.

In the simple topological sort of an acyclic graph, vertices and their outgoing edges are deleted immediately after they have been processed, and one of the remaining vertices with zero indegree is selected as the next vertex to be processed. It is equivalent but computationally simpler to replace the deletion operation by the assignment to each vertex of a rank, initially 0. Thus, the search for a vertex with 0 indegree becomes the search for a vertex whose predecessors all have a non-zero rank.

```
• TOPOLOGICAL SORTING (ACYCLIC GRAPH)
  LET THE VERTICES BE NUMBERED 1,2,. . . ,N
  INITIALLY SET RANK(I)=∞, I=1,2,. . . ,N
  DO WHILE THERE ARE VERTICES WHOSE RANK( )=∞ STILL
  :  DO FOR EACH VERTEX I
  :  :  IF RANK(I)=0 THEN
  :  :  :  COMPUTE PRED( ), THE SET OF IMMEDIATE PREDECESSORS OF I, EXCLUDING I
  :  :  :  SET MXRNK=MAX(RANK(PRED(1)),RANK(PRED(2)), . . .)
  :  :  :  IF RANK≠∞ THEN
  :  :  :  :  RANK(I)=MX RNK+1
  :  :  :  ENDIF
  :  :  ENDIF
  :  ENDDO FOR
  ENDDO WHILE
```

To handle graphs with cycles, we modify the search strategy so that if the search for a vertex whose predecessors all have a non-zero rank fails, we then search for a maximal circuit whose predecessors, excluding nodes on the circuit, all have a non-zero rank. A circuit is maximal if it is not possible to find another circuit that includes at least one of its vertices as well as some other vertex that it does not already contain.
The algorithm can be carried out in two steps:

—replace each maximal circuit by a single substitute vertex having the same immediate predecessor and immediate successor vertices, thus obtaining an acyclic graph but with self loops;
—apply classical topological sorting to the derived acyclic graph, reflecting the rank assignment to every vertex of a maximal circuit when its substitute vertex is assigned a rank.

This approach provides both a proof and a computational method.

In order to find the maximal circuits we can use the following method:

We start with the simple adjacency matrix $A=(a_{ij})$ defined

```
                                                                        524,537,549,563,
              I    .                         I                          574,584,595,607)

Figure 5—Partial MTR of an IBM 370 load module

by

$a_{ij}=1$ if there exists one or more directed edges from vertex v'_i to vertex v'_j, $i \neq j$
$a_{ij}=0$ otherwise

and proceed iteratively to obtain the reachability matrix R.

Let $a_{1k_1}a_{1k_2} \ldots a_{1k_m}$ be the only m non-zero values of the first row of A. We set

$$a_{1j}=a_{k_1j} \vee a_{k_2j} \vee \ldots \vee a_{k_mj} \qquad j=1,2,\ldots,n$$

If the new first row of A differs from the old one, we perform the operation again, using the $m'-m$ new non-zero entries in the first row. If the new first row of A is identical to the previous one, the first row of R has been obtained. We now proceed to obtain the second row, then the third. . . . This process is often known as fusion.

When all n rows have been computed, the non-zero diagonal entries of R indicate those vertices that belong to some directed circuits. If we now compute

$$R=R \wedge R^T$$

where the logical product is taken element by element, the resulting R matrix has the following structure:

if $r_{ii}=1$ vertex i is on a directed circuit
if $r_{ij}=1$ then $r_{ji}=1$ by construction, v'_i and v'_j are on the same maximal circuit.

A4 Selecting entry points

The method for finding descendants that we have just described can now be used to solve a problem deferred earlier, namely, the appropriate selection of vertices to make the graph weakly connected. Such a selection is necessary when the initial graph still has more than one component after all vertices with indegree 0 have been linked to the artificially created begin node v_0. Let us assume that there are p such remaining unreachable vertices $V=\{v_{i_1}, v_{i_2}, \ldots, v_{i_p}\}$. The problem is to find the minimal number k of vertices from V sufficient to cover all vertices in V; i.e., all vertices in V are reachable from 1 or more of the k selected "entry" vertices. Notice that the solution is, in general, not unique since any vertex on a circuit may be replaced by any other on the same circuit.

The following algorithm finds the entry vertices:

```
LET E( ), R( ), C( ) BE P ELEMENT VECTORS WITH VALUE 0, 1
INITIALLY SET E( )=0, C( )=0
DO WHILE THERE EXISTS I SUCH THAT C(I)=0
    FIND THE DESCENDANTS (R( )) OF VERTEX (I)
        I.E. R(J)=1 IF VERTEX J IS REACHABLE FROM I
    SET E( )=(E( )∧7R( ))
    SET E(I)=1
    SET C( )=C( )∨E( )∨R( )
ENDDO WHILE
. . . THE ENTRY VERTICES ARE I SUCH THAT E(I)=1, I=1, . . . , p
```

The selection of entry vertices is illustrated on Figure 5. The arrows '→' in the left margin indicate addresses of the IBM OS/VS FORTRAN run time library which are not directly referenced within the load module.

The impact of program and programmer characteristics on program size

by EARL CHRYSLER
University of Wisconsin-Parkside
Kenosha, Wisconsin

INTRODUCTION

Since the first efforts of Farr and Zagorski[8] to those of Nelson[14] with the System Development Corporation and the more current, on-going work of Walston and Felix of IBM,[22] there has been the desire to develop a method of predicting the ultimate size of a program before the programming effort begins.

A technique for predicting the number of source language instructions necessary to meet a set of program specifications could be of value to decision-makers in facilities which allow programmers to store source language versions of programs on disk for online debugging and revision. Management could then estimate the amount of disk storage area necessary to support the development of each new program.

Management personnel would also find it valuable to be able to predict the amount of object code a specific set of program specifications will require for differing reasons. The basic question of whether the program will fit in main memory would be answerable for those operating in a constrained environment. For those utilizing partitioned memory, the impact upon the workload in each partition would be predictable. For facilities operating in a virtual storage type environment, the ability to predict the number of pages a program will require would be of significant value in determining if current disk storage capacity would be adequate to support projected programs.

THE PROGRAMMING ENVIRONMENT

The model of the programming environment used in this study is the one successfully utilized by this researcher to investigate the area of programmer productivity, shown in Figure 1. The rationale for this approach is straightforward. A set of program and programmer characteristics have previously been analyzed regarding their impact on program development time. Most of the program processing characteristics and all of the programmer experience characteristics hypothesized as being important were found to have a significant effect on program development time.[4] If one accepts the premise that longer program development time is related to larger programs, then it seems reasonable to assume that the variables found related to program development time should, more likely than not, also be related to program size.

PROGRAM AND PROGRAMMER CHARACTERISTICS

The purpose of this research was to determine the effect of program and programmer characteristics on program size, both in terms of source language lines of code and object language memory storage measured in bytes. As a consequence, all the remaining sources of variance in the programming environment had to be held constant. The research setting used was one where programmers coded offline and only COBOL programs were considered. Since this is the most typical business programming setting, it was believed the findings of the research would then have more general applicability. Since the study was conducted in a specific data processing facility within one firm, it was felt that the hardware and organizational variables were then adequately controlled for. Only the programming problem and the programmer, therefore, remained as sources of variance in program size.

In order to develop a reliable technique for predicting program size, the following questions must be answered:

1. What characteristics of the programming task, which can be objectively measured before the task is begun, are significantly correlated with program size?
2. What characteristics of the programmer, which can be objectively measured before the task is begun, are significantly correlated with program size?

When considering the characteristics of processing requirements of a program which one could reasonably expect to have an impact on the size of the resulting program, the same variables examined for possible impact on program development time in previous research[4] were believed worthy of analysis. Those program characteristics are:

1. Total number of input files
2. Total number of types of input records
3. Total number of unique fields of input records

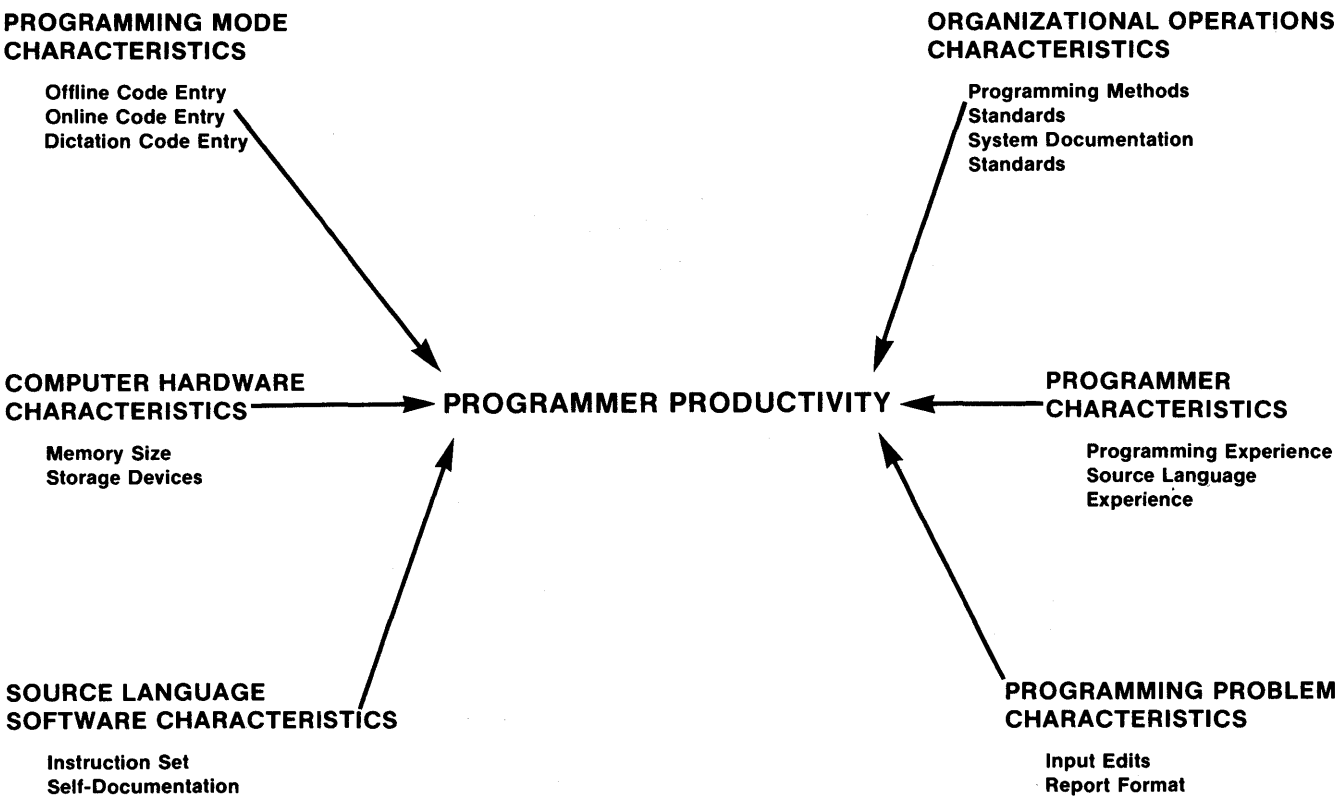

Figure 1—The computer programming environment

4. Total number of edits to be performed on input data
5. Total number of output files and report formats
6. Total number of types of output records
7. Total number of unique fields of output records
8. Total number of output fields not appearing as fields on input records
9. Total number of input files for which presence is optional
10. Total number of input records for which presence is optional
11. Total number of output files for which development is optional
12. Total number of output records for which development is optional
13. Total number of control breaks and/or totals specified for all output reports
14. Optional control breaks and/or totals
15. Mathematical operations other than developing totals

The programmer characteristics considered as possibly having an impact on program development time were similarly believed to be those with the greatest likelihood of having an impact on final program size. Those programmer variables are:

1. Number of months of programming experience
2. Number of months of programming experience using the COBOL language
3. Number of months of experience using the specific COBOL language compiler to be used for the subject program
4. Number of months experience programming business applications
5. Number of months experience programming for the current employer

METHODOLOGY

The purpose of this research was to examine the relationship between various processing characteristics of programs and experience characteristics of programmers and program size. The ultimate objective was to develop a viable technique for predicting the amount of source language lines and object language bytes a program would eventually become.

Research hypotheses

Since there is little research which verified that the program and programmer characteristics discussed have an effect on program size, this research is actually testing the null hypothesis, for each specified program variable, that the variable has no effect on program size versus the alternative hypothesis that the variable is associated with an increase in program size, that is, there is a positive correlation between each program variable and program size.

The specified programmer variables, it is hypothesized, will also be found to be related to program size, but the coefficients will have a negative sign, that is, there will be a negative correlation. Increasing values for programmer variables will be associated with reductions in program size.

Data collection techniques

The first step was to locate a data processing facility which employed a group of computer personnel to create new COBOL programs in an offline environment. The subject firm was selected for two additional reasons. First, there was a wide range of experience among the members of the programming staff, from trainees with eight months experience to senior programmers with over ten years of experience. Second, the firm also performed contract programming for other firms. This implied that one could expect more variation among the types of programs developed at this facility than in an installation where programs were created only for internal systems.

It should be restated here that the program variables to be measured must, if a predictive technique is to be reliable and effective, be measurable *before* programming begins. Since the quality of pre-programming documentation at the subject firm was not adequate to allow such measurements to be made, it was necessary for the researcher to examine the COBOL source statement or compilation listing for each program and measure the variables of interest from the listing. While this was necessarily tedious, it also improved the control over the research data. This improvement in control was accomplished because one could verify that the program was indeed coded in COBOL. Also, one was able to detect and remove from the analysis any program which utilized the Report Writer feature and was therefore not comparable to the other programs. In order to measure the value of the programmer variables, a questionnaire which asked the programmers to report their programming experience was circulated to all programmers by the programming manager.

The size of the program in source language lines of code was measured from the listings, subdivided into Data Division lines and Procedure Division lines. The number of bytes of storage required to store the object code was also taken from the compilation listing and was similarly subdivided into Working Storage bytes and Procedure Division bytes.

Statistical analyses to be performed

The first step would be to provide the data for program size and program variables to a stepwise multiple linear regression computer program for analysis of the interrelationships present. The identical procedure would be followed relating the size of a program to each of the programmer variables for the programmer who created the program. With regard to the programmer variables, however, it would be necessary to adjust the values depending upon the date the programmer started the programming assignment. That is, the value of each programmer experience variable had to be reduced to what the value would have been when the programmer started the task since the variables are all length-of-time experience values.

The last step would be to relate program size to the group of program variables and programmer variables simultaneously to develop a specific predictive equation for use as an estimating device.

Limitations of the study

The major limitation of the study is the lack of enforcement of programming standards at the firm used in the study. Each programmer had his own style in terms of the appearance of the source language code. For example, some programmers would place both the PICTURE and VALUE clauses for a data field on one card or line of code while others would place the VALUE clause entry on a separate card. Another observable difference was that some programmers would place only one verb per line of code in the Procedure Division while others would place as much code as possible on each card. Another limitation is the accuracy with which programmers reported their experience on their questionnaire. Aside from the fact that inaccuracies may be intentionally introduced into the data, there is the problem that a subject was asked to recall how long he performed a given type of programming. Further, if a subject performed some functions other than those of a programmer during a given time period, he was also asked to parcel out that portion associated with only the programming effort. Since future applications of this technique will be using input with these same shortcomings, however, perhaps the reliability of the technique will be improved by the high similarity between the experimental environment and the application environment.

Some assumptions which could be classified as limitations are that the subject programmers were provided with comparable documentation of the processing requirements for each program and that the programs developed were of comparable quality.

It should be noted that the items listed as limitations are sources of the error or unexplained portion of the variance to be found in the analysis. Therefore, the mathematical statements of the relationships found between the sample variables could be considered to be underestimates of the true strength of the relationships between the population variables.

RESEARCH FINDINGS

A total of thirty-six programs were found to qualify for statistical analysis by being written in COBOL and containing no use of special compiler features which made them unusual in terms of coding required or logical construction. The results of the analysis are stated below.

Program characteristics

As can be seen in Table I, the most important program variable in terms of its impact on Data Division source language lines of code was output fields, closely followed by output records, input fields and control breaks and totals. All of these variables were significant at the .005 level. As can be seen, most of the program variables were related to an increase in the size of the source code found in the Data Division.

As shown by Table II, the three program variables which one could reasonably associate with computations and logical complexity emerged as having the greatest effect on the amount of source language code found in the Procedure Division. All three, mathematical operations, output fields without corresponding input fields and control breaks and totals exhibited correlation coefficients of over .9.

In terms of the impact of the program characteristics on the amount of object code generated, Tables III and IV provide considerable insight. The only variables found to be strongly related to an increase in the amount of Working Storage bytes needed for a program, in order of their strength, were input files, optional control breaks and totals and optional output files. With regard to the Procedure Division bytes required, the same variables, mathematical operations, output fields without corresponding input fields and control breaks and totals are the only program characteristics which appear to have an effect.

Programmer characteristics

Although thirty-six programs were available for analysis regarding the impact of program characteristics on programming time, five of those had to be removed from the analysis of programmer variables because the responsible programmers had left the firm and their characteristics were not

measurable. For the thirty-one programs, the four measurements of program size were individually regressed against the programmer characteristics and the correlation coefficient between each characteristic and each component of program size was computed.

The findings shown in Table V indicate four of the five programmer experience variables are related to reductions in the size of the Data Division source code. The three strongest influences appear to be total programming experience, business programming experience and, curiously, experience at this facility. While one can easily accept the business programming and total programming experience variables as important, the relationship between experience at this facility and reduced Data Division code is less clear and may be unique to this data processing installation for reasons unknown at this time.

The analysis of programmer characteristics and source statements found in the Procedure Division provided the most unexpected results. As the correlation coefficients in Table VI indicate, there appears to be no significant relationship between any programmer experience characteristic and the size of the source language Procedure Division. Since previous research[4] has found these programmer variables are all significantly related to reduced program development time, this latter finding raises an interesting question. Does increased experience of the types listed give one the ability to develop the same amount of processing logic code as another less-experienced programmer in significantly less time? That is the implication of these findings.

When relating the programmer characteristics to the object code equivalents of the Data and Procedure Divisions source code, the findings were as shown in Tables VII and VIII. The findings with regard to Working Storage bytes differ only slightly with the source code findings. Total programming experience, business programming experience and programming experience at this facility, however, remain the most important variables. With regard to Procedure Division bytes, the findings are identical to those for the impact of the variables on source code, that is, no significant relationships were found.

Estimating equations

In order to develop equations for estimating the two components of source program size and the two components of object program size, one would use a stepwise multiple linear regression analysis program. The logic of such a program is to continue to add each of the predictor variables into the estimating equation one by one, each time entering that remaining variable which most improves the accuracy of the estimate. A point is eventually reached where the additional value of the next variable in the equation is small and, more importantly, not of statistically significant value. The equations shown here are those which in each case were, statistically, optimum. In order to develop such equations, the variables to be subjected to analysis would be those which appeared to have a significant impact.

The approach decided upon was to first use only the group of program characteristics to develop equations for the source and object code of the Data and Procedure Divisions. The analyses would then be repeated allowing programmer characteristics to enter the equations to determine if predictive power was increased. The equation shown in Figure 2 for estimating Data Division source lines had a multiple

Variable Name	Regression Coefficient
Constant	−26.41

Input Fields	.59
Mathematical Operations	−.62
Input Records	6.03

Figure 2—Equation for predicting data division source lines with program characteristics

correlation coefficient of .94 and, therefore, the variables included explain about 88 percent of the variance found in the number of source lines appearing in the Data Division of the sample programs. The optimum equation for the Procedure Division source lines, shown in Figure 3, using only program characteristics, had a multiple correlation coefficient of .997.

As an example of the use of these equations, assume one wished to estimate how many source lines of code would be required for a program with the following characteristics:

8 mathematical operations
20 output fields
1 input record type
0 optional output records
0 input edits
4 output fields without corresponding input fields
18 input fields
and
1 input file

By placing those values in their appropriate positions in the equations one obtains a value of about 74 lines of Data Division code and 140 lines of Procedure Division code. The program would then be estimated at about 214 lines of code plus the necessary Identification and Environment Division entries, which typically show little variance. Upon allowing the programmer characteristics to enter the equations it was found that, although the equations became more complex, no significant improvement could be made in the estimate.

The next analysis concerned the object code components of the program. The program variables which developed the best equation, statistically speaking, are shown in Figures 4 and 5. The multiple correlation coefficient for the Working Storage bytes equation was .66, accounting for only about 43 percent of the variance in this component of program size. Once again it was found that allowing programmer characteristics to enter the equation provided little additional predictive power.

Variable Name	Regression Coefficient

Figure 4—Equation for predicting working storage bytes with program characteristics

The optimum equation for predicting Procedure Division bytes using only program characteristics, shown in Figure 5, had a multiple correlation coefficient of .998. This implies that the number of bytes required in the Procedure Division is apparently predictable from knowledge of the program characteristics appearing in Figure 5. Programmer characteristics were once more found of no significant value to the equation. A necessary but realistic assumption is that the programming specifications at a data processing facility are of sufficient quality that the program characteristics in the equations are defined before programming is begun. Given this assumption is met, the equations presented in Figures 4 and 5 could be used to predict the amount of storage a program will require by placing the program characteristics in the equations and computing the final value as shown previously for the source statement portions of a program.

SUMMARY AND CONCLUSIONS

Summary

The purpose of this research was to analyze the relationships between characteristics of a programming problem and the responsible programmer and the amount of source and object code necessary to complete the programming problem. For each program characteristic it was hypothesized that

Variable Name	Regression Coefficient
Constant	−31.09
Mathematical Operations	2.97
Output Fields	1.81
Input Records	37.02
Optional Output Records	45.98
Input Edits	−2.32
Output Fields without corresponding input fields	2.90

Figure 3—Equation for predicting procedure division source lines with program characteristics

Variable Name	Regression Coefficient
Constant	−38.64
Mathematical Operations	50.37
Output Fields	26.32
Optional Output Records	626.73
Input Records	659.70
Output Fields without corresponding input fields	63.57
Input Edits	−19.68
Optional Input Records	−218.67

Figure 5—Equation for predicting procedure division bytes with program characteristics

an increase in the value of that variable would lead to an increase in each aspect of program size. For each programmer variable it was believed that an increase in the value of the variable would contribute to a decrease in the program size measurements.

Simple linear correlation coefficients were computed to determine the direction and magnitude of the relationships between the variables in the analysis. In order to develop predictive equations for the components of program size, stepwise multiple linear regression analyses were performed.

Conclusions

Of the fifteen program characteristics examined, nine were found to have correlation coefficients with Data Division source statements significant beyond the .05 level, while only three were found correlated with Procedure Division source statements. The strength of the latter relationships, however, was significant beyond the .0005 level.

In terms of their impact on Working Storage bytes of object code, only three program characteristics were found to be significant, varying in strength from only .05 to .0005 levels of significance. Three different program characteristics, however, were found to be related to Procedure Division bytes of object code, all at the .0005 level of significance.

While all five programmer characteristics were negatively correlated with both Data Division source statements and Working Storage bytes as hypothesized, only four were significant beyond the .05 level. None of the five programmer experience characteristics could be shown to cause a reduction in either the Procedure Division source lines of code or the Procedure Division bytes of object code, a finding worthy of note.

When the program and programmer variables were used to develop predictive equations for the four size components, strong multiple correlation coefficients were found without programmer characteristics present in the equations. The inclusion of programmer characteristics into the equations appeared to provide no significant increase in predictive power.

The findings of this study imply that one could, with a reasonable degree of accuracy, predict the two major source and object components of program size of a program before programming begins by developing equations of the type presented here with data collected at the facility where they are to be used for estimation. As new programs are developed, their program and programmer characteristics and four size components should be measured and added to a history data bank for the firm. These data should then be periodically used as input to a stepwise multiple linear regression analysis program. As the firm continues to increase the number of program data points in its data bank, it will be capable of predicting the size of new programs with increasing accuracy.

Multiprocessing made easy

by RONALD J. PRICE
Perkin-Elmer Data Systems Group
Tinton Falls, New Jersey

INTRODUCTION

The concurrent execution of processes on multiple machines has appealed to system architects for quite some time.* In fact, it is not such a new concept as often thought. According to P. Enslow, "The first operational 'true' multiprocessor was delivered in 1962."[1]

Increased throughput is usually the major objective of multiprocessing, but there are other advantages over interleaved, multi-programming of a uniprocessor that oftentimes take on greater importance.

For example:

- Resource sharing
- Responsiveness to external events
- Expandability in a stepwise manner
- System modularity
- Survivability

There are a number of reasons why multiprocessing is not as popular as perhaps it could be, as Enslow aptly points out in Reference 2. One big problem is software. Program development is difficult because the behavior of concurrent programs is time-dependent and seldom reproducible with a given set of input data. Add parallelism with increased possibilities for time-dependent interactions and deadlock situations, and we have a most complex problem. The lack of software for the number of available multiprocessor systems[1] attests to this fact.

Help is on the scene, though!

A new design concept that combines shared data structures and the operations permitted on them in a single syntactical construct called a "monitor" has been suggested in the literature by C. A. R. Hoare[3] and Per Brinch Hansen[4] as an effective tool for building concurrent system programs. Brinch Hansen based his Concurrent Pascal language on this principle. He extended the sequential program properties of the Pascal language with concurrent programming tools called processes and monitors.[5] This paper is based on the constructs in Concurrent Pascal, although the research works of E. W. Dijkstra[6] and N. Wirth[7] are also relevant.

Evidence exists that the monitor concept, particularly as implemented in Concurrent Pascal, is a powerful tool. Brinch Hansen recorded improvement in programmer productivity while building a complete operating system with his language.[8] The utility of the language has also been tested for many diverse applications.[9]

From personal experience, the author has found that the mere act of decomposing a concurrent problem into logical processes and monitor modules, irrespective of how they might be implemented, is an excellent design methodology. Furthermore, once system facilities are provided to manage process and monitor programs, the systems programmer need no longer suffer through analyses of time-dependent race conditions and interprocess communication protocols. Performance need not be sacrificed either. In fact, the author discovered that performance improved, probably because of a better overall system design.

The monitor concept is a relatively new idea and some weaknesses can be identified. Several researchers seek additional language constructs and operators (for examples see References 9 through 14). This is to say nothing of the age-old question whether compilers can produce optimum time and space code, nor the difficulties of implementing language support for multiprocessing. On the other hand, the system programmer need not wait for the ultimate language. He can reap the benefits of this new software technology for current problems even if he has to use assembly language. All he has to do is build a kernel facility, which manages process and monitor programs, and adhere to the programming conventions promulgated by these experimental languages.

The next section presents a brief explanation of the monitor concept and how it relates to multiprocessing applications. This is followed by a section on implementation techniques for supporting multiprocessors. The last section illustrates an example application and its solution. By employing two assembly language solutions, one with monitors and one without, the example evaluates the fundamental utility of the monitor concept for solving concurrent/multiprocessing problems; i.e., biases of a compiler for generating code and for enforcing programming conventions are not involved. The example also illustrates the value of the monitor as a systems structured programming tool by solving the concurrent problem in stages.

* Tightly coupled, multi-port shared memory systems are assumed in this paper, although much of the presentation equally applies to other types of multi-processor systems.

MONITOR CONCEPT

The reader should consult the references for an in-depth explanation of monitors and how they are employed in concurrent programs. Briefly though, monitors consist of shared data structures combined with a well-defined set of procedures permitted to operate on the shared data. In this context, processes are sequential programs which synchronize their operations and get access to shared data structures by calling monitor procedures in a manner much like subroutines. A run-time kernel executive enforces mutual exclusion on access to a monitor from competing processes.

The simple example in Figure 1 illustrates how processes can asynchronously exchange messages through monitors. Input and output operations are overlapped concurrently with job processing. The INPUT process READs a message from the IN_TERMINAL and PUSHes it on a buffer stack for the JOB process in the IN_BUFF monitor; a similar operation takes place on output. The monitors can be represented by ordinary program code except they are passive modules and do not execute until called. They contain the procedures (for example, PUSH and GET) that operate on the shared buffer stacks. They also contain the counters and flags needed to control the operation.

Inter-process synchronization is achieved through the use of a *delay-queue* construct by which a monitor procedure can *delay* its calling process or *continue* another process waiting in a *delay-queue*. For example, in Figure 1 the JOB process knows nothing of the situation of the INPUT and OUTPUT processes. If it tries to GET a message when none is available, it is *delay*ed by IN_BUFF until *continue*d when one is supplied by the INPUT process. Likewise, if the JOB process tries to PUT an output message when no buffer is available for the data, it is *delay*ed by OUT_BUFF until the OUTPUT process FETCHes a previous message and frees a buffer.

Other applications for monitors include classical reader-writer problems, process synchronization on events, resource sharing, priority scheduling, and so on. The concept is valid because processes, containing their own private data structures, cannot directly intercommunicate, change control (shared) data, or access a shared resource; to do so they must call a monitor, and the kernel permits a monitor to service only one process at a time.

The technique of describing a system program in terms of monitors and sequential processes can be used to represent a multiprocessing program. Any process is a candidate to be executed in parallel with others on separate processors. The three processes in Figure 1 could be executed literally simultaneously on different processors with no more difficulty (functionally) than if interleaved concurrently on one processor. Their combined execution becomes serial only when interacting through the same monitor.

In a multiprocessor configuration, monitor code can be executed out of shared memory or be replicated in each processor's private local memory. That is, if necessary, an instance of a given monitor can be represented on multiple machines. The separate representations can even be implemented differently (for example, microcoded) in different processors provided they execute the procedures as required by their respective processes. Monitor code can be duplicated in different processors because the run-time kernel permits only one version to execute at any given time. However, only one copy of a monitor's variable data structures can exist and it must be located in shared memory to be accessible by the different processors.

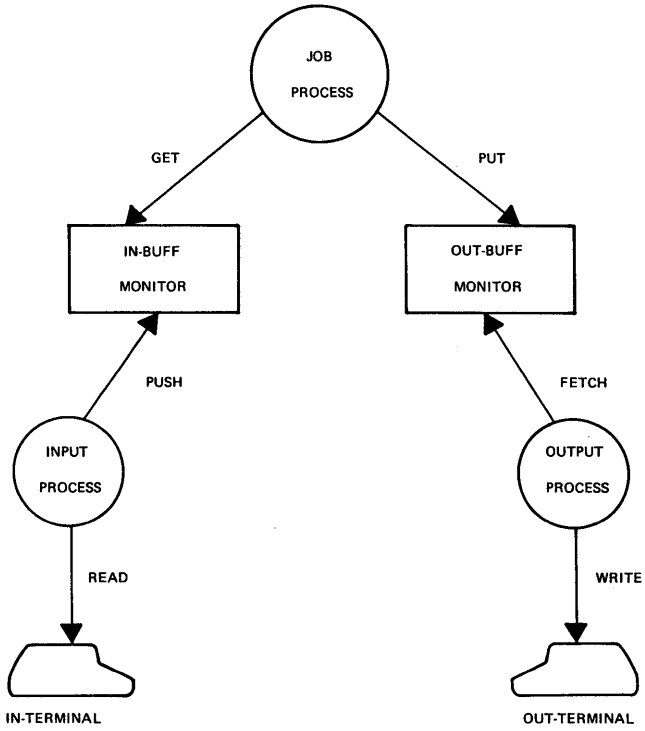

Figure 1—Example application of monitors

Each physical processor contains a run-time kernel. Collectively, these kernels create a virtual machine which supports an integral distributed processing system. In fact, control over processes for scheduling and dispatching is shared among the processors and consequently the virtual machine can be considered truly distributed.[15]

For example, the collection of the processes and monitors in Figure 1 represents a concurrent system program that accomplishes an application function (albeit rather trivial in this case). It consists of disjoint modules which run in harmony as one program where parts of it may execute in parallel. No single processor controls the execution of the others. With adequate kernel support, the application program can be executed on multiple machines or on a single machine without change to any of its code.

In short, the use of monitors in this manner reduces the software implementation effort for multiprocessor systems to the scope of single-processor designs. Or from another viewpoint, greater degrees of performance can be achieved from one basic design simply by adding processors.

IMPLEMENTATION NOTES

A run-time kernel is needed to manage concurrent programs according to the principles of Concurrent Pascal. The kernel is responsible for waiting and dispatching processes (sometimes called short-term scheduling), and essentially is a miniature executive. In this case, it also recognizes monitor program modules and provides exclusive access to their respective shared data structures. Additionally, the kernel manages *delay-queues* and implements the *delay* and *continue* operators.

Given the kernel, the systems programmer builds an application program by coding appropriate process and monitor modules that solve his problem. These program modules are then linked together and loaded into the computer with the kernel. These steps can be automated with a compiler. In fact, the existence of the kernel is transparent to a program written in Concurrent Pascal or equivalent language. (Concurrent Pascal also provides strong type checking and a notion of access rights, both of which are outside the scope of this paper.)

Space does not permit documenting a complete kernel, but Figure 2 is a basic flowchart of four key kernel routines. Illustrated are mechanisms for entering and exiting a monitor and for implementing the *delay* and *continue* operators. These routines are executed in behalf of the using program when requesting the services of the kernel. The DELAY and CONTINUE routines in Figure 2 adhere to the conventions of Concurrent Pascal; note that CONTINUE implies EXIT as well. Alternative kernel designs are possible, as deemed appropriate for given installation objectives and requirements.

Support for multiprocessors is reflected in Figure 2 in several ways. In particular, the kernels (one in each machine) share data structures located in shared memory to control their operations. They need a mechanism for resolving contention when more than one kernel tries to access a common kernel data structure. This can happen when selecting a process to dispatch and when attempting to grant access to a monitor for a process. A hardware read-modify-write function (Test and Set instruction) is employed to lock a data structure before a kernel accesses it. When a kernel finds a structure busy, it "spins" on the lock, testing it until it becomes free. Locking is depicted in Figure 2 by boxes with titles. The kernel need not necessarily treat a busy lock as a busy wait situation, but it is not likely to have anything else to do except spin.

Processor time consumed while spinning on a lock is data contention overhead and will degrade total system performance if the frequency of accessing a given structure is high among the processors. Probability of contention can be minimized by dedicating a separate lock for each monitor and for each process dispatch chain in the system. Although the lock intervals can become a bottleneck when average process execution time between kernel calls approaches the execution time of the kernel routines, this is generally not the case because the lock intervals are relatively short. For example, in Figure 2 the lock interval in the ENTER MONITOR routine is not for the duration of the monitor procedure, but rather only for the short interval the kernel takes to interrogate the monitor's busy flag and to chain the process to the monitor if the monitor is busy with another process. Upon exiting a process from a monitor, the kernel interrogates the monitor's busy chain and makes a waiting process (if any) ready for executing the monitor.

A process can be either dedicated or shared. The code for a shared process is located in shared memory and can be executed by any processor in the system; a dedicated process is located in a processor's private local memory. A shared process has an advantage over a dedicated process in that it can be dispatched by any processor in the system, whereas a dedicated process might be in a ready state but unavailable to idle processors in the system. While there are a number of reasons for having shared processes, they might execute slower than dedicated processes because of memory access contention and particular hardware constraints of a given installation. Processes might also have to be dedicated if they frequently access resources (peripherals, clocks, sensor equipment, etc.) that are accessible only on a given processor.

Process dispatching is distributed (except for the control structures in shared memory) because any processor's kernel can set processes ready for execution on other processors in the system. As illustrated in Figure 2, this can happen when a process waiting on a monitor busy chain is activated and when a process waiting in a *delay-queue* is continued. No single kernel is responsible, nor need be interrupted, for deciding the order of putting processes in a ready state. When a kernel selects a process for dispatching it selects the highest priority process that it is capable of executing (processes inside a monitor have priority over processes not in monitor mode).

Figure 2 reflects some design choices that would not be required for a single processor system. For example, when *continu*ing a process waiting in a *delay-queue,* the kernel might not be able to switch immediately to the *continue*d process because it might be dedicated to another processor. So the kernel routine falls through Dispatch instead. In fact, Dispatch is exercised whenever the kernel has the opportunity in order to insure fair priority treatment of processes in monitor mode. Otherwise, ready processes inside monitors might be blocking resources needed by other processes[6] and therefore idling processors.

An inter-processor interrupt facility enables a kernel in one processor to signal the kernel in another processor when setting one of its processes ready for execution. All idle processors can be alerted when readying a shared process. The interrupt need not convey any information except to cause the recipient kernel to cycle through its Dispatch routine. If processes are not to be preempted, which has merits germane with the philosophy of the monitor concept,[16,17] the interprocessor interrupt need be generated only when the destination processor is idle (or when the readied process is in monitor mode, if so desired to allow monitors to preempt processes). The interrupt facility is not an absolute requirement, however. When in idle mode with no

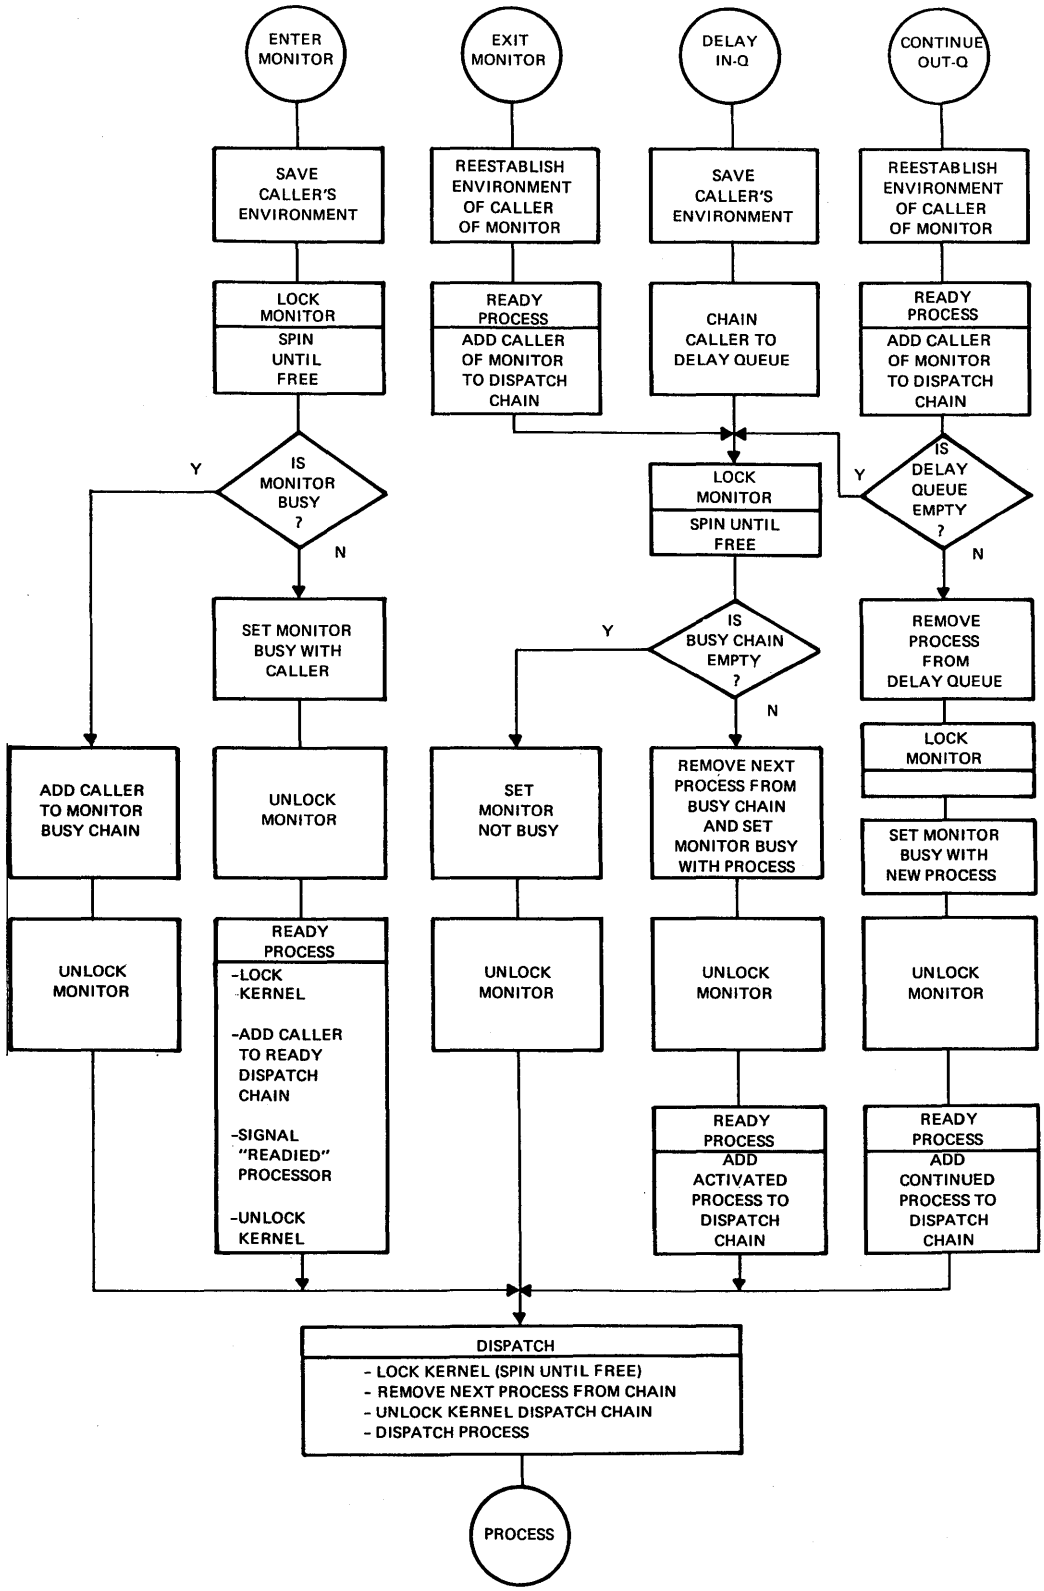

Figure 2—Kernel procedures to support monitors

work to perform, the kernel could continually cycle through its dispatch chains instead of going into a wait state (or perhaps periodically on a clock interval).

EXAMPLE SYSTEM

An example problem is presented to illustrate how monitors can be employed in building non-trivial concurrent programs. The utility of the monitor concept is evaluated by comparing the results with another solution of the same problem that did not employ monitors. Performance measurements are also given of various test runs when applying the monitor solution, as a multiprocessing program, to a dual processor configuration.

The following example application was defined as a benchmark model for investigating kernel designs and for evaluating relevant performance aspects. The benchmark is intended to reflect much of the character of a highly interactive transaction processing system, but actually it is a hypothetical application wherein data formats and processing functions are kept to a minimum (simulated) in order not to obscure the inherent interactions in the application problem being solved.

The benchmark application was implemented twice on an existing multi-tasking operating system in assembly language. Conventional operating system features for interprocess communications and synchronization were employed in the first implementation. This was done before any monitor capability was even designed. The second case employed monitors. A kernel facility employing the techniques described in the previous section was developed to run under the environment of an operating system task.

The application can be briefly described as terminal operators being able to exchange messages and to start concurrent job processes which execute disc I/O and computing functions according to the operator's request. The job programs send their results to the terminal specified in the originator's message. Job operations and terminal message exchanges run concurrently. Terminal I/O is overlapped so that an operator can input a message while the previous message is being processed. Output messages preempt input; job output takes presidence over terminal messages; job requests are serviced first-in-first-out. Each message delivered to a terminal contains a header identifying the source unless the previous output was from the same source.

Only the monitor approach to the benchmark problem is described here. Documenting the solution employing conventional techniques would serve no useful purpose. The monitor solution is itself somewhat arbitrary; there are probably many other ways of solving the benchmark problem in terms of monitors and processes. The approach taken here attempts to balance performance with conservation of memory. The benchmark program is built up in stages to simplify testing. Five terminals and two job processes are supported.

The benchmark program is described in pictorial form in Figures 3 through 5 with circles representing processes and boxes representing monitors. Program modules are identified by a global name and a type name in parentheses.

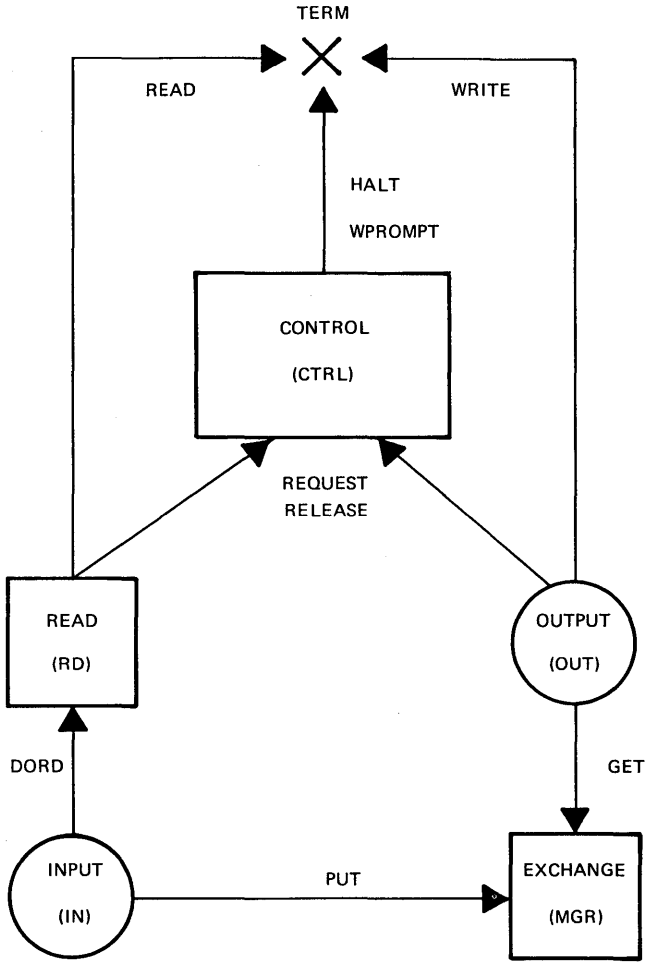

Figure 3—Benchmark terminal subsystem

Program modules of the same type have identical code; their data structures are replicated during program integration to build separate instances of the same module type.

The first stage consists of a single terminal subsystem as illustrated in Figure 3. The INPUT process continually inputs messages and passes them on to the message EXCHANGE monitor. The OUTPUT process continually gets messages from the EXCHANGE monitor when available and outputs them to the terminal. The terminal resource CONTROL monitor is responsible for granting exclusive access to the terminal and for maintaining its read/write/idle mode. The CONTROL monitor preempts a pending read I/O by executing halt I/O if the OUTPUT process requests access while the terminal is in read mode. The purpose of the READ monitor is to insure, by being a higher priority program module than the OUTPUT process, that the read I/O will be physically posted before the OUTPUT process can attempt to preempt it and cause contention problems with halt I/O. The CONTROL monitor also writes the prompt character while granting read access to avoid potential contention with halt I/O.

The next stage is to add the JOB processes as illustrated

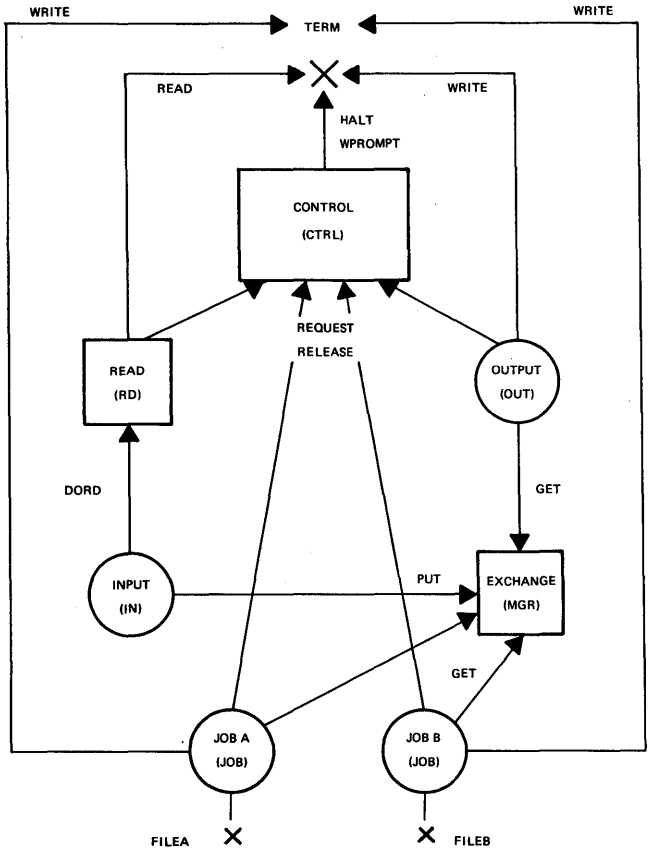

Figure 4—Single terminal benchmark system

in Figure 4. The aspects of controlling the JOB processes is much the same as for the OUTPUT process. However, with the addition of the JOB processes, the CONTROL monitor must maintain the identification of the last writer in order to indicate whether or not a header message is required on a new output request. It must also provide a delay queue for the JOB processes separate from the OUTPUT process in order to give priority to job output versus terminal output. Separate EXCHANGE monitors could have been provided for the JOB and OUTPUT processes, but a combined monitor approach was selected to conserve memory. Code in the EXCHANGE monitor is kept to a minimum to avoid contention losses in multiprocessor configurations.

Adding terminals to Figure 4 impacts the buffer requirements of the EXCHANGE monitor. It must provide an exchange mechanism for each source-destination pair, times two to allow overlapped I/O. This number in terms of buffers is not actually required by the application (in fact two times the number of terminals is adequate), so a buffer pool is employed in EXCHANGE to dispense message buffers, two per INPUT at most. With the addition of Pop and Push procedure calls in EXCHANGE for obtaining and releasing buffers, the full benchmark program is illustrated in Figure 5 (for five terminals and two job processes).

Although this third stage appears to be complex, it is actually a trivial extension. All complex logic (of CONTROL and EXCHANGE in particular) was verified in the previous two stages (CONTROL and EXCHANGE were initially written with all the features needed in the final stage).

The total application consists of:

- 5 input processes of type IN
- 5 output processes of type OUT
- 2 job processes of type JOB
- 5 read monitors of type RD
- 5 control monitors of type CTRL
- 1 exchange monitor of type MGR
- 5 logical terminals of type TERM
- 2 logical devices of type DISC
- 27 delay queues (not described)

Clearly the system is highly modular and structured.

Comparisons between the two implementation philosophies for a single processor configuration are summarized in Table I. Development effort for the kernel is not included in Table I, as it is a generalized facility taking the place of the tools otherwise provided by the conventional operating system.

Although the design effort was the same, coding and testing of the monitor solution took less time which resulted in nearly a doubling of productivity. Documentation, acceptance testing, and other activities normally encountered in a production environment are not included in these figures; however, the overall improvement should still be significant considering the understandability, modularity, and structured design of the monitor approach. While developing the monitor solution to the benchmark application, we experienced no aggravation in resolving race conditions and in defining correct inter-process communication protocols as occurred in the conventional case. The translation from design to code was also smoother, and the design itself was much more lucid. For example, when running tests to measure minimum buffering requirements we were unable to explain the conventional-system results, but the monitor-system results were predictable.

TABLE I—Benchmark Comparisons

	Conventional System	Monitor System
Development Time (work-days)		
Design	5	5
Code	11	5
Test	9	3
Total	25	13
Memory Size (1,000 bytes)		
Sharable code	3	3½
Total including data (monitor system includes over ½K for multiprocessing)	12¾	13¼ (note)
Performance Tests (messages per unit time)		
User transactions with minimum job processing	157	192
Execute-bound exchanges	273	416
I/O-bound exchanges	143	228

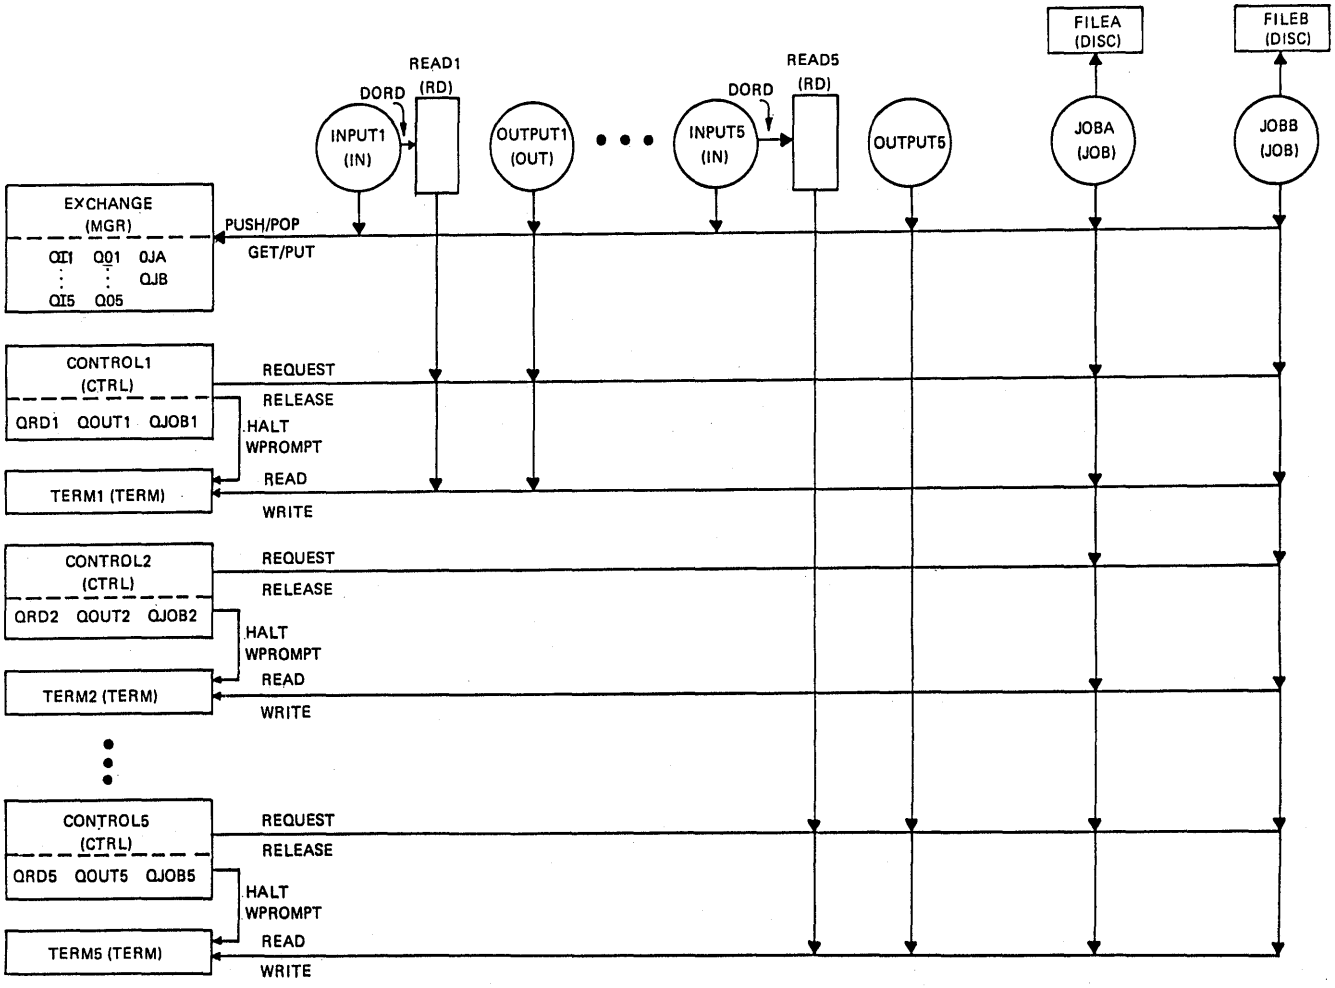

Figure 5—Benchmark system

The two solutions required approximately the same amount of memory. It should be noted that the kernel for the monitor solution was designed to support multiprocessing while the conventional-system was intended to run only on a single processor. The monitor solution therefore incurred unnecessary overhead when applied to a single processor.

The single processor monitor-system ran considerably faster than the conventional-system. The execute-bound test simulated maximum loading for terminal to terminal message exchanges. The I/O-bound test was performed with a single high-speed "terminal" (magnetic tape) sending to a low speed terminal. The better performance of the monitor solution, even with its resident multiprocessing overhead, is attributed to a better design and to more efficient interprocess communications with monitors versus existing operating system features.

The conventional-system was not designed to support multiprocessing because it seemed to be a very laborious and unproductive task. The real test of the monitor approach came about when we were able to bring up two different multiprocessor versions—a dual processor and a four-processor configuration with shared JOB processes—of the identical application program in only the short time needed to build load modules for each machine. After debugging the application on a single processor, *no errors* were uncovered during any of the multiprocessor tests on real hardware. Indeed, the processes which ran interleaved concurrently on a single processor ran in parallel on multiple processors *without change to any of the application code.*

Performance comparisons between single and dual processor configurations are given in Table II. In these tests the processors were the same model, and the data structures stored in shared memory for the dual processors were located in the same physical memory module for the single processor tests; furthermore, code was not executed out of shared memory. Consequently, memory access times were the same for the two configurations.

In the first test case, messages were exchanged between "null" terminals which did not involve real I/O nor much processing. The result is that the extra processor helped little (33 percent) because the application exhibited little

TABLE II—Multiprocessing Comparisons

	Single Processor	Dual Processor
	(Messages per unit time)	
Terminal-to-terminal exchanges with "null" devices	383	510
User transactions with job processing (per processor)	182	181
Concurrent execution of job transactions	182	357

parallelism in this test run and because data contention (spinning on locked data structures) was a bottleneck due to the very short execution periods of the application routines.

The second test represents a more realistic situation. The rate of processing user transactions was measured on the single processor. In the dual processor case, one processor was kept busy executing job computations while the second processor processed the same user transactions as in the single processor case. The dual processor was able to process essentially the same number of messages as the single processor (99 percent) along with heavy computing loads.

The third test was derived from a different, but similar, application. It allowed the compute functions of job processing to be executed in parallel. The dual processor was able to process 1.96 times as many messages per unit time as the single processor.

CONCLUSIONS

We conclude that the monitor concept is indeed an effective tool for building concurrent system programs. Furthermore, the concept can be applied as a useful design methodology, irrespective of the implementation mechanisms. Highly modular and structured systems will result with minimal opportunities for obscure time-dependent bugs and deadlock situations.

We applied the monitor concept to multiprocessing and demonstrated its particular utility for such applications. System programs intended to run on multiprocessor configurations can be reduced to the scope of single processor designs by employing monitors. We also illustrated techniques for implementing a run-time kernel to support multiprocessing. With such a kernel, integrated distributed processing programs can be built that accommodate different multiple processor configurations without change to the application code.

ACKNOWLEDGMENT

Messrs. G. Anderson, J. Goettelmann, T. Kibler, and D. Schmaltz are thanked for their helpful contributions and review.

Data accessibility in structured programing

by NED CHAPIN
Data Processing Consultant
InfoSci Inc.
Menlo Park, California

INTRODUCTION

C. A. R. Hoare, N. Wirth, E. W. Dijkstra, and some others active in structured programing have described and tacitly recommended a hierarchical accessibility of passed data in structured programing (see for example, References 11 and 26). This fits well, they and others indicate, with both the theory and the practice of structured programing (see for example, References 15, 18, 19, and 25).

This paper does not question that the hierarchical accessibility with parameter passing can be made to work. It may even be the most elegant data accessibility for some interesting academic problems. However, this paper does argue that for most practical software design situations, other approaches are on balance superior, especially for the kinds of situations commonly implemented using COBOL, FORTRAN, PL/1, JOVIAL, or BASIC. To support this argument, this paper presents first some definitions of terms, and then an examination of some evidence in nine categories. Following a ranking evaluation, the paper draws a conclusion.

DEFINITIONS

For purposes here, a system or program designed and implemented with structured programing techniques is characterized as having a proper nesting of functions in three basic control patterns with single entrance and exit, in the sense defined by Mills.[20] This paper does not use "structured programing" to mean "structured coding," but rather uses it in the sense sketched by Dijkstra.[5] Further, structured programing is characterized by a hierarchical structure of modules (segments) again in the sense defined by Mills, which to people appear to specify the performance of specific single functions, as defined by Parnas and McGowan.[19,22] The function parsing techniques that lead to the creation of such proper-nested structures have been described elsewhere.[9] The object is ease of human understanding.[7,16]

For the purposes of this paper, a level of abstraction as it applies to data is defined to be a grouping of data based upon the recognition by people of some common characteristics, often semantic rather than structural.[11,19,24] Data conforming to levels of abstraction is referred to in this paper as "leveled data." For example, a file (composed of records in turn composed of fields) is regarded as more abstract than the component fields individually. In contrast, a disjoint string is defined to be a string data structure which has as member elements items of data with no necessity of similarity in level of abstraction. Thus a disjoint string might be composed of two Boolean variables, a record from a file, three tables, and a queue. Pointers may be among the elements of a disjoint string.[17] Because of the potential diversity, each member element in the string is specifically enumerated and described.

For the purposes of this paper, a flow graph is defined to be a graphic presentation of part or all of a control flow in a system or program.[1] The edges in the graph represent an explicit flow of control unaccompanied by the manipulation of data but accompanied by the implicit or explicit communication of data. The nodes in the graph represent an implicit flow of control accompanied by successive steps in the explicit manipulation of data, and accompanied by some means for the communication of data among the steps.

EXAMINATION

Access volume potential

The access volume potential is a count of the maximum possible number of data items with assigned values which are accessible to any given module upon invocation, summed for all modules. Ideally, this count should be small, since the larger it is, the greater is the difficulty of human understanding in design, implementation, and maintenance.

The calculation of the access to data items has been described by Allen and by Cocke.[1,2] Following "procedure A" as an "algorithm for finding intervals," a partition can be made of a control flow graph into basic intervals. If the hierarchy of modules is a true tree conforming to a proper nesting of functions, then it is possible to reduce selectively the basic control graph to yield nested intervals of higher and higher order, as diagramed in Figure 1. These nested intervals can correspond not only to the modules, but also to the levels in the hierarchy, since proper nesting in the hierarchy yields a reducible control flow graph.[13] Such a selectively applied flow-graph reduction is roughly equiva-

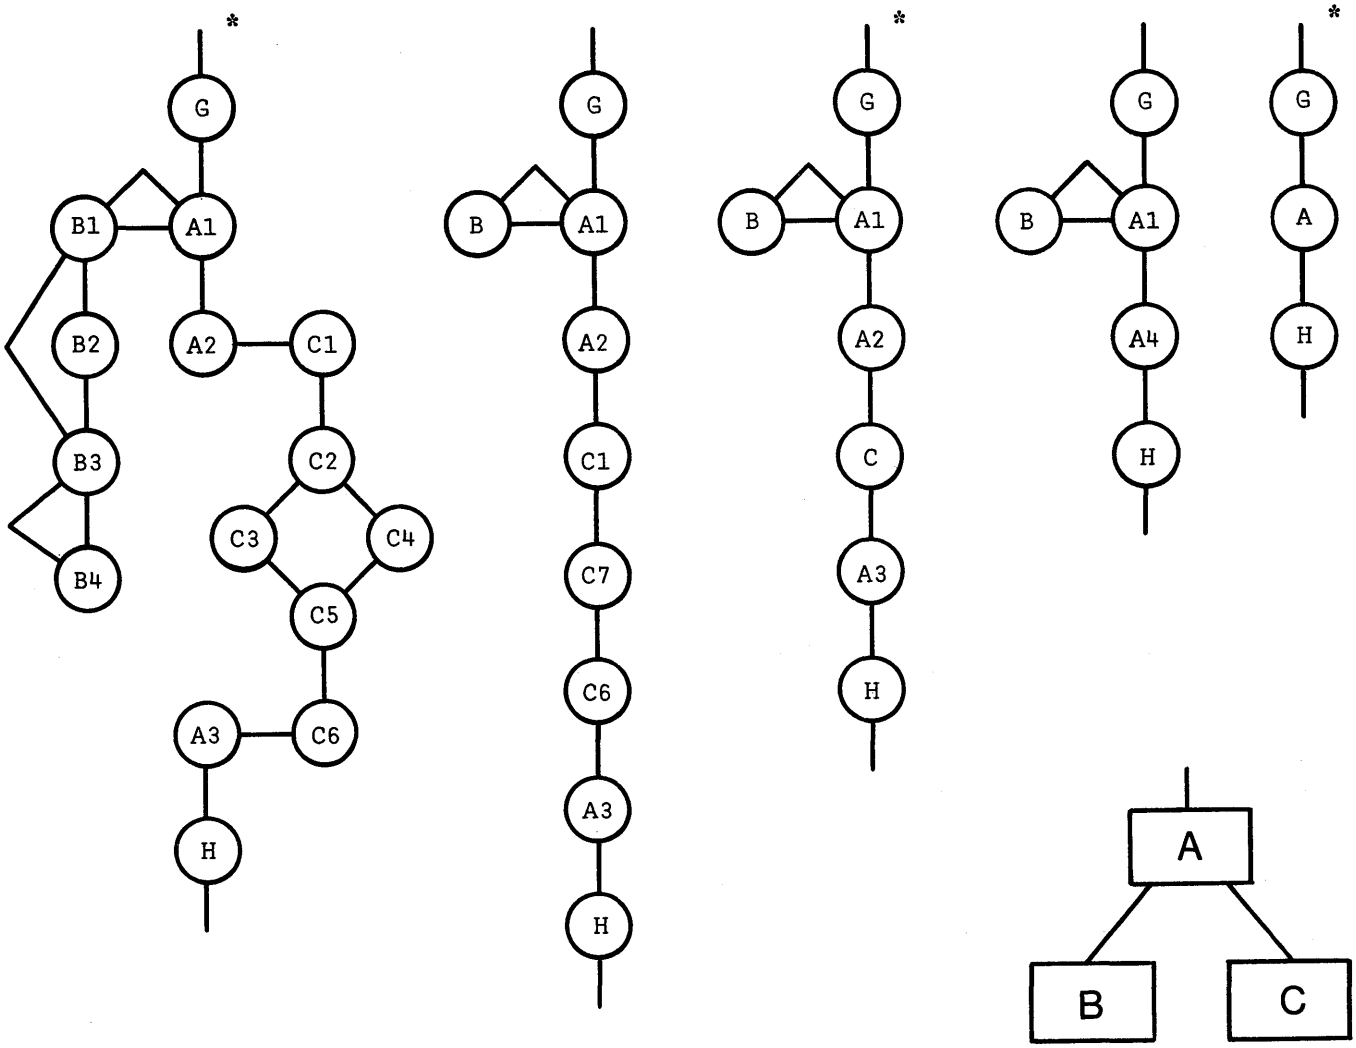

Figure 1—Successive (left to right) interval reduction in a control flow graph illustrating different module correspondence, as marked by *, and by use of identifying letters and subscripts, such as A2 (a part of Module A) etc.

lent to the reverse of a top-down application of function parsing guidelines.[9]

Because of this correspondence, the control flow graph can be used as a basis for determining the intrasystem access to data, given a structured programing design, and implementation. With global data, the "live" access potential (L) for any one module is given by the union of (a) the union (U) of the assignments (AN) and definitions (DN) of data within the module, with (b) the union of the data assignments and definitions available on the entrance edge of module i that do "reach" (R) that module:[1,2]

$$L_i = R_i U (AN_i U DN_i) \tag{1}$$

Note that the questions of whether or not the module i preserves or changes the definition of assignment, or whether or not data so specified are used in the module is irrelevant in determining the live access potential at any one module. If modules be identified in execution sequence, then the reach (R) expands as the control flow covers more modules. Thus, the access potential increases with each module executed by the new assignments AN and new definitions DN effective in each module.

If ρ indicates a count function, then the volume or amount of live access potential (A) in a program or system of n modules with global data communication is estimated by:

$$A = \sum_{i=1}^{n} \rho L_i \tag{2}$$

With passed data, the amount of live access potential is much smaller than for the global case with the use of structured programing techniques. The live access potential is given by expression (1) as before, but now the set R_i is much reduced because it is a subset of the global data case, limited to the data deliberately communicated between the i^{th} modules and other modules. This also keeps expression (2) much smaller.

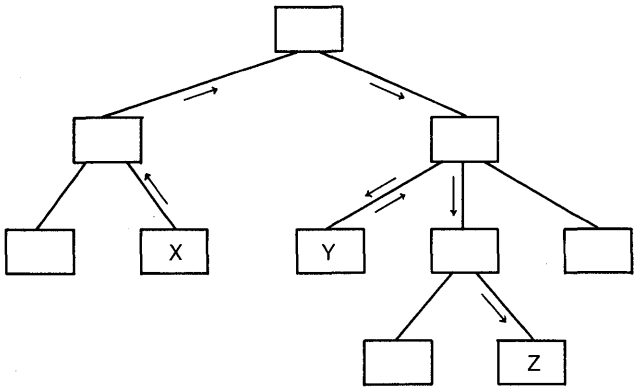

Figure 2—Illustration of data pass-through and pass-through chains

With leveled data, the minimum total number of data items assigned values (AN) or defined (DN) is never smaller, and is usually larger, than the corresponding values for the disjoint strings. This is because the disjoint strings make provision only for data items actually accessed, whereas leveled data may include data defined or assigned for consistency, elegance, or symmetry of conception.

Expressed as a ranking, with 1 for the most desirable, and 4 for the least, passed disjoint strings are of rank 1, and global leveled data are of rank 4. This is summarized as the top row in Table I.

Access values

The access to data values treats each item of data as a different item of data when it takes on a different value. A count of these is an indicator of the diffuseness of function in the hierarchy and of the difficulty of debugging and maintaining a system of program.

The estimating procedures for access to values *used* for global data has been well presented by Allen and Cocke.[2] Domains are difficult to specify from the flow graph and from the hierarchy.[10] In practice, the availability of input-output tables is helpful.[7]

With passed data, the access to data values is much restricted, and domains for data entering a node from along any edge of the control flow graph can be cleanly specified. In terms of data values *used* in the module, the access is the same as for the global case noted above. But to this must be added the access to values arising from the communication of the data through the module. Much data may have to be passed through some modules unchanged in value or identity in a hierarchical structure. Diagramed in Figure 2 is a situation where an item of data is assigned an identity and value in module X and accessed in module Y to be modified in value but not identity for use in module Z. The communication from X to Y involves a pass-through chain containing three pass-through nodes, and from Y to Z of two pass-through nodes.

With leveled data, the count of the data values accessed is greater than for the disjoint string, because extraneous values are presented in a module at levels above the lowest in the hierarchy.[23] Hence, the ranking for access to values as summarized in Table I is best for the global disjoint string, and worst for the passed leveled data.

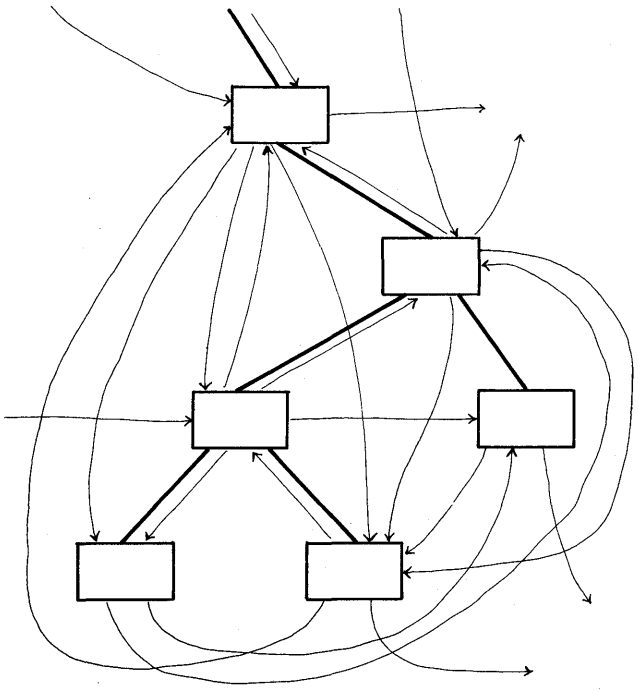

Figure 3—Illustration of weak congruence between control flow marked as heavy lines, and data flow marked as light lines

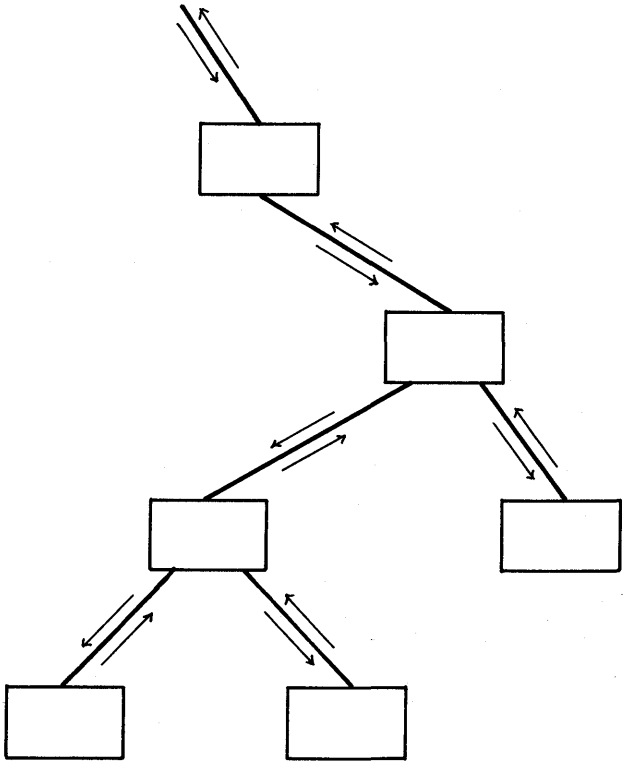

Figure 4—Illustration of strong congruence between control flow and data flow

Congruence

When the pattern of the data communication among the modules of the hierarchy has a high degree of congruence with the pattern of the flow of control, design, implementation, and maintenance work is easier. People only have to know one pattern to understand two aspects of the program or system. The use of input-output tables helps reveal the degree of congruence between data and control flow.[7]

Global data offers little congruence with the nested hierarchy of the tree, as diagramed in Figure 3. This is the case for both leveled data and disjoint strings. This is because the data flow is not constrained to match the control flow, and in practice is usually a network, not a tree if the modules be treated as nodes for data flow.[14]

Passed data offers excellent congruence with the nested hierarchy of the tree, as diagramed in Figure 4. This is the case for both leveled data and disjoint strings, but the disjoint string reduces the presence of unused data. The ranking, therefore for congruence places the passed disjoint string in the best position, and gives a tie for the two alternatives in the global data case, as shown in Table I.

Coupling

While the concept of coupling comes from structured design, it can be applied to software designs done with structured programing. Using the definition and scale of coupling as laid out by Myers, the global data case is at best common coupled.[21] This scale position is the same for both leveled data and for disjoint strings.

The passed data case requires a closer inspection. Using leveled data results in stamp coupling except sometimes at the leaf position in the hierarchy. Using disjoint strings enables the consistent use of elementary items of data throughout the hierarchy, and results in the more desirable data coupling between modules on adjacent levels vertically in the hierarchy. In either situation, no coupling at all characterizes all of the other coupling relationships between modules. In short, the ranking of coupling is the same as for congruence, as noted in Table I.

Strength

While the concept of strength comes from structured design, it can be applied to software designs done with structured programing. Using the definition and scale of strength as laid out by Myers, the evidence on strength is moot.[21] Sometimes one alternative seems to go with higher strength and sometimes not. Hence, the ranking for strength is a tie for all, as shown in Table I.

While not evidence, an observation may add insight. Since in structured programing, the focus is on the function of a module, the data flow into and from a module serves effectively as a definition of that function. For high strength, a module must require all of its input to yield its outputs, and not be partitionable into two or more parts with no increase in the number of intermodule items of data needed, ignoring pass-throughs. Therefore, a partitioning of functions implies a partitioning also of data flow if high strength is to be maintained, as diagramed in Figure 5.[6,8] The means of achieving that data flow is really an independent question. In a high-strength design, the actual access of data for use is generally closely similar whether the design or the implementation be passed data or global, but the "pass-through unchanged" pattern is very different.

Overhead

Execution overhead in an implemented program or system depends on many factors, including the computer configuration, the language, the compiler, the operating system, the shop practices, etc. Even if attention be given only to two aspects, such as CPU cycles used, and amount of internal storage committed, only general trends can be described. No firm consistent evidence is available, or probably even possible beyond an instance by instance basis.

Global data are the most economical of storage space and fastest in execution speed if disjoint strings be handled. Both measures are impaired by using levels of abstraction because of the increased size of the units of data handled. This is reflected in the rankings shown in Table I.

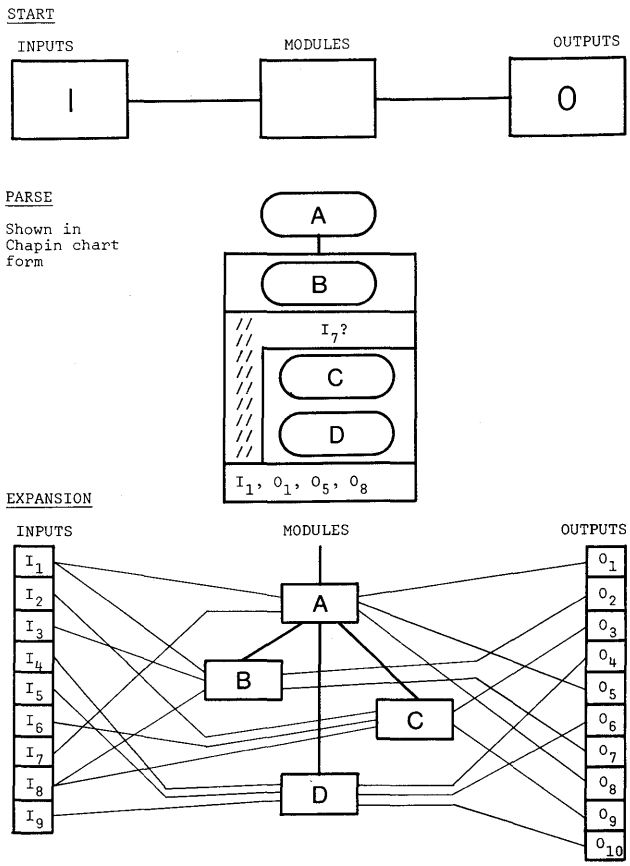

Figure 5—Diagram of some data implications of high strength

Passed data are still less economical and slower, again in the same two steps, because of the increased handling of data that are involved. The higher the strength of the modules, the smaller is the impairment because the more elegant is the use of data. But the smaller the modules the larger is the impairment, because calling and passing becomes a larger proportion of the total work to be done. This degrades the ranking for the passed data alternatives, as shown in Table I.

Human convenience

Both the global and the passed data are convenient for people, but in different ways. The global data offers single description (declaration), economy of effort, and ease of reference to the description for people. But global data also offer the least visibility into the steps in the use, transformation, and production of the values of the data—a critical matter in a function-oriented approach.

The passed data offer uniformity in conventions and high visibility. But the cost is in redundancy and repetition, both in the designs and in the code. At the compile stage the language conventions provide an automatic check on human performance. This enforcement helps keep the data visibility high.

Convenience is also both aided and hurt both by leveled data and by disjoint strings. The leveled data provide an easily comprehended grouping of data but hide data identities—a serious matter in debugging and maintenance. The disjoint strings lack the mnemonic quality that aids the human memory, but do focus attention on actual functions.

A ranking of the human convenience of necessity is subjective, and reflects value judgments about operating environments as well. An informal survey conducted over half a year's time involving persons who design computer software and try to use structured programing techniques, and including people from all across the continent, indicated the preferences shown in Table I on convenience.

Maintainability

Provided the visibility is good, the reports from people doing the work seems consistent on maintainability: the passed data in disjoint strings has the lowest cost of maintenance. Some of this comes from the access measures noted earlier, some from congruence, and some from coupling. People can follow the items of data more easily, and the functions are usually more clearly specified and understandable with the passed data in disjoint strings. By contrast, the leveled data have to be peeled away to specifics, and hence involve more maintenance effort.

For these same reasons, the global data offer less aid in maintenance. The value changes in the data are more difficult to follow, especially when leveled data are used. In the absence of countermeasures, it takes people longer to find out what is going on. Hence, in the summary ranking, the passing of disjoint strings is shown as a 1, and the leveled global data is shown as a 4.

System quality

System quality has many measures. One is number of bugs encountered over some period of time. Using techniques described by Haney and Myers, it is possible to give a quantitative tinge to measuring system quality in terms of bugs.[12,21]

Applying those measures to examples drawn from industrial and governmental computer applications, indicates that passed data in disjoint strings has the lowest expectation of bugs. Passed leveled data has an expectation about one-third higher. Global data in either form yield an expectation for nearly double the number of bugs. This gives a tie in the ranking shown in Table I.

Criticism of these techniques and the use of bug counts as quality measures has been heard. Both are admittedly imprecise—but they are also the best quantitative measures currently available. Some of the quantitative observations offered by Brooks are not inconsistent with the rankings shown in Table I for system quality.[4]

EVALUATION

A review of the evidence indicates a strong leaning in one direction as the Overall summarizes in Table I. The availability of this evidence gives the opportunity to take a fresh look at some alternatives and make rational choices to fit given situations and needs. Let us consider local, internal, and external data, for example.

Local variables are items of data made available in the design and implementation to only selected modules. If they are accessible only in the modules in which they are declared or defined, then they are true internal variables. If they are accessible to other modules, then all of those modules must be in the same branch of the tree that represents the nested hierarchical relationship among the functions. Effectively, the locals thus used become "restricted" globals. Local variables are well regarded in the theory of structured programing.[19,27]

Used with global data, local data are a step in the direction of passed data. Used with passed data, local data offer a relaxation of the visibility enforced with passed data. But the use of true internals degrades neither passed data nor global data usage. Internal data use may even enhance either but especially global data.

"External" data are another possibility. These are items of data communicated between specific modules anywhere in the hierarchy—not just between immediate superiors and subordinates. It is like a private line for communication external to and addition to those provided by the passing of data.

External data are better regarded in structured design than global data because they are more visible to people.[21] But their flow does not follow the tree, and as they are usually

TABLE I.—The Most Favorable Rank is 1, the Least Favorable is 4.

SYNOPSIS OF RANKING

Evidence	Passed Data		Global Data	
Factor	Leveled	String	Leveled	String
Volume	2	1	4	3
Values	4	3	2	1
Congruence	2	1	3.5	3.5
Coupling	2	1	3.5	3.5
Strength	2.5	2.5	2.5	2.5
Overhead	4	3	2	1
Convenience	2	1	4	3
Maintainability	2	1	4	3
Quality	2	1	3.5	3.5
OVERALL	2	1	4	3

used, they provide another (sometimes complicating) data flow for people to understand simultaneously with either passed or global data. A common use of external data accessibility is the use of scratch files to communicate data between selected modules, often relatively high in the tree.

Is there some form of intrasystem data communication that would rate better than any of those discussed thus far? Consider the following possibility, termed "monitored data," that combines the strong features of the forms and varieties already discussed.

1. Define or declare with a unique name each and every data item only once in the software system to be created. Incorporate in the definitions or declarations any list-linking or component or group-element relationships among the items of data.
2. Enable by a specific visible means in the documentation for the module, each module that may access the value of any given item of data or may assign the value, on an item by item basis, noting the role of the item of data. The roles may be for control, for processing, for modification of value, or for communication through unchanged.
3. Record and associate with the definition or declaration, the identification of the accessing and assigning modules and the roles of the data in those modules. This documentation, while not intrinsic to monitored data, adds substantially to the human convenience and to the maintainability.
4. Disenable all other modules for all items of data by a means that prevents their implementation if any access is explicitly or implicitly attempted in or by them to any item of data for which they have not been specifically enabled.
5. Make any access to any item of data be to *all* parts of that item of data (for example, enabling for a 1000-byte record yet only using a 2 byte field in it would be illegal) except where explicit decisions result in alternative access.

Some comparison of monitored data with the forms and varieties considered earlier may be interesting (see Table I). For systems and programs involving more than about 50 intermodule items of data, on volume, congruence, coupling, and strength, the monitored data alternative ranks the same as the passed-string alternative. On values and overhead, it ranks the same as the global-string alternative. On system quality, it ranks better than the passed-string alternative, by close to a factor of two. For systems and programs of smaller size and for some strongly mathematics oriented systems, the passed-string alternatives appear to be superior to the use of monitored data. But from the limited experience thus far, for most non-trivial systems and programs implemented in COBOL, FORTRAN, PL/1, JOVIAL, and BASIC, the monitored data appear to be the superior alternative.

Insufficient experience is available to give a confident ranking on convenience and maintainability. Some observations may be indicative, however. On convenience, the monitored data appear to offer all the advantages of both the passed and the global alternatives, and avoid the low-visibility of the global and some of the redundancy of the passed data alternatives. The verification of the enabling in points # 2 and # 4 requires either a manual or a software step. An automatic software step improves the human convenience. The usefulness and precedent for such steps already exists in some structured programing practices using precompilers, data base administrators, librarians, and project files.[3] Input-output tables can also be a useful aid.[7] Because of the excellent visibility it produces, the monitored data alternative appears to offer a maintainability potential superior to that of the passed-string alternative.

CONCLUSION

Among the four alternatives considered, the weight of the evidence favors the passed form of intrasystem data communication, especially where the overhead is not of serious concern. The disjoint string ranked superior or equal to the use of data in levels of abstraction on all nine factors considered. Except on convenience and maintainability where little evidence exists yet, the monitored form of intrasystem data communication appeared to be superior or equal to the passed-string alternative.

INTRODUCTION

There is currently interest in measuring the complexity of a computer program with the evaluation of a program's control structure via its flowgraph representation.[1,2] However, the inclusion of the effects of data on these measures is often lacking. This paper proposes a new measure of program complexity that attempts to identify regions of locality by combining a control structure approach with information about data usage to get a valid measure of overall program complexity. The need for objective measures of program structure is important if the area of programming language design and implementation is to take on a more formal basis from the ad hoc techniques currently used.

This work is related to that of Hellerman,[3] Savage,[4,5] and Chaitin[6] in that the complexity of an algorithm is defined as the number of bits in the algorithm's representation, i.e., the number of bits in a program implementing the algorithm. A program implementing a given algorithm is considered to be better than another program implementing the same algorithm if it has fewer bits in its representation. In order to provide a standardized representation for algorithms, the concept of a Hierarchical Abstract Computer is defined (HAC). Based on a primitive-level HAC, hierarchical levels of HAC modules are used to specify the structures and sequences of a specific algorithm. The modules are chosen according to the concept of a Prime Program Parse,[7] which defines a particular, unique sequence of subroutine decompositions from an original flowgraph representation of an algorithm. The complexity of the total program is defined to be the sum of complexities of each of the modules used to form the hierarchy.

The difficulty of writing program code to implement an algorithm has been related to the amount of information that must be manipulated in the process of writing the program. There have been many attempts recently to simplify the process, most conspicuously aimed at the control structure complexities. Structured programming has been expounded as a method by which programs can be written with minimum difficulty, and mainly involves restraints on the use of control structures. There are also some methods which are directed at data structure complexities, such as the concepts of data abstraction and information hiding. These methods are concerned with the simplification of the data that is manipulated by the program code. By reducing the data available for referencing to only that which is directly needed by a section of code, the possibility for confusion is reduced. As much as possible, references to data are maintained in small sections of code, and are kept exclusive, in that only those sections are allowed to act on the data. In this manner, local data responsibilities are easy to isolate and to maintain. These local responsibilities are known as clusters, and their exclusiveness and privacy is known as information hiding.

It is assumed that a program is well-structured if clusters of data and control activity are small. The resultant small subroutines are thus accompanied by correspondingly small data spaces. The purpose of this research is to be able to measure different implementations of the same algorithm so as to determine the particular implementation which is best in the sense of being well-structured or least complex. The next section discusses some relationships between an algo-

* Research supported in part by Air Force Office of Scientific Research grant 77-3181 to the University of Maryland.

rithm and the set of programs which implement the algorithm.

ALGORITHMS AND PROGRAMS

An algorithm has been defined to be a finite set of rules which specify a sequence of operations used to solve some specific problem. The operations specified by the rules are selected from a set Ω of operators used by the algorithm. The proper sequencing of these operations depends on the state of the data items used by the algorithm, and is described with the use of a meta-algorithm or program which directly implements the algorithm. The essential difference between an algorithm and its implementing program is the specification of the operation sequencing through the use of control statements. Each algorithm has an infinite number of programs which implement it, some of which are considered to be well-structured, or less complex. It is this class of programs which a complexity measure attempts to identify.

Algorithms are rarely completely specified, in that assumptions are made about the characteristics of the data types and the operators which manipulate the data. Yet each operator is itself described by an algorithm at a lower level, and so on, down to some indivisible, lowest level set of operators and data types. Computer programs are written in high-level languages whose operators are implemented in machine languages, whose operators are in turn implemented in micro-code, whose operators are implemented in hardware gates, etc. The next section proposes a primitive set of operators and data types to be used as a basis upon which complete specifications of algorithms can be hierarchically built.

Rarely, however, does the operator set of the algorithm match the operator set of the programming language. A central problem in programming is identifying and building the inherent operators and data types that make up the algorithm, using the available, lower-level tools. Usually, the algorithm description given to the programmer does itself not adequately recognize the structures within the algorithm specified, and so, severely complicates the problem facing the programmer. His task is to perform certain transformations to the algorithm specification without altering its basic structure so as to implement the request as simply as possible.

Let Δ be the set of data items used by an algorithm or program, and let D be a subset of Δ. The *Execution Sequence* of an algorithm relative to D is defined to be the sequence of states assumed by the members of D.

Two programs are *execution equivalent* relative to D if they have the same execution sequence for all inputs. Different programs can be execution equivalent because the occurrence of control operations is ignored, having no effect on the execution sequence.

Two programs are *functionally equivalent* if, given the same input values, they produce the same output values.

Two programs are *semi-execution equivalent* relative to D if, for each $d \in D$, the programs are execution equivalent relative to d. That is, each data item of interest takes on the same set of values, but not necessarily all in the same relative order as the other data items.

It is a trivial result that if two programs are semi-execution equivalent, then they are also functionally equivalent. Functional equivalence is the weakest restriction, in that there need be no similarity in the two algorithms used by the programs. Execution equivalence is the strongest restriction, requiring two programs to have identical data transformations. The restriction of semi-execution equivalence is felt to be a reasonable criteria for comparing different programs, in that the implemented algorithms are not only functionally equivalent, but also structurally similar, in that all of their data items are undergoing similar transformations. There is a certain latitude available to the programmer in this situation to strive towards a simple implementation.

HIERARCHICAL ABSTRACT COMPUTERS

The concept of a set of programs interacting at different levels, and working together to implement an algorithm, leads naturally to the following definition of a Hierarchical Abstract Computer (HAC).

Def: A Hierarchical Abstract Computer (HAC) is a quadruple (Δ, I, Ω, T) where Δ is a set of distinct named data items, each of which is associated with a member of T, the set of legal data types, I is a set of named instructions, and Ω is a finite set of operation codes. Each instruction is of the form:

$$\omega d_1 d_2 \ldots d_n x_1 x_2 \ldots x_m$$

where $\omega \in \Omega$, $d_i \in \Delta$ and x_i is the name of an instruction in I, or $x_i = 0$. The d_i's are the data arguments for the operator ω, and the x_i's represent the possible alternatives for the next instruction to be executed. The data items and the instruction addresses (names) are numbered beginning with 0, and a transfer to address 0 means to halt execution for that HAC.

Operation codes are either composite or primitive. A composite code is itself implemented by a lower-level HAC, carrying out some specific algorithm on the input data. A primitive operation code is, in some sense, indivisible, and is defined to be one of the three operators:

TEST d x_1 x_2
SET d x_1
CLEAR d x_1

where $d \in \Delta$, and is associated with the data type BIT, having the value 0 or 1, and $x_1, x_2 \in I$. These instructions have the semantics:

TEST	If the contents of $d=0$, then the next instruction is to be found at address x_1; otherwise, the next instruction is at x_2.
SET	Set the data item d equal to 1.
CLEAR	Set the data item d equal to 0.

These three codes form the Primitive Basis, Ω_p, and, if

a HAC consists of Ω_p together with the data type $T=\{BIT\}$, then the HAC is said to be a Primitive HAC, or PHAC. An important characteristic of Ω_p is that it is complete, that is, it can compute all finite functions $f: \{0,1\}^n \rightarrow \{0,1\}$. This result follows directly from the PHAC implementation of the basic Boolean functions AND, OR, and NOT.

As described, a HAC program can be decomposed into lower and lower level modules until only Primitive HACs are obtained, thus forming a tree of modules. Conversely, given a PHAC implementation of an algorithm, sections of code can be removed and replaced by a single invocation to a new composite operator, with as many parameters as there were global variables across the code segment.

While a HAC is only as powerful as a finite state automata, it is still sufficiently powerful to model real computer programs that do not use auxiliary storage, and, unlike finite state models, can easily be measured with a complexity measure. This model can, however, be easily extended to include tapes. As in real hardware, specific addresses for data, control, and status registers can be defined resulting in a memory mapped I/O. Placing information into these registers causes information to be read or written from a tape and to appear in the data register. Thus storage may actually be infinite, but accessible only via a finite set of specific addresses.

PROGRAM COMPLEXITY

Given a HAC implementation of an algorithm, it is now necessary to define a complexity measure on this set of modules. The complexity of a HAC H is defined to be the sum of the complexities of each of the instructions in the HAC:

$$C(H)=\sum_{j\in I} C(j)$$

Let $L_\Delta=\log_2|\Delta|$=number of bits needed to address the data space,
$L_I=\log_2|I|+1$=number of bits needed to address the instruction space I (with the addition of address zero to be used as a STOP instruction), and
$L_\Omega=\log_2|\Omega|$=number of bits needed to specify the operation code.

Then, the complexity of an instruction i with m data arguments and n addresses is:

$$C(i)=L_\Omega+m*L_\Delta+n*L_1$$

For PHAC programs, the complexity of each TEST instruction is $(1.58+L_\Delta+2*L_1)$ and the complexity of each SET and CLEAR instruction is $(1.58+L_\Delta+L_1)$.

Thus, the complexity of a HAC implementation of an algorithm is defined to be the sum of the complexities of each of the HAC modules which form the implementation. For each program, however, there are many possible modularizations, any one of which could be chosen by the programmer, but which may not reflect the structure of the program itself. It is desirable to have a canonical modularization for a program to avoid this problem. This representation should be unique for a given program, and should correlate closely with the structural properties of the program. The Prime Program Parse meets these criteria.[7]

A *proper program* is a flowgraph with a single input arc, a single output arc, and with each node in the flowgraph being on a path from the input arc to the output arc. A *prime program* is recursively defined as a proper program with no proper prime subprograms of greater than one node. The process of identifying the hierarchy of prime programs which make up a compound program is known as a prime program parse. Such a parse is unique up to associativity of sequences of statements.

PROPERTIES OF MEASURE

This measure has been used to measure the complexity of several programs implementing common algorithms. In one example, an 8-bit adder was programmed on a primitive HAC, using 78 instructions, and resulting in a complexity of 918.26. The prime program parse of the program yielded 8 subroutines, all invoked by a single controlling routine. This program was restructured by forming three composite operators, resulting in a complexity of 471.76. This savings in

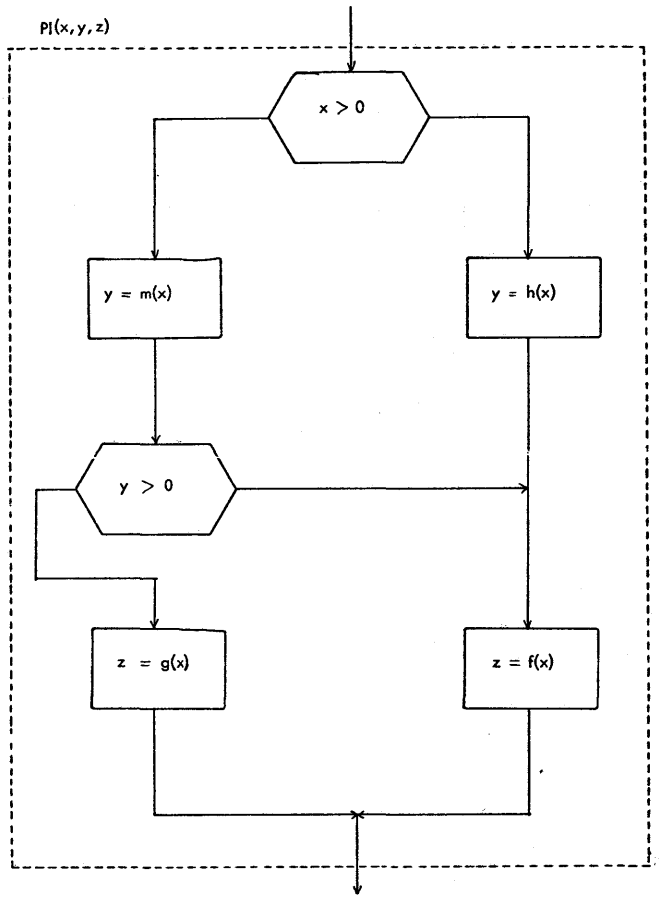

Figure 1—Unstructured version of program

complexity was due primarily to the recognition that 6 of the 8 modules in the prime program parse performed the same function, and thus represented a large degree of redundancy. The two programs are execution equivalent.

As an example of the comparison of two programs which are semi-execution equivalent, consider those shown in Figures 1 and 2. Figure 1 illustrates a nonstructured program which has a complexity of 53.16, as determined from the prime-program parse. Figure 2 illustrates a structured program, having a complexity of 52.02, and consisting entirely of small (size 1 or 2) prime programs.

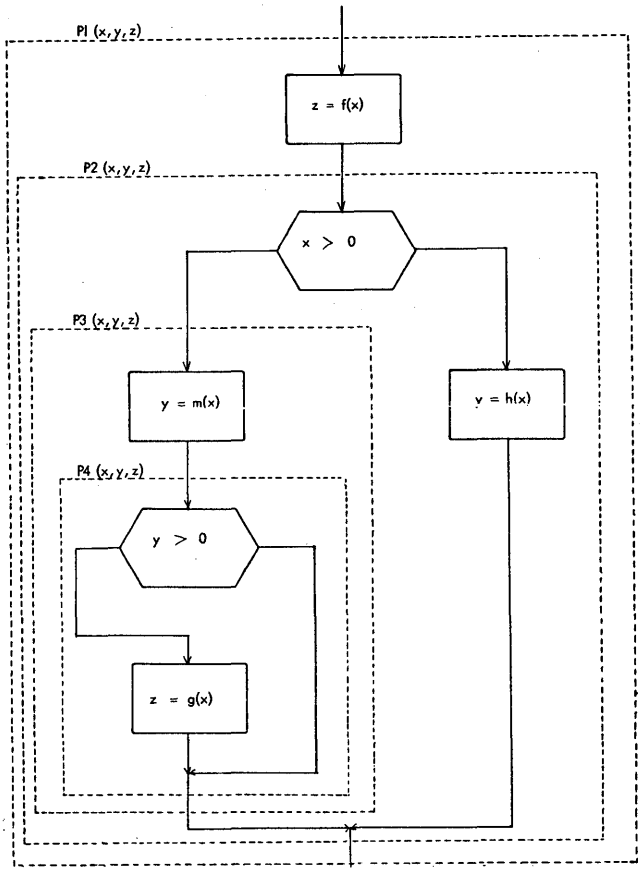

Figure 2—Structured version of program

The second example illustrates a basic result, namely that for HAC programs which consist of two prime programs with all variables being global, the minimum complexity occurs when the number of instructions is equally divided between the two subprograms. This result is obtained directly from a minimization of the expression for the complexity of such a program. Repeated applications of this result yield the conclusion that the minimal complexity for a program occurs when only a structured basis for the control is used, i.e., only the control structures sequence, if-then-else, do-while, repeat-until, do-while-do, if-then, and function.

This proposed measure has a demonstrated sensitivity to both control and data structuring within programs, and, because of its close relationship to the structured programming control graphs and prime programs, is felt to be a valuable tool in the quantification of overall complexity in the effort to formalize the intuitive concept of a good program.

A language for specifying software tests

by DAVID J. PANZL
General Electric Company
Schenectady, New York

INTRODUCTION

The execution of software test cases and the verification of test results may be performed automatically by a new type of program called an automatic software test driver. When using an automatic test driver, a formal test procedure is coded in a special test language. The test procedure takes the place of the test data and test setup instructions of conventional testing, and controls the automatic test driver. An automatic software test driver applies one test procedure to all or part of a target program, executes all of the test cases specified in the test procedure, and verifies that the results of each test case are correct. This paper describes the Fortran Test Procedure Language (TPL/F) which was developed at General Electric and is used for specifying test procedures for Fortran software.[1]

The concept of automatic software test drivers is a new idea that has been evolving slowly over the past six years and just now seems to be approaching the point where soon it may play a significant role in the development and maintenance of production software. Two other automatic software test drivers that were developed independently in recent years and have their own software test languages are described in References 2 and 3.

The Fortran Test Procedure system is illustrated in Figure 1. One test procedure coded in TPL/F and the source code for one or more modules of the target program are processed by the automatic test driver which executes all of the test cases specified in the test procedure, and produces a brief test execution report (Figures 2 and 3) stating which test cases failed, if any, and the degree of testing coverage actually achieved by the test procedure.

Test cases consist of input data for the target program and model output data. The automatic test driver actually executes the target program for each test case, feeding the input data to the target program and comparing outputs from the target program with the model outputs specified in the test procedure. Incorrect outputs produce a diagnostic in the test execution report (Figure 3).

Since the TPL/F system has access to the target program's source code, it can monitor which statements were actually executed and which branches were actually traversed while executing a test procedure. This type of information provides valuable feedback to the test designer and is generally not available when testing is done manually.

The specific goals of the TPL/F automatic software test driver are as follows. The need for writing drivers and stubs for module and subsystem testing is eliminated since the TPL/F system can test any combination of one or more modules independently of the rest of the target program. The TPL/F test language provides a standard format for specifying software tests and the test procedure processor provides a standard test execution setup. Since formal test procedures specify the correct outcomes of test cases, the test procedure processor automates the verification of test execution results.

TPL/F TEST PROCEDURES—AN OVERVIEW

TPL/F test procedures and the major elements of the TPL/F language are introduced in this section by means of an example. The following section describes the TPL/F language in greater detail. For the present example, we show a simple test procedure for the Fortran target module of Figure 4. The target module, IOSUB, is a subroutine and needs to be called by a higher level module for execution. IOSUB also invokes a lower level subroutine, LABEL, which is not under test and must be simulated when testing IOSUB. On each entry to IOSUB, one unformatted record is read from logical unit 12 and LABEL is called once.

A simple test procedure to test IOSUB is illustrated in Figure 5. The test procedure contains three test cases, each of which causes an actual execution of the target module, IOSUB. The MODULES statement names the target modules (IOSUB of Figure 4) under test.

TPL/F test cases are executed in three steps. First, initialization code is executed and puts the target program in a known initial state. In the example, the first two statements of each test case are used to initialize the target program. In the first test case, for example, they assign the values 1 and 0 to the variables N1 and N2, respectively, of IOSUB.

Second, the target program is executed. The form of the EXECUTE statement used in Figure 5 causes execution to begin at the first executable statement of IOSUB and terminate the first time a STOP or RETURN statement is encountered in IOSUB.

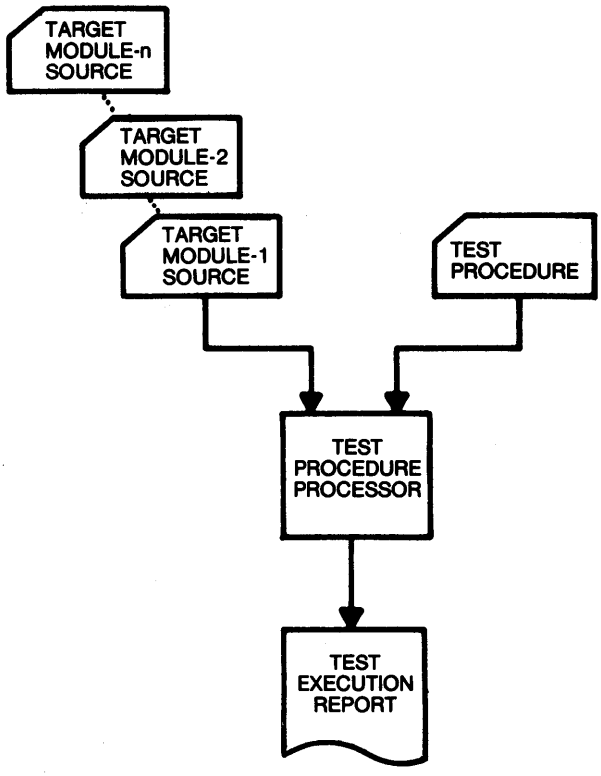

Figure 1—The TPL/F automatic software test driver

Third, after the test case execution has terminated, an assertion about the final state of IOSUB is verified. In the first test case of Figure 5, the variables N1 and N2 of IOSUB are verified to have the values of 6 and 0, respectively.

In TPL/F, stub versions of missing subprograms called by the target program are coded as Fortran-like subroutines and functions embedded in the test procedure. In Figure 5, for example, a stub version of subroutine LABEL begins at the SUBROUTINE statement and runs thru the following END statement. #TEST is an integer system variable whose value is always the index of the test case currently executing. The stub version of LABEL verifies that the argument passed by IOSUB when executing under the first test case is 10 and returns the value 0 for the argument on return. Should LABEL call IOSUB with an incorrect argument value, the ABORT statement would terminate the current test case (but not the test procedure) and put a diagnostic message in the test execution report.

The six statements beginning at the I/O SIMULATOR statement and continuing through the following END statement specify an I/O simulator for logical unit 12 of the target program. An I/O simulator can supply input data to the target program in response to READ statements or verify outputs from WRITE statements in the target program. The I/O simulator of Figure 5 specifies three unformatted records containing five integer values each, followed by an end-of-file mark. The first three records read by the target program from logical unit 12 will be taken from the I/O simulator. An attempt to read a fourth record would produce an EOF return in the target program.

```

STATEMENTS EXECUTED: 100%
BRANCHES TRAVERSED:  100%
```

Figure 3—A failed test procedure execution report

Although the test procedure in this example contains only three test cases, most test procedures contain a much larger number. Typically, a test procedure for a single Fortran target module of 50 to 100 statements may contain 20 to 50 test cases, depending on the complexity of the target module's control logic. Therefore, a more compact notation usually is required to represent test cases. TPL/F uses a built-in macro processor which allows the general form of a test case to be specified as a macro prototype and each specific test case is represented by a single macro call. In practice, test procedures tend to contain only a small number of forms of test cases (often only one) which are invoked many times with different specific data values. Figure 6 shows the three test cases of Figure 5 as they would appear when coded as TPL/F macro calls.

THE TPL/F TEST LANGUAGE

The previous section introduced the control structure and the four major components of TPL/F test procedures (test cases, subprograms, I/O simulators, and macros). This section contains an informal and intuitive introduction to all of the constructs of the TPL/F test language. Complete descriptions of the TPL/F language and the Fortran test procedure system are contained in References 4 and 5.

Figures 7 thru 13 describe the syntax of TPL/F by means of syntax graphs. Rounded boxes represent terminal symbols of the language. Rectangular boxes are non-terminal symbols requiring further definition. The following Fortran syntactic forms (marked with an asterisk in the syntax

```
SUBROUTINE IOSUB(N1,N2)
  .
  .
CALL LABEL(ICOUNT)
  .
  .
READ (12) (K(I),I=1,5)
  .
  .
END
```

Figure 4—A sample target module

IOSUB:N2 = 501
VERIFY (IOSUB:N1 .EQ. 1 .AND. IOSUB:N2 .EQ. 1)
EXECUTE

FIN
```

Figure 5—IOSUB test procedure coded in the TPL/F test language

graphs) are embedded in TPL/F. Their grammer depends on the syntax of the host Fortran dialect.

identifier	declaration statement
label	format
integer constant	I/O list
string	data list
relational operator	logical expression
subprogram statement	

The symbol "Ftn statement☆" refers to any statement of the host Fortran dialect.

Test procedures

Test cases are the primary element of the control structure of a test procedure (Figure 7). Executing a test procedure consists of executing each of its test cases. Subprograms and I/O simulators defined in the test procedure only influence the performance of test cases. Fortran declaration statements may be included in test procedures to define COMMON blocks whose variables are referenced by the test procedure.

The MODULES statement names all of the target modules affected by the test procedure. The first name on the MODULES statement is the *primary target module*. All test procedure references to target program variables or statement labels, not qualified by an explicit target module name, are directed to the primary target module.

```
MACRO MAC(P1,P2,P3,P4)
IOSUB:N1 = P1
IOSUB:N2 = P2
VERIFY (IOSUB:N1 .EQ. P3 .AND. IOSUB:N2 .EQ. P4)
EXECUTE
MEND

MAC(1,0,6,0)
MAC(0,100,0,1)
MAC(500,501,1,1)
```

Figure 6—The three test cases of Figure 5 recorded using a TPL/F macro definition

Test cases

Each test case (Figure 8) in a test procedure causes an actual execution of the target program.

The EXECUTE statement specifies where to begin and where to terminate a test case execution, and how many times to execute it. For example, the following statement would cause its test case to be executed three times, each time beginning at statement label 50 of the primary target module and stopping whenever either statement label 25 of target module SUB2 or statement label 35 of target module SUB3 is executed

```
EXECUTE*3 FROM :50 TO SUB2:25,SUB3:35
```

An exclamation mark preceding a termination label reference means that the test case is to terminate without executing that statement. Otherwise, it would be terminated immediately afterward. The beginning statement, when specified, is always executed, regardless whether or not its reference is preceded by an exclamation mark. If no beginning label is specified, execution starts at the first executable statement of the primary target module. Regardless whether or not termination labels are specified, test cases always terminate whenever a STOP statement or a RETURN statement in the primary target module is executed.

All test case statements other than EXECUTE, VERIFY, and USE are executed immediately prior to the start of a test case execution. These are usually modified Fortran statements (see below) supplying initial values to the target program.

The VERIFY statement specifies an assertion about the target program. The AT clause, if present, specifies when, during the test case execution, the assertion is to be verified. The following statement causes an assertion to be verified whenever statement label 100 in SUB1 is executed, as well as immediately after the test case terminates.

```
VERIFY AT SUB1:100,#TERM (SUB1:N .EQ. 0)
```

An exclamation mark preceding an AT clause label reference causes the assertion to be verified immediately before executing the specified statement. Otherwise, verification occurs after executing the referenced statement. When no AT clause is specified, the assertion is verified after the test case terminates. An attempt to verify a false assertion ter-

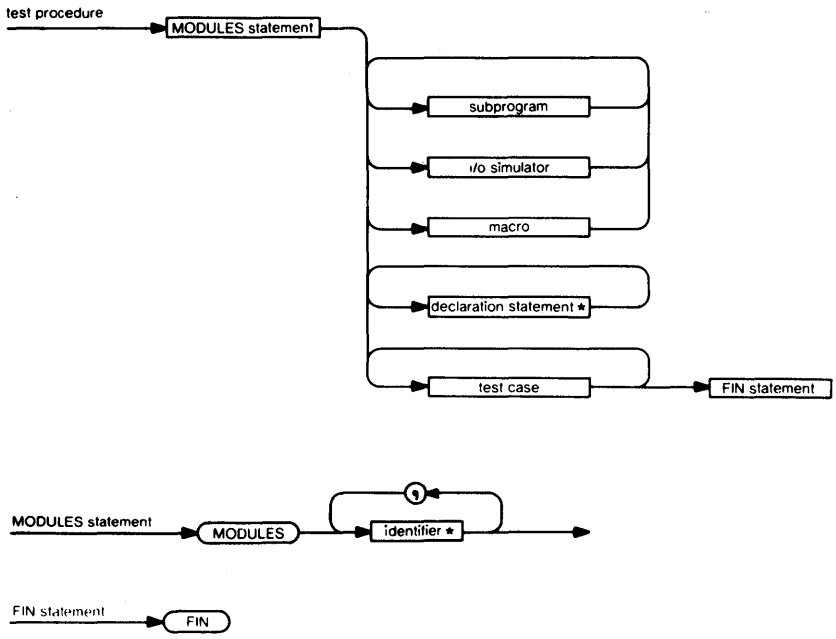

Figure 7—Test procedure syntax

minates the current test case (but not the test procedure) and causes an error message to appear in the test execution report as in Figure 3.

The USE statement modifies the mapping of target program I/O references to I/O simulators and affects only the test case in which it appears. For example, if a test procedure contains I/O simulators for logical units 20 and 30, all target program I/O references to these logical unit numbers would ordinarily invoke I/O simulators for those units in the test procedure. The following statements appearing in a particular test case, however, would direct all target program references to logical unit 20 to I/O simulator 30; and all target program references to logical unit 30 to an actual logical unit of that number.

```
USE 30 FOR 20
USE #ACTUAL FOR 30
```

The #SCRATCH clause directs target program I/O operations to a temporary scratch file.

Subprograms

Fortran subroutines and functions defined in a test procedure (Figure 9) may be referenced inside the test procedure or may be used as subprogram stubs.

When referenced inside a test procedure, subroutines may be used to perform complicated recurrent test case initialization tasks or Boolean functions may be used to verify complicated assertions about the target program. When used as subprogram stubs, subprograms defined in the test procedure are surrogates for missing subprograms called by the target program. Any subprogram defined in a test procedure can be used in either manner.

I/O simulators

I/O simulators are used to simulate I/O devices and files referenced by the target program. An I/O simulator (Figure 10) is a closed subroutine and is entered each time its logical unit number is referenced by a target program I/O statement.

Each I/O simulator has a unique record counter which always points to the current record on the simulated I/O unit. Prior to each test case execution, all record counters are reset to zero. While executing a test case, each time the target program reads or writes the simulated unit, its record counter is incremented.

I/O simulators can simulate either random or sequential devices. The NO RESET clause on the I/O SIMULATOR statement preserves the record counter value from one test case to another. The NO REWIND clause inhibits target program REWIND statements on the I/O simulator. Examples:

```
I/O SIMULATOR 12 RANDOM(1000)
I/O SIMULATOR 16 NO RESET
```

The first statement defines a random I/O simulator for logical unit 12 with a maximum record index of 1000. The second statement defines a sequential I/O simulator for logical unit 16 whose record counter is not reset between test case executions. The latter form is used for providing multiple test cases with different data files from the same logical unit.

The RECORD statement is the primary I/O simulator statement for simulating I/O devices and files. When the target program executes a READ or WRITE statement on a simulated logical unit, the target program is interrupted and control passes to the I/O simulator. The I/O simulator executes until an operable RECORD statement is encoun-

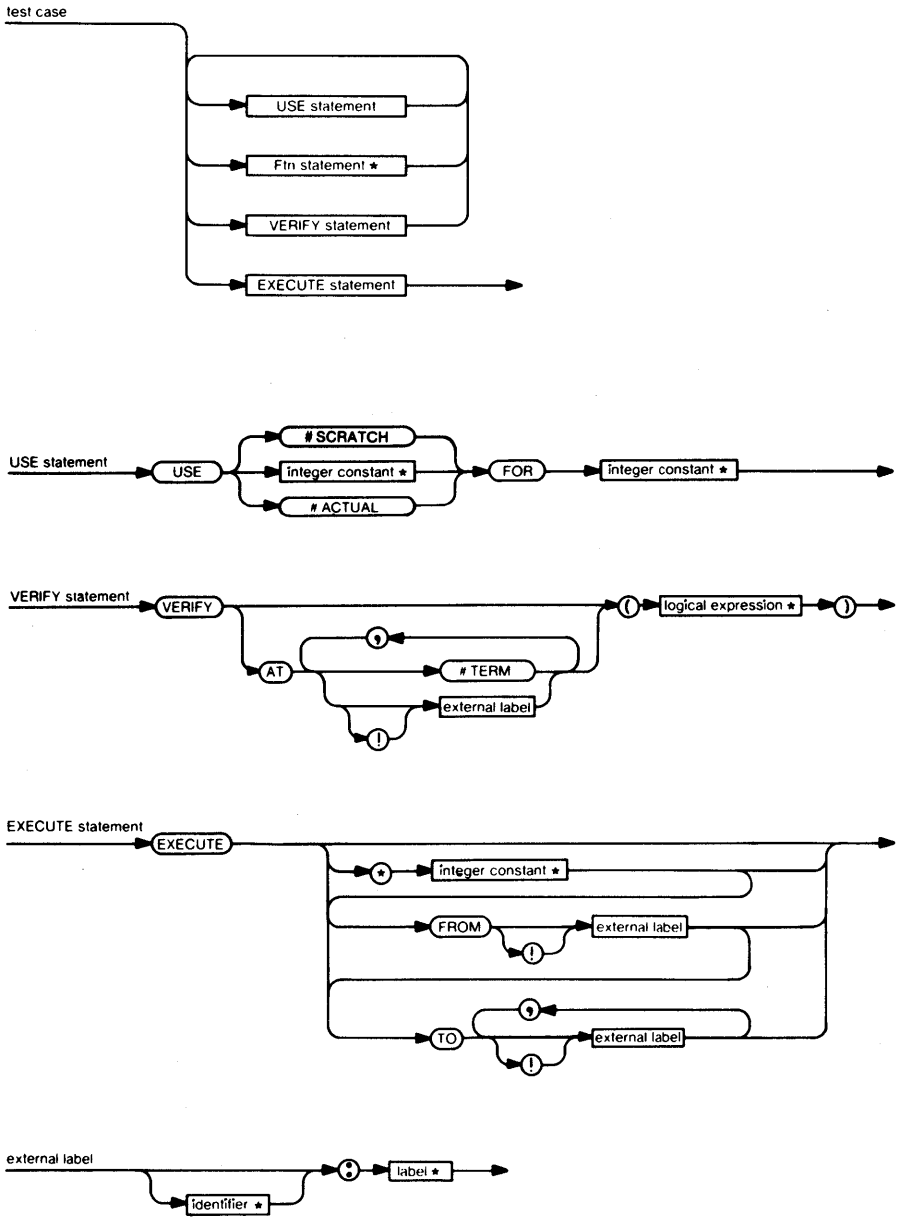

Figure 8—Test case syntax

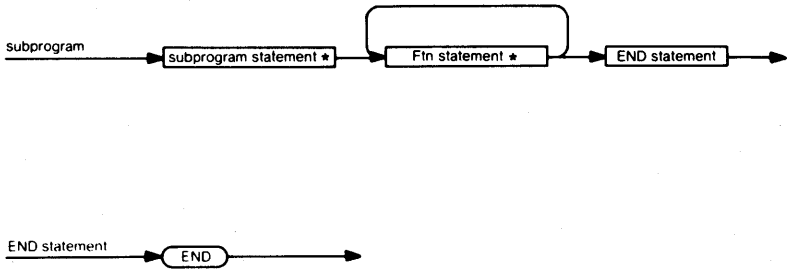

Figure 9—Subprogram syntax

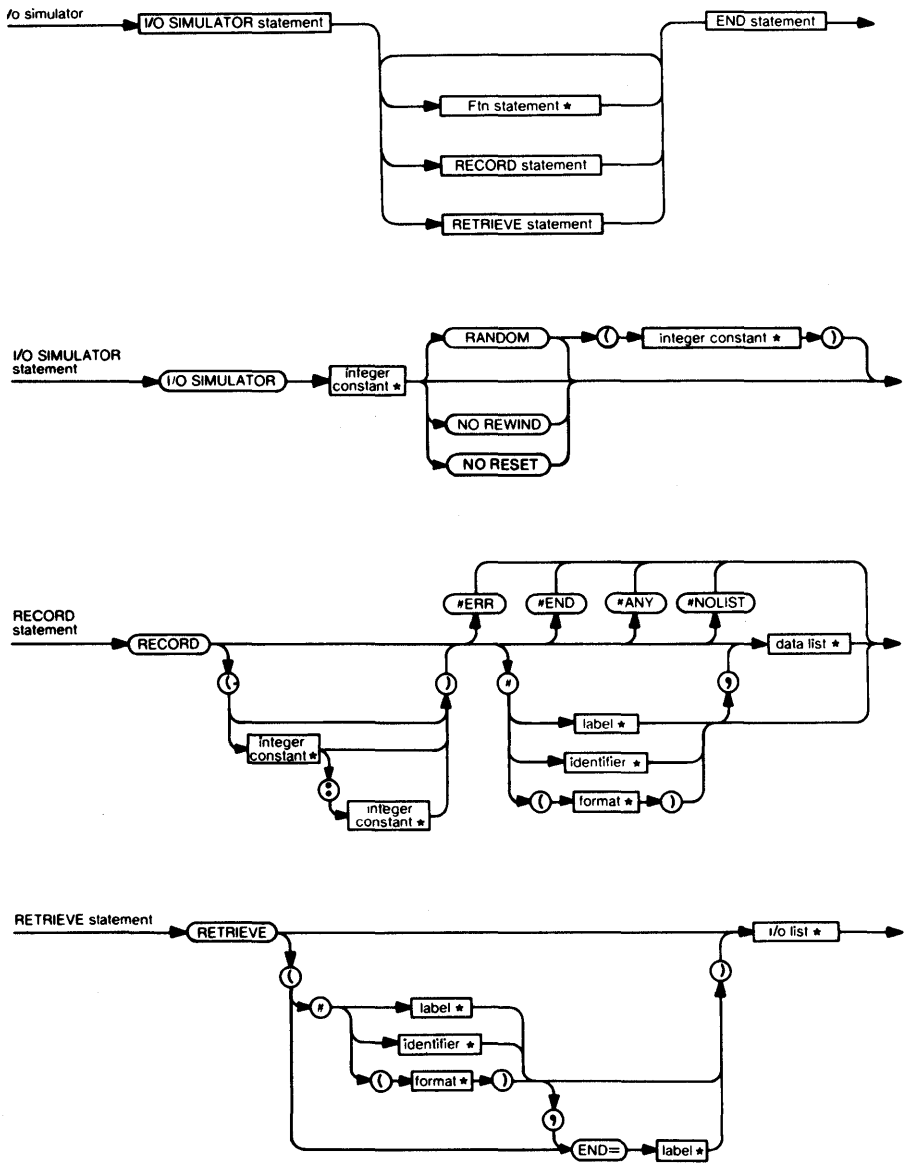

Figure 10—I/O simulator syntax

tered. If the I/O simulator was invoked by a target program READ statement, input data values from the RECORD statement are passed to the target program READ list and control is returned to the target program. If the I/O simulator was invoked by a target program WRITE statement, the data output by the WRITE statement is captured and compared with data in the RECORD statement. If the comparison is satisfied, control returns to the target program; otherwise an error message is written in the test execution report.

RECORD statements that specify a record range are operable only when the value of the host I/O simulator's record counter falls within the specified range. Otherwise, the RECORD statement is treated as a no-op. A record range may be specified as a single record number as in

RECORD (5) . . .

or as a minimum and maximum value as in

RECORD(5:10) . . .

The first statement is operable only for the fifth record on the simulated device and the second statement for the fifth thru tenth. A RECORD statement with no record range is always operable.

A RECORD statement may describe either formatted or unformatted records, depending on whether or not a format reference, indicated by a #, is specified, as in the following examples.

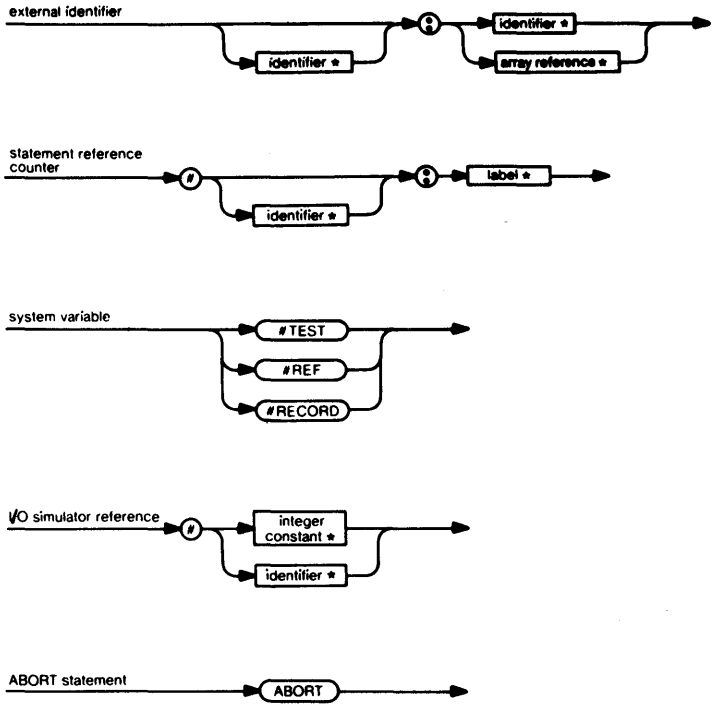

Figure 11—TPL/F modifications to embedded Fortran statements

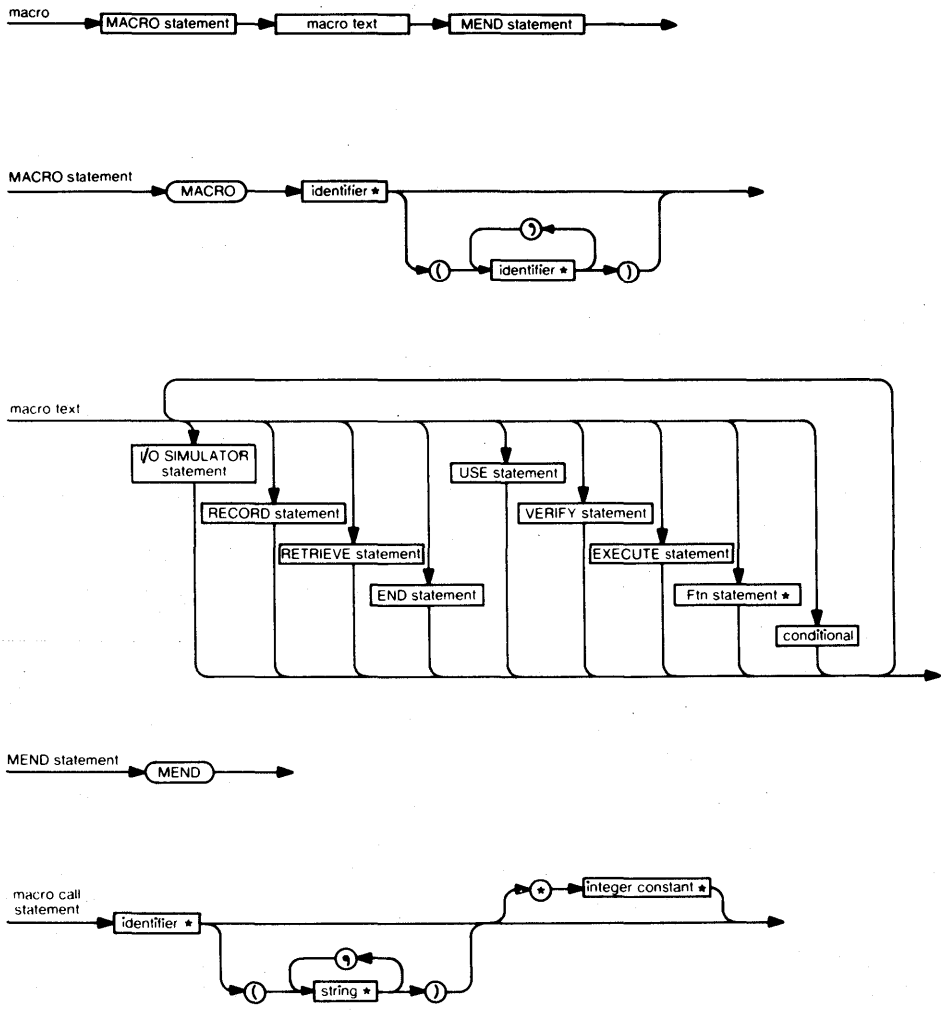

Figure 12—Macro syntax

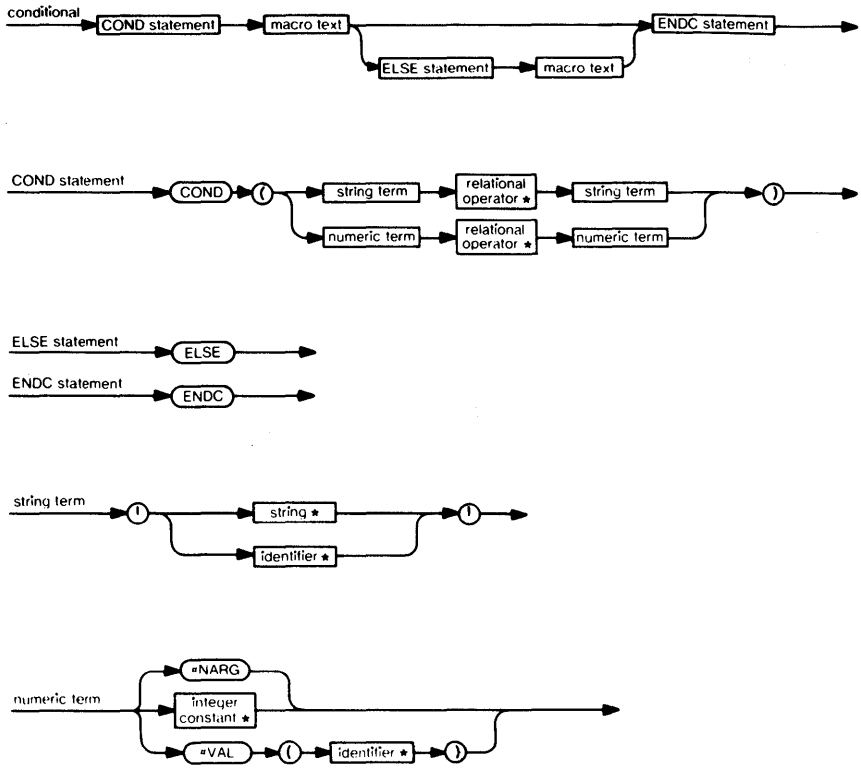

Figure 13—Conditional construct syntax

RECORD #(3I5), 10,20,30
RECORD #999, (X(I),I=1,10)
RECORD 7,12,(18,I=1,10)

The first two statements simulate formatted records and the third, an unformatted record. Formatted records must be generated in response to target program formatted I/O statements and unformatted records must be generated in response to target program unformatted I/O statements.

The #ANY clause in a RECORD statement verifies that the I/O simulator was invoked by any target program write operation. The #NOLIST clause verifies that the I/O simulator was invoked by a formatted write operation with no I/O list and is used primarily for skipping titles and formatting information when verifying formatted output records.

The #ERR clause in a RECORD statement simulates an I/O error and causes the ERR=label exit to be taken from the corresponding target program I/O statement. The #END clause simulates an end of file condition and is used to verify a target program ENDFILE statement or cause the END=label exit to be taken from a target program READ statement.

The RETRIEVE statement is used for verifying complex assertions about target program outputs. When the host I/O simulator is invoked by a WRITE or PRINT statement, the output record is captured, optionally interpreted according to a format, and assigned to variables in an I/O list. While the RECORD statement is limited to simple tests of equality between output variables and known values, the RETRIEVE statement makes output records available for any type of test. The first example of the following section (EXAMPLES) illustrates the use of the RETRIEVE statement.

TPL/F modifications to embedded Fortran statements

Fortran statements may appear throughout test procedures. The initialization part of a test case definition, for example, usually consists of Fortran code only. When appearing inside a test procedure, any Fortran statement may be modified as follows.

External identifiers, statement reference counters, and system variables (Figure 11) may be referenced wherever a variable would usually appear in a Fortran statement.

An external identifier refers to a variable or array in the target program. The initialization code and assertions in the example of the previous section contained external identifiers pointing to the variables N1 and N2 of target module IOSUB.

Statement reference counters provide a means for verifying the number of times a target program statement is executed. Every test procedure reference to a statement reference counter causes an integer-valued counter to be associated with the indicated statement in the target program. Prior to each test case execution, all statement reference counters are reset to zero. During test case executions, statement reference counters are incremented each time their associated statements are executed. The following

statement, for example, verifies that the statement at label 100 of target module SUB1 was executed exactly five times during the current test case execution.

```
VERIFY (#SUB1:100 .EQ. 5)
```

Three special symbols are used to reference system variables whose values are controlled automatically by the test procedure processor.

The value of #TEST is the index (e.g., first, second, etc.) of the currently executing test case.

#REF is defined as follows. Every subprogram and I/O simulator has a reference counter associated with it. All reference counters are reset to zero prior to each test case execution and incremented by one on each entry to their associated subprograms. Inside a subprogram or I/O simulator, #REF has the value of the subprogram or I/O simulator's reference counter. In all other places, #REF is always equal to zero.

Inside an I/O simulator routine, #RECORD has the value of the I/O simulator's record counter. Elsewhere, the value of #RECORD is always zero. Examples:

```
Y=VAL(#REF,#TEST)
IF (#RECORD .EQ. N) GO TO 100
```

Ordinarily, Fortran I/O statements embedded in a test procedure are not affected by I/O simulators. A logical unit designator prefixed by a pound sign in an embedded Fortran I/O statement temporarily suspends this rule and causes the I/O statement to be treated the same as a target program reference to the logical unit. For example, the following statement appearing inside a test procedure references the I/O simulator for logical unit 10, not the actual logical unit 10.

```
READ (#10) X,Y,Z
```

The ABORT statement is used inside subprograms and I/O simulators to terminate the current test case when an error is detected. Terminal assertions of aborted test cases are not verified.

Macros

The primary role of macro definitions (Figure 12) is that of an efficient shorthand notation for describing test cases. Macro definitions are entered in a macro definition library under the symbolic name specified on the macro statement. When invoked by a reference to the macro name, formal arguments appearing in the text of the macro definition are replaced by actual arguments supplied by the call. The modified text of the macro definition then replaces the macro call statement.

The conditional construct (Figure 13) allows statements to be conditionally included in a macro expansion. The Boolean expression in the COND statement is evaluated each time its host macro is expanded. If the expression evaluates to true, all statements following the COND statement, down to the ELSE statement, if present, are included in the macro expansion. When the COND statement expression evaluates to false, only those statements between the ELSE statement, if included, and the ENDC statement are included in the macro expansion.

```
MACRO MAC(N,ALPH)
COND (#NARG .EQ. 1)
:A = 0.
  COND(#VAL(N) .NE. 0)
  :B = 0.
  ENDC
ELSE
:C = 0.
  COND (ALPH .EQ. 'ABC')
  :D = 0.
  ENDC
ENDC
MEND
```

Macro Call	*Macro Expansion*
MAC(0)	:A = 0.
MAC(2)	:A = 0.
	:B = 0.
MAC(2,XYZ)	:C = 0.
MAC(2,ABC)	:C = 0.
	:D = 0.

Figure 14—Conditional macro expansion examples

String terms in COND statement expressions are either quoted strings or formal arguments of the host macro definition which are replaced at macro expansion time by strings.

Two special forms of numeric terms may appear in COND statement expressions. #NARG is the number of actual arguments supplied in the current call on the host macro. The numeric value of #VAL(arg) is determined as follows. Usually, arg is a formal argument in the host macro definition. After argument substitution, if arg is a numeric constant, then that is the numeric value of #VAL(arg); otherwise the macro expansion terminates in error. Figure 14 illustrates conditional macro expansions.

EXAMPLES

The test procedure example in the beginning of this paper illustrates the basic structure of test case definitions, the use of macro definitions for replicating test cases, I/O simulators and subprogram stubs. Two additional examples in this section illustrate common styles used for writing test procedures.

Figures 15 and 16 illustrate the use of I/O simulators for testing I/O-oriented target modules. The target module of

Figure 18—A test procedure for the target module of Figure 17

the use of internal references to I/O simulators for generating large amounts of data for test case initialization and verification. The target module, SUB2, of Figure 17 performs a transformation on the array M.

The test procedure of Figure 18 contains four test cases, each of which supplies SUB2 with 24 input values for the array M and verifies the contents of M returned by SUB2. The input and output values are contained in two I/O simulators read only by the test procedure.

DISCUSSION

The notation that software tests can be specified in a formal language, just as are computer programs, will likely improve the quality of software test design since, for the first time, software tests reside in a medium (the test pro-

cedure) that is both executable and readable and therefore available for peer review and criticism. Automatic software test drivers should also influence the quality of software test design by providing feedback on the degree of testing thoroughness actually achieved by a test procedure.

Perhaps the strongest effect of automatic software test drivers and formal test procedures will be on the maintenance of production software. It is widely agreed that the majority of errors appearing in production software are introduced as unintended side effects of post-release program modifications. This is due, in large part, to the absence of a convenient mechanism for preserving test cases throughout a program's life-cycle so that they can be used to check out post-release program modifications. In order to effectively retain software tests for post-release regression testing, it is necessary that someone other than the original test designer be able to execute them and verify the correctness of test results. Formal test procedures should facilitate the retention of software test cases throughout the entire life cycle of computer programs since they are completely self-contained, they execute automatically without special test set-up instructions, and they are self-checking. The adoption of automatic software test drivers should therefore lead to significant software cost savings since it is often estimated that up to 70 percent of the life-cycle costs of computer software are attributable to testing and debugging.

A software quality plan for higher education—An abstract

by BARRY L. BATEMAN and CHADWICK H. NESTMAN
Southern Illinois University
Carbondale, Illinois

As the number of institutions of postsecondary education facing financial exigency increase, a method of tracking the progress of software projects in a systematic and unbiased manner is extremely critical. The software quality plan commonly found in business and industry can aid the college and university in developing guidelines and tests for the software development process, thus reducing costs.

Traditionally, testing and evaluation of software has been a minor or non-existent part of the programming effort within a university. If testing and evaluating does exist, it has normally been carried out by the programmer responsible for project development or by his close associate. This could mean that objectivity and selectivity in testing and evaluating can be lost because of a programmer's proximity to his work. This could also mean that more of the operating budget of the computing center has to be spent on testing and debugging after installation has been carried out. Testing and debugging in the user's environment can cause unnecessary problems in public relations and system acceptance. Some industrial companies, such as TRW, Inc. and the NCR Corporation, have recognized this problem and have established formal Software Quality Assurance (SQA) departments or interest groups whose responsibilities include the task of assuring that software is free from as many errors as possible. In carrying out their functions, the SQA organization utilizes a formal plan or guideline known as the Software Quality Plan (SQP). The SQP is a document prepared by each of the participating internal departments within computer services (programming, operation, training, production, etc.) and the customer or client. The plan, once prepared, spans the entire development cycle and becomes a coordinating agent between all interested groups in the establishment of activities, schedules, commitments and budgets.

Within the institution of postsecondary education, responsibility for the development of the SQA should be under the direct supervision of the Director of Software Quality Assurance or his designate. In institutions where there is no formal quality assurance office, the plan could be produced by the internal auditor or at least by the chief officer in charge of computing services. Although the SQP is initiated early in the development cycle, it must be updated as the project moves from one development phase to another. When writing a SQP, the following criteria must be considered: financial and budgetary analysis, manpower requirements (by departments), program dependencies (hardware and software), milestone schedules, and commitments by the intended user in relation to their support and acceptance criteria. Test plans and responsibilities should clearly be outlined including the control procedure, methodology, limitations, and acceptance criteria for each test to be used. It is suggested that there be at least a review or test during the feasibility stage, in order to check architectual proposals; the coding stage, in order to assure proper design; pre-installation, in order to exercise programs with near real data; installation to insure users are adequately trained and that proper documentation is available. Resource requirements, in the sense of stating needed hardware, software, special test tools, additional manpower and required documentation should also be provided in the SQP.

In essence, software quality within the university framework is a necessity, especially in light of financial exigency. This quality can be attained by better control during the project development process and by assuring test objectivity by having the evaluation of software carried out by non-partisan people—people not involved with the actual writing and coding of the software. These non-partisan persons would be part of a Software Quality Department and would be responsible for the implementation of a Software Quality Plan, that is, a guideline for the monitoring of software quality throughout the development process. Above all else the plan would describe the various tests to be conducted, responsibilities in carrying out those tests, and the results expected. This plan is not intended as a panacea for all postsecondary quality ills, but is intended as a starting point for the assuring of quality software in the university environment by reducing costs normally incurred when errors are corrected on the "fly."

The design of a prototype mutation system for program testing*

by TIMOTHY A. BUDD, RICHARD J. LIPTON and FREDERICK G. SAYWARD
Yale University
New Haven, Connecticut

and

RICHARD A. DEMILLO
Georgia Institute of Technology
Atlanta, Georgia

INTRODUCTION

When testing software the major question which must always be addressed is "If a program is correct for a finite number of test cases, can we assume it is correct in general." Test data which possess this property is called Adequate test data, and, although adequate test data cannot in general be derived algorithmically,[1] several methods have recently emerged which allow one to gain confidence in one's test data's adequacy.

Program mutation is a radically new approach to determining test data adequacy which holds promise of being a major breakthrough in the field of software testing. The concepts and philosophy of program mutation have been given elsewhere,[2] the following will merely present a brief introduction to the ideas underlying the system.

Unlike previous work, program mutation assumes that competent programmers will produce programs which, if they are not correct, are "almost" correct. That is, if a program is not correct it is a "mutant"—it differs from a correct program by simple errors. Assuming this natural premise, a program P which is correct on test data T is subjected to a series of mutant operators to produce mutant programs which differ from P in very simple ways. The mutants are then executed on T. If all mutants give incorrect results then it is very likely that P is correct (i.e., T is adequate). On the other hand, if some mutants are correct on T then either: (1) the mutants are equivalent to P, or (2) the test data T is inadequate. In the latter case, T must be augmented by examining the non-equivalent mutants which are correct on T: a procedure which forces close examination of P with respect to the mutants.

At first glance it would appear that if T is determined adequate by mutation analysis, then P might still contain some complex errors which are not explicitly mutants of P. To this end there is a COUPLING EFFECT which states that test data on which all simple mutants fail is so sensitive that it is highly likely that all complex mutants must also fail.

Readers wishing a further exposition of the ideas of mutation and substantiation of the assumptions made are referred to References 2 and 10.

THE SYSTEM

A pilot system has been built to implement mutation analysis on programs written in a subset of FORTRAN. The key features of this system are summarized in Figure 1. The system itself consists of 10,000 lines of FORTRAN code, and required six man months to design, implement and debug.

Notice we claim the system is man/machine interactive. In general an attempt is made to assign tasks to both the user and the machine processors which are best suited to using their particular capabilities. One way to see this is to view the system as a sort of "Devils Advocate", which when confronted with a program asks very difficult questions about the motivation behind it ("why did you use this type of statement here, when an alternative statement works just as well?"). The job of the human is then to provide justification (in the form of test data), which will give an answer to such questions.

An overview of the structure of the system is given in Figure 2. We point out that the language FORTRAN was chosen for the first implementation merely as a matter of convenience since it is in common use and there is a large body of software in existence to experiment on. The heart of the system (roughly that shown within the dotted box) is however, language independent, and given a sufficiently general internal form to implement a new language one would merely write a new input/output interface. Projects are currently under way to implement mutation analysis on

MODULAR DESIGN
INTENSIVE MAN/MACHINE INTERACTION

Figure 1—Key features of the pilot mutation system

COBOL and C (an ALGOL like language) using the structure represented by the box contained in the dotted lines.

An attempt was also made to keep the structure of the system largely machine independent. The system was originally programmed to run on a PDP-10 at Yale University. Currently we are in the process of transferring it to a CDC 7600 at the Georgia Institute of Technology.

A single run of a mutation system divides naturally into three phases the RUN PREPARATION phase, in which the necessary variables to send to the mutation executor are defined, the MUTATION phase, in which the actual mutations are produced and executed, and the POST RUN phase, in which results are analyzed and reports are generated. In the following we will describe in more detail the structure and effects of each phase.

The role of the run preparation phase is to initialize the various files and data buffer areas used by the mutation executor. It is characterized by a very interactive nature. The first object the user is requested to supply is the name of the file on which the FORTRAN subroutine resides. Then depending on whether PIMS has been run previously on this routine (in which case the internal form is stored on one of the many files PIMS constructs, see below) the subroutine is parsed into a concise internal format which is subsequently interpreted to simulate execution of the program. A

[SCALAR. p]
[CONSTANT.1]
[ASSIGN.O]
```

Figure 3

fragment of the internal code generated for a given statement is shown in Figure 3.

The user is then interactively prompted for the test data on which the program and mutants are to be tested. After each test case has been specified the original program is executed on the test case and the results displayed so that the user may satisfy himself that the results produced are indeed correct.

After the test data has been entered the user is prompted for a listing of which mutant operators he wishes to enable. At present there are 25 mutant operators. These range from very simple low level ones, such as replacing each data occurrence (where a data occurrence is a scalar, constant or array reference) with all other syntactically correct data occurrences, to very high level mutations, such as deleting statements or altering the control structure of the program. A more detailed description of the mutations performed can be found in Reference 3.

Instead of constructing multiple copies of the program, for each mutant a short (four word) description of the mutation to be performed is kept. Each time the mutant is to be run the original program is then mutated according to the contents of this descriptor.

After the user has specified to the system his program, test data and the mutant operators he wishes applied, the system then enters the MUTATION phase. During this phase there is no user interaction. Mutation descriptor records are read in, one by one, and the mutation is produced. The mutant program is then executed on the test data and marked either "dead," meaning it produced results differing from the original program on at least one test case, or "living." A dynamic record is kept of the number and percentage of living mutants of each mutation type.

When all the mutant programs have been tested the post run phase is entered. In this phase statistics are displayed indicating the results of the mutation run. In addition the user can interactively view descriptions of those mutations which have survived. He can also specify that certain re-

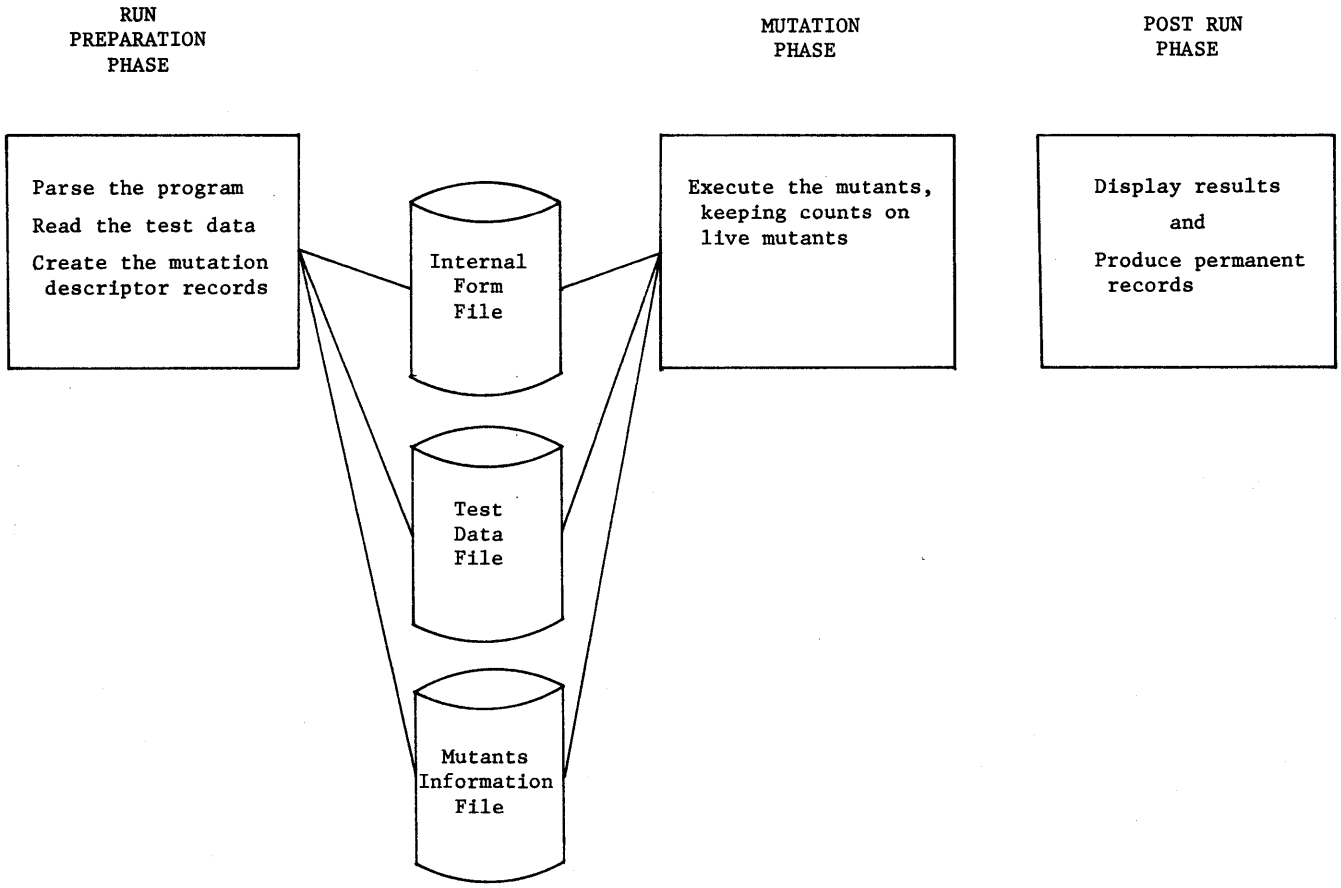

Figure 4

ports be generated in order to provide a detailed permanent record of the mutation run.

At this point, or at a later date, the user can re-run the system and augment his test data in an attempt to make the remaining mutants fail. He may also specify that additional mutant operators be applied to the program. This cycle can continue until the user is satisfied that the current test data adequately tests his program.

There are several files the system produces in order to store information from one run to the next. These are shown in Figure 4, which outlines the major functions of each phase. The internal form file stores the parsed version of the program. The test data file stores for each test case the test data input and the results of execution of that test data. The mutants information file keeps the mutant descriptor records plus various other counts on what types of mutants have been produced.

A COMPARISON OF PIMS TO OTHER DATA TESTING SYSTEMS

Various systems have been discussed in the literature for increasing confidence in the adequacy of test data, as the PIMS system does, or automatically constructing test data which meets some criterion. In this section we will report on experiments which show that the PIMS system is an improvement in this area over other systems which have been proposed.

The most widely known method of constructing test data automatically are those systems which utilize path analysis.[4-7] Essentially, these procedures attempt to construct data which force each statement to be executed at least once, and furthermore which transverse each feasible flow path through the code at least once. In some cases, such as loops, only an approximation to this can be made as the number of flow paths may be infinite. Here it is usual to just construct data which cause the loop to be executed at least twice.

These same objectives are met with mutant analysis in a number of ways, some directly by mutant operators, others indirectly by the coupling effect. There are mutants which cause each statement in the original program to be replaced by a TRAP statement, a special type of statement which if ever executed causes the program to immediately abort. Obviously, then if there is some statement in the program which is never executed, changing that statement to a TRAP statement will not alter the output of the program and hence will easily be detected.

Checking that every decision path is taken is essentially

```
      DO 10 I=1.J
           :
           :
      10 CONTINUE
=================
      DO 10 I=1.1
           :
           :
      10 CONTINUE
```

A LIVE MUTATION IF THE LOOP IS ALWAYS EXECUTED ONLY ONCE.

Figure 5

the same as checking that every predicate in the program evaluates at least once to both true and false. If this is not the case, say the predicate always evaluated to TRUE, then we can mutate the predicate in any way we desire as long as it retains this property of always remaining TRUE. These types of mutations are also usually quite obvious and easily detectable.

Mutation analysis can also insure that each loop is traversed at least twice. The only way a loop can be traversed only once (and all loops must be traversed at least once to pass the TRAP statement mutations) is if the terminating condition is the same as the starting condition. But in this case the mutant which replaces the terminating condition by the starting condition will survive (see Figure 5). This is once more easily detected.

With this, mutant analysis possesses all the capabilities of

```
      SUBROUTINE BSERCH(X.Y.N.A.IHIGH.LOW.ERR)
      INTEGER X(N).Y(N).N.A.IHIGH.LOW.ERR.MID
C     BINARY SEARCH PROCEDURE. IF X CONTAINS A ON RETURN
C     X(IHIGH) = A.IHIGH=LOW. IF NOT X(LOW) < A < X(IHIGH).
C     IF A IS OUT OF RANGE ON RETURN ERR CONTAINS 1
      ERR = 0
      IF ((X(1)-A).GT.0) GOTO 11
      IF ((A-X(N).LE.0) GOTO 5
 11   ERR = 1
      RETURN
 5    LOW = 1
      IHIGH = N
 6    IF ((IHIGH-LOW-1).NE.0) GOTO 7
      RETURN
 7    MID = (LOW+IHIGH)/2
      IF ((A-X(MID)).GT.0) GOTO 10
      IHIGH = MID
      GOTO 6
 10   LOW = MID
      GOTO 6
      END
```

Figure 6

```
Replace  IF ((IHIGH-LOW-1).NE.0) GOTO 7
by       IF ((IHIGH-LOW-1).GT.0) GOTO 7

Replace  MID = (LOW+IHIGH)/2
by       MID = (LOW+IHIGH)-2
```

Figure 7

path analysis systems which have been discussed in the literature.

Another class of systems for which extensive claims have been made are those which detect uninitialized variables and dead code.[8] Uninitialized variables are caught as a consequence of the interpretation process in the mutant system. Dead code is easily caught since an assignment made to a dead variable can be mutated in any way whatsoever and the program will remain the same.

A third class of systems for which there has recently been much discussion involves symbolic execution of the program. In one study[9] Howden analyzed 12 programs containing a total of 22 errors. He found that symbolic execution would catch 13 of those errors, while path analysis would discover only nine. In a similar study we estimated that mutation analysis, using only the mutant operators in the present PIMS system, would uncover 18 of the 22 errors. Of the remaining four, three would probably be discovered if we added two new mutant operators which the authors simply had not thought about. Hence, mutation analysis is in certain cases an improvement over symbolic execution.

As an example of the very subtle errors which mutation analysis can discover consider the program to perform binary search shown in Figure 6. If it happens that N=1 when the subroutine is called (i.e., the vector to be searched contains only a single element) then it is not difficult to see that the program will loop indefinitely. It is not clear that either symbolic execution or path testing would be sufficient to discover this error.

When mutant analysis is applied to this program there are two mutants generated (shown in Figure 7) which can only be eliminated by a test case consisting of one element. Hence the error is easily detected using mutant analysis. (There is a second error in this program which is also uncovered by mutant analysis. The discovery of that second error is left to the reader).

FUTURE WORK

There are several directions in which work is currently being pursued with respect to mutation analysis and the pilot mutation system. The most obvious is to show how a similar system might be built around another language, and research is under way to construct systems for COBOL and for C.

Another area of study is the design of an easy to use language for the description of test cases which allows for a variety of features. Test datasets can often be quite lengthy, yet two test cases can be very similar. Also, a user often wishes just to construct a number of random test cases following some specification. (Some of the pitfalls of using random data to test programs are discussed in Reference 10

where it is seen that mutation analysis can help in deriving "good" random test data.) Finding an easy yet powerful method of solving this problem is the goal of one area of research.

Finding a method to detect equivalent mutants is another area currently being pursued. It is often the case that a mutation will not produce a significantly different program (replacing the sequence I=1 J=1 with the sequence I=1 J=I is a trivial example). We have observed that programs tested have between one and two percent equivalent mutants. A method to automatically detect and remove equivalent mutants would allow us to provide even more significant measures of the adequacy of a test data set.

We point out that as a consequence of the modular design of the pilot system either of the above two major extensions can be added without a significant reprogramming effort.

A final area of current interest is the study of mutant operators. Certain operators seem to have a much greater ability to detect errors then others. Analysis of data along these lines would allow us to discover an order of application of mutant operators which would maximize the cost/benefit ratio.

CONCLUSIONS

It has been shown that the ideas of program mutation can be quickly and easily implemented as an interactive system for program testing. The resulting system represents a cost effective engineering approach to testing real world software. Large subroutines (over a hundred statements long) have been analyzed by our system with relative ease.

Mutation is a method of program testing which will significantly raise the level of reliability in both new and existing software, and is a major advance in the area of software testing.

PANEL OVERVIEW—Victor R. Basili

The development of correct, reliable, less expensive software continues to be a major problem. A great deal has been written and said about various techniques and methodologies for software development and how they are meant to aid in the development process. Unfortunately, most of the available material is by the author of the technique, be it individual or company. This does not always allow the outside user of the technique a fair appraisal or full understanding of how good the technique is, how to use it, and how to adjust it to his environment. This is true for several reasons. First, the author's experience is often limited to a specific application or set of applications and specific environments. There are some genuine questions that arise when taking a technique and moving it to a new application or environment that the developer of the technique had not anticipated. Second, the author does not always tell the prospective user everything he needs to know. Often this is just due to a lack of documentation, or a set of basic assumptions and background that the author did not realize was even necessary. Lastly, one cannot normally expect the author to emphasize the weak points or problems in the methodology. That is just human nature.

The purpose of this panel and the following set of papers is to discuss a set of techniques available in the open literature, some very new, some that have been around for awhile, and ask for an analysis and evaluation by current users. Each of the panelists is not the author of the methodology but a member of a company that is using the methdology or overseeing a contract on the use of the methodology. Some of the users are old hands at the technique; some are novices. I have asked each of the panelists to prepare a short paper covering a brief description of the technique and an evaluation of the technique in a real environment. Suggested ideas to be included in the paper and the oral presentation are given below.

I. THE TECHNIQUE
- The techniques you have been using.
- A description of the project you are using it on.
- The phase of the project in which it is used.
- The phases of the project it affects.
- An overview of the technique.
- Why you chose it.
- The extent to which you are using it.

II. EVALUATION OF THE TECHNIQUE IN A REAL ENVIRONMENT
- What have you felt are its good points and how they have shown to be good.
- What have you felt are the weak points and why.
- How you have adapted it to your environment.
- Would you use it again and if so how would you change or have you already changed the way it should be applied.
- What would you recommend to someone else applying it.

Certainly lots of techniques could have been covered but there was limited time and space available. The techniques chosen were based partially on my own interest and partially on the availability of people willing to discuss specific techniques. Discussants and topics include:

PSL/PSA—Donald J. Reifer,
SADT—Donn Combelic, ITT Telecommunications
Structured Design—Dr. J. A. Rader, Hughes Aircraft
Jackson's Methodology—Clifford M. Bernstein, EXXON Corporation
Boeing's IPAD Methodology—Susan Voigt, NASA Langley Research Center
Correct Program Design—F. Terry Baker, IBM Corporation

The methodologies deal with various phases of the software development process, from requirements to program development, some emphasizing one specific phase and some covering several phases. PSL/PSA and SADT deal predominantly with the requirements phase. Structured De-

sign, Jackson's Methodology, and Correct Program Design deal with various aspects of design and development. The Boeing IPAD Methodology covers the gamut from requirements to completed product.

What follows is a position paper for each of the panelists. Each is meant to be self contained, complete with references to the appropriate material.

EXPERIENCE WITH PSL/PSA—Donald J. Reifer

INTRODUCTION

This paper briefly describes the experience we have had in using the University of Michigan developed Problem Statement Language (PSL)/Problem Statement Analyzer (PSA).[1] We are using these computer assisted requirements tools to document and analyze operational flight software requirements developed for the Titan 34D segment of the Space Transportation System. The Titan 34D segment is providing real-time guidance, checkout and control requirements for implementation on the Interim Upper Stage. These boost phase requirements are highly time-critical and computation-bound. In addition, they must be documented in accordance to the Software Part I Specification format of MIL-STD-483.[2]

PSL/PSA DESCRIPTION

PSL is a machine processable language for expressing functional and performance requirements for a data system in a rigorous and uniform manner. PSL contains a set of simple declarative statements that allow you to name conceptual objects in a proposed system, describe properties of these objects and display relationships between them.[3] PSA is a software package that accepts PSL statements, analyzes each statically for correct syntax, generates a requirements data base from the input statements, performs consistency and completeness analyses on the data base and generates various kinds of reports and the requirements document. The command language with which users invoke the PSA services is also simple and user oriented.[4]

SELECTION CRITERIA

We selected PSL/PSA from several alternatives for several reasons. First, it is commercially available and supported. There is a commitment to keep the system current and fix errors. Second, it is well documented and good training is available. Third, it is operational on many large computing environments including the IBM 370, CDC 6000/7000 and Honeywell series. Lastly, it is currently being used by several diverse commercial and military users. The multi-user feedback has made the system mature faster than the alternatives. Readers are directed to Davis and Vick's paper[5] for an excellent comparison of PSL/PSA with other techniques.

We elected to use the tool on the Titan 34D application because we felt there was relative low risk inherent in their requirements. Titan 34D requirements are based on flight-proven equations and logic. We felt that the potential benefits justified the risk associated with using a new tool to document known and mature requirements.

EXPERIENCE

The ISDOS staff of the University of Michigan was retained by the Martin Marietta Corporation to install the PSL/PSA system on their CDC 6500 computer and conduct training classes. Installation began in April 1977. Several problems occurred as the package was adapted to the machine. First, the number of pages that resided in core had to be adjusted in order to make the system more efficient in terms of internal charging algorithms. Second, a machine-dependent executive routine that generated control instructions to do routine calling had to be developed. Training was held in the April/May timeframe with general orientation classes, user classes and maintenance classes being held.

The PSL/PSA system was then used to generate operational requirements for the Titan 34D segment of the Space Transportation System. The positive results of its use can be summarized as follows:

1. It forced the user to understand his problem and address it in a disciplined manner.
2. It documented requirements in a uniform manner and eased the task of document maintenance.
3. It assisted in the identification of errors primarily in the areas of incompleteness and inconsistencies.

The negative features of the system are as follows:

1. The system was too general to be used for a specific application. An internal groundrules document had to be developed to tell the user what to do and what not to do (e.g., limited number of attributes, naming conventions for decimal numbers, keyword conventions, etc.)
2. The PSL/PSA systems used large amounts of computer time that were not planned for.
3. The system is oriented towards a business environment and makes assumptions that make it difficult to describe requirements for realtime systems (e.g., concept of counters and interfaces hard to describe, notation is not compatible with scientific symbols, etc.).
4. The system was hard to sell to the users who were engineers. Therefore, changes had to be made to overcome user criticism (e.g., illegal characters like / in ft/sec had to be made legal).
5. The system had to be extended in order to provide I/O tables required by the B5 specification[7] format. A FORTRAN program was developed to search existing files and generate the tables.

The positive benefits resulting from use of PSL/PSA compensated for the negative experiences. Plans have been made to utilize the system to describe software requirements for other military systems.

ACKNOWLEDGMENT

The work reported in this paper was accomplished by the Martin Marietta Corporation under contract to the Air Force System Command's Space and Missile Systems Organization (SAMSO). I would like to thank them for their assistance in the preparation of this report.

EXPERIENCE WITH SADT—Donn Combelic

BACKGROUND

SADT, Structured Analysis and Design Technique, is a registered trademark of SofTech Inc., Waltham, Mass. ITT has used the "Structured Analysis" part of SoftTech's SADT since early 1974. In mid-1975 we began to develop for real-time switching software our own structured design technique, called FP2 for Functions-Processes-Flowgrams-Programs, based upon precepts and syntax of Structured Analysis. Thus the technique we are now using for analysis and design is called SA/FP2.

GENERALITIES

The principal basic ideas of the technique are: determine the "what" before the "how", docomposition from the top down to reveal successive levels of detail, output in the form of diagrams each of which gives a limited amount of detail, each diagram is critiqued in writing by one or more persons other than the author of the diagram, needed information unknown to an author is obtained by interviews with outside experts. Each diagram is comprised of boxes that represent "activities" interconnected by arrows that represent "data" used by an activity for input, output and control. A box plus its arrows constitutes the "context" of that activity—it is that (bounded) context which is decomposed to understand and show more detail in a diagram at the next level.

OVERVIEW OF SA/FP2.

SA/FP2 is carried out in five phases, one of which is concurrent with two of the others. The first phase is that of Structured Analysis (SA); the remainder are those of design, that is, FP2. A brief summary of each of the five phases is given in the following paragraphs.

Structured analysis phase

SA is ideally applied to the total system. However, in most applications we have applied it only to real-time switching software. In such a case, the primary inputs are a list of customer requirements plus functional specifications of the telephone hardware of the system. The output is a Functional Requirements Model (FRM) in the form of a set of activity diagrams many of which are accompanied by a page or two of explanatory text and definitions of terms. The FRM shows what functions the software must contribute in addition to those of the telephone hardware in order to fulfill the customer functional requirements. To the greatest extent possible, software design considerations, such as data layouts, scheduling, priorities, handling of queues, buffers and computer peripherals, are kept out of the FRM. Thus the FRM emphasizes the "what," not the "how".

Transfer phase

This is the first phase of design. Its principal inputs are the FRM and the software design constraints. Typical constraints are: choice and arrangement of computers, computer peripherals, programming language, requirements for traffic handling, engineerability, extensions, maintainability, etc. The outputs of the transfer phase are a high level data layout model and a single level "action group" model. (A software action is defined as a sequence of instructions which, once started, can run to completion without waiting because all needed inputs were available at its start.) For each action group, a convenient set of one or more contiguous activities, along with the data arrows at the boundaries, is selected at an appropriate level of detail from the FRM and transferred (as a single box) to the action group model. The action groups are interconnected as the corresponding sets of activities were interconnected in the FRM. The high level data layout model is developed before and during the transfer procedure. The transfer phase is complete when all activities of the FRM have been accounted for in the action group model.

Action group decomposition phase

All action groups are decomposed to the level of individual actions. The output is a set of activity diagrams where each box at the lowest level of detail represents an individual action. An additional output is further detail of the data layout. During this and the preceding phase the decomposition rules are the same as for the SA phase, but the SA syntax is augmented to handle action starts and completions.

Flowgram phase

Each action is decomposed, according to its implicit control flow sequence, down to the level of individual routines, each of which appears as a separate box on the lowest level diagrams. The control flow is shown on each diagram in a special syntax, hence the name "flowgram." The output of this phase is a "flowgram model" for each action. The previous syntax is augmented to handle control flow. It turns out that when the control flow sequence and the individual routines are coded the resulting set is a structured program. Thus there is a structured program for each action.

Coordinator phase

The coordinator is that software which, among other things, starts all actions and to which all actions return upon completion. It thus includes the functions of scheduling, handling of queues and management of memory. It is convenient to include within the coordinator the treatment of interrupts and the handling of telephone and computer peripherals. It is interesting to note that none of these functions relate directly to the customer's basic functional requirements, rather they all depend on the nature of the system. The functional requirements for the coordinator begin to emerge as early as the SA phase, become more clear by the end of the transfer phase, but cannot be known completely until the action group decomposition phase is finished. By that time the coordinator can be completely specified and designed. Note that the techniques described for the preceding phases can be applied to the analysis and design of the coordinator.

EARLY EXPERIENCE—1974-1976

Development of the FP2 design methodology reached the point where it could be used in practice only at the beginning of 1977. Thus all our prior experience was limited to Structured Analysis as taught by SofTech and refined by ITT and SofTech together. We adopted SA in early 1974 for two main reasons. First, it provided a disciplined way of understanding requirements in detail before starting design. Second, it offered a method which promoted teamwork. The latter was a particularly difficult problem on some of our projects in Europe where a team would consists of members with widely varying experience from up to eight different ITT companies speaking six different languages. Of the approximately twenty ITT projects where SA has been used, all but one are in Europe.

Strong and weak points

A partial list, derived from our early experience with SA, is as follows:

- SA estimated to decrease overall software development cost by at least 20 percent and significantly improve software quality—estimated 2 to 10 times less bugs found during integration testing, varies with project.
- Very definitely promoted teamwork.
- Hard to think all the time in purely functional terms.
- The written comments (by other than the author) required for each diagram resulted in continual review, in effect "walkthroughs." (Note : Commentators should normally be other authors in the same team.)
- Interviews of outside experts proved efficient method of obtaining specialized information.
- Forced making high level decisions early, thus providing a sound basis for later lower level decisions.
- Encouraged agreement on requirements before start of design.
- Lack of follow-through on design methodology (later overcome by FP2) was bothersome.
- Permitted non-software people to understand the contributions of software functions to system operation.
- Much more useful information per sheet (diagram) than with documents in prose.
- Provided easy way of measuring progress during analysis.
- SA excellent for many applications other than real-time switching software, but space does not permit elaboration.

Some mistakes made and lessons learned

A partial list follows:

- Method was oversold in the beginning as a panacea.
- Proper use of SA requires a fundamental change in mental outlook—difficulties of achieving such a change were underestimated.
- Mere "training" is inadequate—"education" is required.
- Potential authors must be selected on the basis of intelligence and willingness to try a new way rather than purely on experience.
- Constructive critics of the method are to be cherished, but destructive critics must be eliminated from the SA group as soon as they surface.
- Method takes much more time before design starts than previous methods. Inevitable if requirements to be thor-

oughly understood and agreed before design, but causes impatience in some participants and management.
- Need one "friendly" group to try method first. Afterwards it's better to "offer" the method to other groups than to try to "sell" it—hard sell doesn't work.
- "Discipline" in use of method is very important: syntax, conventions, rules, author-commentator cycle, completion of a level of decomposition before going to next, each diagram must increase understanding, etc.
- Large amounts of paper generated. Project librarian must be assigned, as recommended by SofTech.
- Formal training is lengthy—two to three weeks full time—but necessary.
- Potential authors must have a project in mind during training and be assigned full-time to it immediately thereafter.
- Follow on assistance by a trained "monitor" is obligatory during initial application of method.
- Monitor must confine his attention to proper use of the method rather than become involved in the substance of the analysis.
- Training plus monitoring by SofTech is costly: 20 to 40 thousand dollars per course for up to ten authors, but worth it.
- Ideal team during SA phase for our type of large switching projects seems to be two or four persons each from systems, hardware and software.

Recent experience—1977

It is our estimate that about two-thirds of the value of SA/FP2 is in the SA part. Nevertheless, the availability of a follow on design method, in our case FP2, makes the application of SA easier because the SA authors are more ready to defer design considerations to the FP2 phases.

The development and acceptance of FP2 has proved extremely difficult and its success has not yet been fully demonstrated. We wanted to use the same basic precepts and syntax as in SA so that the designers, some of whom will have also participated in the analysis by SA, would not have to learn a new syntax and set of principles—we wanted a sort of "continuous" method, starting with a list of requirements and constraints and ending up with detailed coding specifications. This "continuity" and similarity of syntax is important to software maintenance personnel and will assist comprehension by interested customers.

This section concentrates on our 1977 experience with FP2; subsequent experience will be covered during the presentation at NCC 78.

- Underestimated importance of providing detailed guidelines for carrying out the Transfer phase.
- Initially called the output of the Transfer phase, the "process model." "Process" has many meanings and caused great confusion. The neutral phrase "action group" conveys the intent without confusion.
- Software design still requires great skill, but FP2 permits easy comprehension after key design decisions have been made.
- FP2 criticized for not rendering high level software design "semi-automatic" or at least "semi-algorithmic."
- Direct coding from flowgrams is in most cases straightforward and can be done by programmers other than the designers.
- The fallout of a "structured program" for each action has proved very appealing.
- Test plans can be developed throughout FP2 in increasing detail and related directly to diagrams.
- Much debugging is done by reference to flowgrams instead of listings.

EXPERIENCE WITH AN APPLICATION OF STRUCTURED DESIGN—J. A. Rader

INTRODUCTION

The application of structured design to a 20 man year project which generated 100,000 lines of code is described. Included are a description of the project, productivity figures, and a discussion of strengths and weaknesses of the technique as practiced on the project.

THE APPLICATION

Introduction

The Computer Aided Design (CAD) Department in the Hughes Aerospace Groups contains about sixty employees. The department provides Computer-Aided Design/Test/Manufacturing software and services; it operates and supports a DEC system 10 computing facility; and it operates and maintains a Gerber photoplotter and several digitizers.

Most of the software is data manipulative in nature—files are read; fields are extracted from records and massaged; arrays are built, operated on and sorted; reports are generated; and data bases are accessed and updated. The primary language has been and continues to be FORTRAN. In addition, there is an extensive library of FORTRAN-callable assembly language routines to perform bit and character manipulations as well as other special functions. Where very heavy CPU utilization is expected, assembly language is also sometimes employed.

Conversion decision

Several years ago, a corporate decision was made to phase out the Honeywell G635, the computer on which the CAD System at that time ran. Among the many alternatives considered for rehosting the CAD System, the one finally chosen was to purchase a DEC system-10 and convert the CAD system to run on that computer. The primary reason for selecting the DEC-10 was a proven time-sharing capability.

The conversion from the G635 to the DEC-10 was a conversion only from the standpoint of function.

Existing programs were inventoried and for each it was decided which would be converted essentially as is, which would be modified, and which would be discarded.

Goals and advanced plan

As we started to plan, we recognized that it was very important to firmly establish our goals, and to determine very specific milestones. Thus we would be able to measure our progress and to report on it to our management, who was picking up the tab.

Succinctly stated, the major goals were: (1) to create a unified system tied together by a central data base; (2) to create software that was reliable and maintainable; (3) to provide a user interface that was easy to use and that was consistent across all software; and (4) to proceed in a manner that allowed us to measure how well we were meeting schedules.

In late 1973, an advanced planning and development activity was formed. The advanced planning group was to define the overall structure of the system, and to specify the procedures to be followed in specifying and implementing the system.

In November of 1973, the author attended a 6-day in-plant seminar on structured design. This seminar was taught by Larry Constantine and proved to be of immeasurable value. The value arose not from revolutionary concepts but rather from a well reasoned and coherent discussion of the relevant concepts. The ultimate result of attendance was the generation and documentation of a methodology for practicing structured design in our organization. This methodology is described in the next section.

Outputs of advance group

In the approximately 18 months of its existence, the advance group produced 4 basic outputs. First, it produced a system concept. Second, it defined the standards and procedures to be followed in rewriting the system. These were documented in a Standards and Procedures Manual issued to all programmers. Third, it defined most of the applications support software. Fourth, it provided a test vehicle for the standards and procedures defined, and provided the first productivity figures for the methodology. These figures were used in estimating the effort required to implement the main body of CAD software.

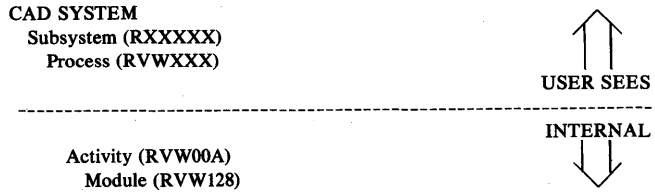

Figure 1—Software hierarchy

STRUCTURED DESIGN

The following hierarchy, illustrated in Figure 1, is used to identify levels of CAD software: system, subsystem, process, activity, and module. System means the whole CAD System. A subsystem is a major functional area. Examples of subsystems are routing, digital test and simulation, design capture, etc. A process performs an identifiable user function which may be simple or complex. The process level is the lowest level visible to the user.

A process consists of one or more activities, where an activity is an executable core image or job step. A module, which is the lowest level, is a single FORTRAN or assembly language subroutine. Our FORTRAN modules contain an average of 35-45 statements. Assembly language modules have an average length of 50-60 statements.

Each activity and module is uniquely identified by a six character code. Examples are shown in parentheses in Figure 1. Thus module RVW128 would be module 128 in the View (VW) Process of the Routing (R) Subsystem.

Structured design, a la Constantine, is applied either at the process or activity level, depending on the complexity of the process and constituent activities. Design documentation always includes a structure chart (hand drawn, as generated in the design process) and a completed module description form (MDF) for each and every module. A module description completely defines the *function* of a module so that it can be coded from this documentation alone, with perhaps reference to appropriate data structure documentation.

For an easily grasped function, e.g., the binary search of a single precision array, a description of the calling sequence may be adequate documentation. However, it has been our experience that many modules require either flow charts or pseudocode for unambiguous documentation. This is true even though the emphasis is on the function not the detailed coding of the module. Typically, this situation obtains for the higher level modules in a structure chart. At that level it is frequently the case that the function of the module and the flow of control within the module are not really separable.

RESULTS OF APPLYING STRUCTURED DESIGN

Productivity figures

The advanced planning activity implemented 336 modules of applications support software. These modules contained

	Advance Group (336 Modules)	Main Development Effort (2200 Modules)
Man Hours Per Module		
Specification	3.3	5
Structured Design	3.0	5.4
Coding and Integration	8.8	9.8
Total	15	20

Figure 2—Manpower statistics

11,104 lines of code, an average of 33 lines/module. There were 180 FORTRAN modules (average length 25 lines), and 156 assembly language modules (average length 42 lines).

The manpower figures were specification and analysis, 28 MW (man weeks); structured/implementation design, 25 MW; and code and integration, 74 MW. Figure 2 displays the corresponding figures per module.

The largest activity in this collection of software contained 117 modules (3551 lines), of which 105 (2936 lines) were FORTRAN. The distribution of calendar time for this program was: specification and analysis, 26 weeks; structured design, 6 weeks; and coding and integration, 20 weeks. Thus, although specification and analysis only accounted for 22 percent of the manpower it consumed 50 percent of the calendar time.

Column 3 of Figure 2 summarizes the figures for the bulk of the CAD software. This data represents approximately 18 man years of effort including supervision time. Accounted for are 27 processes, 53 activities, and over 2200 modules.

Problems encountered

Although our experience with structured programming has been strongly positive, we did encounter some problems. Moreover, looking back, we see areas where improvement is needed.

The biggest need for improvement has to be in the area of specification. Once a good specification has been generated things become very manageable. However, we have found it extremely difficult to write a specification which on the one hand a user can read and understand, and which on the other hand defines things well enough to allow design to begin in earnest.

A second problem area is related to one of the design goals. From the start it was impressed upon the programmers that they were to put design before efficiency. As a result a couple of activities were implemented which were very much more expensive to execute than they should have been. These subsequently, had to be modified for efficiency.

In most cases this efficiency problem might well have been avoided had we more strictly followed one of our own published procedures. We did not require each module to be reviewed by another programmer as we said we would. The excuse tends to be "we just don't have the time", and is used by programmers and supervision alike. In the face of tight schedules, this excuse is not easily dismissed. This problem will doubtless be struggled with for some time to come.

A final problem is the difficulty in training enough programmers to be good designers. The training problem is particularly troublesome because there is no way to give years of experience, and the attendant design maturity, to even a highly capable junior individual. This is important because the structured design of a large process requires the judgment to make numerous decisions, which involve tradeoffs between strict adherence to structured design principles, on the one hand, and effective use of human and machine resources on the other. The best solution is to employ the most qualified designers on critical designs, and to use less critical designs for training. But when schedule constraints force many important designs to overlap, less desirable compromises have to be made.

Summary of benefits

Although we did not have any solid prior productivity data, we definitely feel that structured design has improved productivity. This, however, was not a goal in our adopting structured design, but has been just a happy side-effect. What was anticipated were increased reliability, increased maintainability, and increased visibility.

There is no doubt that we have achieved increased visibility. Moreover subsequent experience with modifying structured programs convinces us that increased reliability and maintainability have been achieved.

It was found that structured design allowed us to make very good use of personnel. We have been able to really load up an activity in the module coding and checkout phases without introducing confusion. It has also been easy to quickly move a programmer from one activity to another, with little loss in effectivity. Moreover, we have gotten excellent productivity from beginning programmers.

Only mild reluctance to adopt structured design techniques was manifested by the staff. Junior personnel adopted easily with no apparent "loss of individuality" response. There was some initial thrashing with senior personnel as we all strove to understand the implications and tradeoffs of modularity. For instance, not everyone accepted at first that structured design was indeed distinct from what they were already doing.

A final word on interpreting our experiences with structured design. We feel that our experience is unique to our application and our environment. A different application in a different environment might yield better or poorer results. Nonetheless, we are confident that, for most applications, structured design will yield more reliable and maintainable systems, while providing good visibility of the design and implementation processes.

EXPERIENCE WITH EXXON'S IMPLEMENTATION OF THE JACKSON PROGRAM DESIGN METHOD —C. M. Bernstein

In 1973, Exxon's Mathematics, Computers and Systems Department conducted an evaluation of the new technologies of program development. The project was motivated by the increasing manpower cost for software development and maintenance and the increasing business vulnerability to software failure. We concluded that a program's structure is the key to its effective development, enhancement, execution and support. Without a program's structure we could not reliably construct the program in parts, put the parts together such that their interactions would be predictable, and have the whole structure achieve its specified purpose.

Michael Jackson, now of Michael Jackson Systems Ltd., was then an ACM lecturer. We found that he had a teachable method for the logical design of structured programs and a precise notation to express them. In addition, his method was effective at attacking practical programming problems where the designer is not free to define input and output formats and user interfaces. Michael taught three program design courses at our Florham Park, New Jersey offices in the winter of 1973. The courses were well received and, together with Michael's consulting on specific applications, provided the knowledge we required. We adapted Jackson's Methdology to our environment and renamed it Program Structure Technology, PST.

It is important to remember that PST does not address the systems design process. PST is not concerned with defining the organization or contents of files, specification of input and output formats or transactions, designing data bases, or defining required processing. PST is concerned with the work of designing and implementing the program which meets those specifications. PST incorporates the technologies of top down design, structured programming, top down development and test, and structured walk-thrus.

We conducted our first in-house PST course in August of 1974 and aggressively fostered the assimilation of PST over the following three years. Over 1,000 programmer/analysts have been taught PST. All Exxon regions can now provide their own training and support. This includes training for supervisors, consulting, and the support of standards. PST is being used in both large and small installations to develop batch commercial and interactive data base applications, as well as minicomputer, process control and program product software.

The Jackson Program Design Method defines hierarchical program structures whose components are dissected. There are four basic component types:

Elementary, which are not dissected
Sequence, whose parts are executed once each, in order
Selection, one of whose parts is executed, the choice part depending on a condition
Iteration, which has only one part which is executed zero or more times

The four component types have exact analogies in data usage structures for files, records and in internal data. The program's structure is designed to correspond to the usage of the data to be processed. Alternative usages of data can be imposed on a given set of data and the alternative program structures evaluated. Each operation carried out by the program appears in an appropriate component. For example, "INITIALIZE CUSTOMER TOTAL" should appear in a component which happens once per customer. If no appropriate component exists, the program structure is deficient. Where there is a conflict between data usages to be processed by one program, the program is designed as if it were two or more separate programs. The separate programs are subsequently combined by the technique of program inversion. Where a data usage cannot be handled simply, more elaborate forms of iteration and selection must be used.

The major benefits of the Jackson Methodology are as follows:

Reduced program complexity
Eliminated logic errors at design instead of debugging in the testing stage or later
Identified sensitive points in the problem specification
Easily maintained programs
Effective program documentation as a by-product of design
Step-by-step methodology has enabled effective use of software to support the process

Four PST projects of varying size (.5, 1, 5.1, and 25 work years of effort) were evaluated and productivity was found to be above 7000 lines per work year in every case. This compares favorably with the New York Times Archives project's 9000/WY and the "Industry Averages" of 2000-4000 lines/WY. In the case where we attempted to measure program quality, we found less than one error per program during the first six months of production.

We have done little to the Jackson Methodology to adapt it to the Exxon environment other than minor changes in terminology and emphasis. We have complemented it with our own material on structured programming in PL/I, top down development and test, and structured walk-thrus. We have also employed different pedagogical techniques to enable programmers who are not experienced instructors to teach the PST course.

The Jackson Methodology has been extremely successful in Exxon and is now virtually a standard throughout the world. I recommend not underestimating the difficulty of teaching programmers "how to program properly" and develop an assimilation plan and a skilled staff to accomplish it.

INITIAL EXPERIENCE WITH A METHODOLOGY FOR CORRECT PROGRAM DESIGN—F. T. Baker

In the forthcoming book, *Structured Programming: Theory and Practice,*[1] the authors describe three techniques which have been incorporated into a Methodology for achieving correct designs. These are:

1. A view of program correctness as a demonstration of a correspondence between the function of a program design (i.e., the set of ordered pairs corresponding to input states and output states) and the function required by its specification. This approach, when used with stepwise refinement, permits selective and incremental correctness proofs to be carried out, since it incorporates a procedure for verifying the correctness of the expansion of a specification into any one of a basic set of control structures. (The expansion of a specification at any level into a program design can thus be verified, contingent on the correctness of lower-level specifications and their expansions.) Furthermore, proofs can be carried out with varying levels of rigor, ranging from a set of questions the designer may use to validate an expansion to a formal demonstration recorded in a precise manner.
2. A method for incorporating specifications into program designs to support correctness demonstrations when desirable. Each specification (either initial, or those generated in the expansion process) is retained as a comment (logical commentary) directly associated with the control structure which refines it.
3. A design language (Process Design Language) to assist in the design process and to record the history of a design. PDL includes a standard "outer syntax" of essential control and data structures, and encourages development of an "inner syntax" appropriate to each design environment.

Figure 1 is an example of a design for a program which is to save the maximum value occurring in an input sequence. In that design, each of the paired brackets encloses logical commentary which is a functional specification for the control structure which follows it (sequence, ifthenelse or while do in this case). For each of the structures the appropriate proof procedure can be carried out to demonstrate the correspondence between its specification function and its program function. Furthermore, this can be done prior to the completion of the expansion process, or even on selected portions of the design.

The methodology is primarily aimed at the detailed design of a program. It covers the period between the formulation

```
[m:=maximum(inputseq)]

  fi
  [m:=maximum(m,remainder of inputseq)]
  while
    inputseq≠empty
  do [m:=maximum(m,next(input)]
    temp:=next(input)
    [m:=maximum (m,temp)]
      if
        temp>m
      then
        m:=temp
      fi
    od
  od
```

Figure 1

of an effective system design, and the translation from the design language into an implementation language. It was developed to introduce more precision into the design process and to encourage more consistent expression of designs. Whether or not formal correctness demonstrations are carried out, the stress on viewing programs as functions, developed from specifications through a rigorous refinement process, should help achieve the goal.

Experience to date suggests that the methodology is capable of being practiced in the application development environment. We believe that the control structures inherent in PDL are sufficient to support all levels of the design process, from system and module specification down to precise algorithms. The invention and use of logical commentary direct attention to specification and program functions, as they were intended to do. In particular, they encourage the designer to specify and deal with boundary conditions and anomalies which frequently are poorly attended to and which sometimes lead to difficult-to-find errors. Finally, the view that each progrm should be designed as if it is to be proved correct, means that even if correctness demonstrations are not formally carried out, the program has a greater likelihood of properly embodying its specification.

Experience to date also indicates several areas where more work is needed. The nature of the expansion process, and the desire to record the design history, mean that much copying is done as the design is developed. An interactive support tool appears useful to assist designers in this expansion and recording. The data structures in PDL (stacks, queues, sequences and sets) are useful ones, but better proof techniques to validate operations with them must be developed. There is a notational problem inherent in specifying functions precisely, particularly in nonmathematical envi-

ronments, which must be solved through a combination of inventing better notations and abstracting operations. Finally, the ability to demonstrate correctness does not mean that it is appropriate to do so in all cases; better guidelines for applying the varying degrees of rigor possible in the methodology must be developed.

EXPERIENCE WITH THE IPAD SOFTWARE DEVELOPMENT METHODOLOGY—Susan Voigt

NASA is sponsoring the development of a computer-aided design system for use by the aerospace industry. The system, denoted IPAD, is being designed and implemented by Boeing Commercial Airplane Company and Boeing Computer Services. IPAD is a software system to enhance the computer complexes of aerospace companies to improve speed, efficiency and reliability of the design process for complex aerospace vehicles. The contract calls for application of an effective software engineering approach to minimize programming and software design errors, as well as to produce highly portable software.

THE TECHNIQUE

NASA established general guidelines for phases of the development and release of software in stages, to allow early user testing and experience. The development phases are:

1. Definition of the Problem (namely the Aerospace design process)
2. Requirements Definition (integrated information processing and functional requirements)
3. Development of IPAD System Specifications
4. Preliminary Design
5. Detailed Design, Code, and Test for each incremental release
6. Acceptance Test and Demonstration with sample problems for each release
7. User Training and feedback
8. Software maintenance during remainder of development contract

Several plans and specific documents were called for in order to encourage a systematic approach and a well documented product:

1. Management and Technical Plans to describe general approach
2. Configuration Control Plan to control and track all changes to requirements, design, code and documents
3. User Involement Plan to insure the sytem developed is satisfactory to the users
4. Test Plans to establish systematic procedures for development and acceptance testing
5. Software Standards Handbook
6. Requirements and Preliminary Design Documents
7. Preliminary User's Manual written during design so early user feedback can be obtained
8. User and Demonstration Manuals
9. Installation and Maintenance Manuals

As the basis for the IPAD software engineering methodology, the Boeing IPAD Development Team selected the Boeing Computer Services "Systematic Software Development and Maintenance (SSDM)" approach. SSDM is basically a set of general guidelines for all phases of the software life cycle, and it corresponds well with the NASA requirements.

An Industry Technical Advisory Board (ITAB) was established at the start of the contract to closely involve the prospective user community. They have helped review and critique the requirements definition and software design phases. Subsequently, they will have the opportunity to install and test the software at their own computing facilities.

EXPERIENCE AND EVALUATION

At the time of this writing, the development is in phase 4, Preliminary Design. The techniques used to date and an assessment of their usefulness in the software development process is described below.

In phase 1, a reference aircraft design process was documented in flow diagrams indicating activities and decision points, with accompanying discussions. Also communications between various disciplinary groups participating in an aircraft design project were diagrammed to illustrate the complex network of interfaces. Separate volumes were written to document the interactions between designers and the manufacturing organization and the activities in managing a product development. These three volumes written by engineers representing potential users defined the problem to be addressed with the IPAD system.

The requirements were defined by the engineers in phase 2. The BCS technique SAMM (Systematic Activity Modeling Method) (Reference 1) was used to chart the inputs and outputs (description and quantity) for each activity in the flow-charts of phase 1. The user's view of his requirements for computer-aided support in the aerospace design process also was documented.

The results of phases 1 and 2 represent a very thorough definition of the aerospace design process and CAD users' needs. These were well-received by the user community and have provided guidelines for their own analyses within their respective companies. The flow diagrams of the design process and the SAMM charts of the data flow are well correlated and provide a very systematic look at the problem.

Phase 3 was done by the software team, assisted by the engineers. They developed a concise set of IPAD requirements based upon the engineering documents and NASA requirements for the IPAD system. A formal analysis checked that each requirement was complete, correct, unambiguous, precise, consistent, relevant, testable, traceable, free of unwarranted detail, and manageable. The engineering team developed criteria for acceptance testing for each requirement. Each test criteria was summarized in a paragraph which accompanies the requirement statement in the IPAD Requirements Document. The requirements were reviewed carefully by both NASA and ITAB, with considerable feedback and revision resulting. A set of IPAD system specifications were not produced, per se; the IPAD Requirements became the baseline for further development.

The formal analysis of requirements was not successful. Ambiguities, inconsistencies, and redundancies were very difficult to eliminate, especially between similar requirements. These arose from using secondary sources in developing the IPAD requirements and giving them weight equal to the primary source, the engineering definition of the problem. A satisfactory set of requirements was obtained through careful reorganization and joint review by software and engineering team members and NASA. The inclusion of the summary for acceptance test was very helpful in clarifying the intent of a requirement, as well as setting the stage for later testing. It also forced the engineering and software teams to collaborate, and is highly recommended for future projects.

In Preliminary Design, phase 4, a user interface model was developed using state transition diagrams (Reference 2). This included a set of user functions correlated to the IPAD requirements. These state diagrams have been used to walk through "user scenarios" to illustrate the functioning of IPAD from a user point of view in performing a specified set of tasks. The other major components of IPAD are: the executive, the information processor, and the other systems interface and are currently undergoing design by separate subteams. Coordination among the various subteams in producing an integrated design has been difficult.

While the approach used has been successful in achieving a good set of requirements, IPAD is not yet developed and the design methodology is unproven. The basic concepts appear to be an effective approach and further assessments can be made when the software is developed.

Formal methods in programming and microprogramming

Two of the three sessions in this area are about microprogramming, and the third is about programming in general. The dominant theme in all the sessions is the current attempt by researchers and practitioners to make programming a formal process. Roughly speaking, this means the use of mathematical rigor in defining, specifying, translating, transforming, analyzing and verifying programs (including microprograms).

The work is motivated not by a love of formal methods for their own sake, but by hard economic objectives. Users are now demanding increased confidence in the adequacy and reliability of delivered software, greatly reduced cost of production and maintenance, and greatly increased flexibility with respect to change, growth and transportability. These demands are not being met by the informal techniques that have accumulated over the years. The work on formal methods is intended to make major advances in the way software practice meets these demands.

With few exceptions, the old techniques—and the tools that support them, have aimed to help the programmer to describe, encode, recode, package and probe his large and complex product. The task of fully understanding the product and of ensuring that it and all the steps used in its production are correct, has been left to the human judgement of producers and consumers. With some serious exceptions, present practice has been generally successful due to the dedication of computer professionals, the effectiveness of social processes in dealing with errors in output data, and, of course, the great economic benefit of using computers for solving problems. This success has come at high costs that are no longer acceptable. Furthermore, new applications and market conditions have arisen that bring very high penalties for error, inflexibility and inefficiency.

The response of the computer science community has been to attempt to put mathematical rigor into the task of understanding what a program does (its "semantics"), or, in linguistic terms, what is the meaning of its text.

Of course, understanding precisely what a program does implies knowing precisely also what the translators, optimizers and interpreters do that may operate on the program. If the description and analysis of programs and their processors could be put on a firm mathematical basis, and if there were effective procedures for carrying out formal analyses, the consequences would be very significant. For example, one could build powerful optimizers, and be confident

that they would not change the meaning of a program. Also, one could verify that a program implemented a requirement for all possible values of data in the intended input domain, without having to use test data samples (a most costly and unsatisfactory process if high confidence is demanded).

As long as ten years ago, theoretical results showed that a formal basis for programming could be constructed. Since then much effort has gone into creating methods of formal specification and analysis, and tools to implement the methods, that are effective enough to be incorporated in software engineering practice. At the present time, several methodologies are reported to be in practical use in special application domains such as microprogramming, or on an experimental basis, for general programming. The methodologies require skilled practitioners. Because of this, one cannot say that a methodology is "ready" or "not ready" without saying who is going to use it. Nevertheless, it is claimed that there will be enough practitioners of the requisite skills to make a very significant economic impact on software production, especially as the methodologies mature.

The papers and panel sessions of this area give the attendees an opportunity to judge how valid these claims are, and to assess the relevance of the ideas and tools of the new methodologies to their own practice.

An approach to firmware engineering*

by DAVID A. PATTERSON
University of California
Berkeley, California

INTRODUCTION

Although microprogramming has only been a research topic for the past 10 years, the concept is nearly as old as computers.[1] Wilkes originally defined microprogramming as a systematic and orderly approach to the design of the control section of a computer. Rather than using an *ad hoc* approach with counters and decoders to generate control signals, Wilkes proposed that the control be organized as a matrix. This memory like approach to control remained largely of academic interest until the late 1950s. The first large-scale microprogrammed computer was the IBM 7950 in 1961. However, it was the introduction of the IBM System/360 line (with all but the largest system microprogrammed) that revived interest in microprogramming. The advance in speed and the reduction in cost of read-only memory (ROM) technology transformed microprogramming from an academic concept of mild theoretical interest to a practical approach to the design of commercial computers.[2] IBM was able to offer several internally different models with the same instruction set in order to provide a spectrum of cost and speed through the use of microprogramming. With the success of the 360, several microprogrammed computers were and are being built. In the late 60's some manufacturers made microprogramming available to the users. Nearly all computer manufacturers have at least one computer implemented via microprogramming, and the expanding list of manufacturers that provide user microprogrammable computers include Burroughs (E1700), Control Data Corporaton (Cyber-17), Data General (Eclipse), Digital Equipment Corporation (PDP-11/60) and Hewlett Packard (HP-21MX). This has expanded the potential domain of microprogrammers from computer architects to systems and applications programmers.

While microprogramming and "ordinary" programming have existed for almost the same amount of time, little of the considerable research in programming languages and methodologies has impacted the microprogramming field. Unfortunately, the following statement is a fairly accurate description of the state of the microprogramming:[3]

> "At present, microprogramming is an elite activity, performed effectively only by a small number of expert practitioners. The work is detailed, precise, time consuming, and considerably more expensive than present-day software programming. But, computer manufacturers have found they can get dramatic improvements in system performance by converting software into microprogrammed form."

An approach to expanding the group of practitioners of microprogramming is to reduce the complexity and expense of firmware by providing tools similar to those that have reduced the cost of software. The Strum system was designed as a prototype to explore the benefits and detriments of such an approach.

SOFTWARE ENGINEERING TECHNIQUES

The most obvious technique to enhance the production of microprograms is to provide a high level microprogramming language (HLML). One reason HLMLs have not been used is the importance of efficient firmware. With restricted size and execution times being primary characteristics of microprogramming, some doubt whether a HLML could ever be useful.[15] With the newer computers control memory has expanded (e.g., 16K control memory of the HP-21mx) thereby relieving some of the concern about size. A more important aspect is the influx of applications microprogrammers who have a very different set of constraints from the microprogrammer of the native instruction set. In the latter case one may be able to justify doubling the effort to reduce execution time by 10 percent. In the former case it is likely that ease of use, development cost and maintainability are much more important than small gains in execution speed. The necessity of a high level microprogramming language is further illustrated by the Figure 1. It is widely accepted that the programmer spends half his time testing the program. This figure indicates that a microprogrammer may spend half his time coding the microprogram. As it is widely accepted that a high level language will reduce coding time it makes eminent sense to provide a high level microprogramming language if it can produce reasonably efficient code.

Another technique that has reduced the time to develop software is structured programming. This phrase is so widely used that the criteria that determines whether a program is

* This research was supported in part by the Department of Energy under Contract EY-76-S-03-0034, PA214.

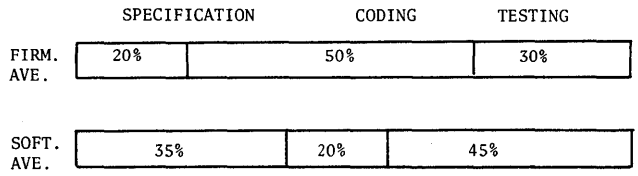

Figure 1—Percentage of time spent in specification, coding and test phases of microprogram and program development (from Reference 4).

structured is vague. By structured programming we mean a disciplined approach to programming that starts with the highest level of abstraction and proceeds with a topdown hierarchical development of levels of modules that are successively refined and expanded until the bottom refinement is the program in some programming language. A key aspect of this approach is for every module at each level to be "intellectually manageable," i.e., restrict the size and flow of control to create modules that are easy to read and to understand. Although assembly level programming does not preclude structured programming, it is easier to follow these concepts if the programming language supports this methodology. We believe that a cleverly designed microprogram language can hide the "unstructured" aspects of microprogramming plus provide tools conducive to structured microprogramming.

A final aspect of software engineering is validation. Here an attempt is made to determine whether a program is "correct." Unfortunately testing does not guarantee that a program is correct; it only means that someone (probably the creator of the program) is satisfied that the program preforms properly for some subset of the total input domain. As Dijkstra states:[5]

> "Program testing can be used to show the presence of bugs, but never their absence!"

If we conclude that testing is inadequate, our only alternative is formal program verification. This work began with the inductive assertion method of Floyd[6] that was elaborated by Hoare and Manna. This method first requires the addition of redundant text called assertions. Assertions are nonexecutable comments that describe the desired state of the variables of the program. These assertions can then be mechanically combined with the program text to produce logical formulas. If proven true, these formulas show a kind of consistency, usually called partial correctness, between the text and the assertions.

It is not clear that program verification is a practical tool for validating microprograms. In fact, there is a great deal of skepticism of the practicality of proofs of correctness in any environment.[7] The criticism is that only "toy" programs are proved, i.e., programs that use only integers or vectors of integers, deal with numeric algorithms (e.g., division), and are relatively short. Using these measures, one would have to conclude that microprograms are "toy" programs. Microprograms deal with integers (usually two's complement binary numbers) or integer vectors (memories), deal with numeric algorithms (instruction sets), and are relatively short (frequently less than 1024 words). Thus, the application of correctness proof techniques to microprograms may prove beneficial.

STRUM SYSTEM

The prototype system developed to test this approach to firmware engineering is called Strum (from STRUctured Microprogramming). This system includes a Pascal-like high level language, an optimizing compiler that produces microcode for the Burrough's D-machine, and a verification system.[4,8] The Burroughs D-machine is a general purpose microprogrammable, multiprocessor computer.[9] The computer was designed by the Burroughs Advanced Development Organization in 1968-1969 to be used in future Burroughs systems. The D-machine has several innovations. It was designed to be used in multiprocessor configurations. The arithmetic section of the machine is expandable in 8-bit increments from 8 bits through 64 bits. It was the first machine to use two levels of control memory (micromemory and nanomemory) to try to obtain the advantages of horizontal and vertical microprogramming. And at the same time it was built, it was one of the few computers to offer a control memory that could be altered by the user during program execution. The D-machine allows up to 4096 56-bit microinstructions.

THE EXPERIMENT

As a meaningful test of the system we decided it was essential to emulate a real computer. If a paper computer were to be emulated one might wonder whether the design of the new instruction set had not been compromised in order to avoid difficulties with the high level language or to simplify the verification of the emulation. Although this test would be emulation of a real computer on a real microprogrammable machine, some would wonder whether program verification, high level languages, and structured programming would not lead to correct yet inefficient code. As speed and size are very important in the microprogramming environment, it is possible that the overhead incurred using such techniques makes this approach unusable in the "real world."

To overcome these possible objections, an emulation of the same real computer was done twice. The first version was implemented via techniques traditionally used with microcode on the D-machine, i.e., assembly level coding, debugging the microcode on the machine, and testing the microcode using programs written for the machine being emulated. The other version was written using techniques proposed in this paper. Unfortunately it is difficult to create tests that are free from the appearance of bias. If one person did both emulations, one could correctly argue that the experience gained on the first emulation project would improve the results of the second project. To avoid this criticism, a different person did each project. The argument, then, is that with two people the differences in education, experi-

ence, motivation, etc. affect the accuracy of the results and possibly affect the fairness of the comparison. One could also claim that the choice of a minicomputer for the experiment rather than a large-scale computer does not allow generalization of the results.* We can only respond that both microprogrammers are bright, capable people, that there are fewer and fewer distinctions between minicomputers and large-scale computers, and that we can only hope that the reader will appreciate our attempt to make a fair experiment. The test case was the emulation of the HP-2115 computer.

The Hewlett-Packard HP-2115 computer

The Hewlett-Packard HP-2115 is a predecessor of the HP-2100 and HP-21MX computers currently marketed by Hewlett-Packard. The HP-2115 has 70 basic instructions that operate on two accumulators, two flags, and (in this emulation) 8192 words of 16-bit main memory. This instruction set includes several special input-output instructions for up to 64 devices and provides for multi-level indirect and paged addressing. The HP-2115 will handle up to 64 different interrupts. Although the Hewlett-Packard manual lists 70 basic instructions, most of the opcodes in the shift-rotate group and alter-skip group can be combined to form more than 100 additional useful instructions.

HP-2115 emulation using traditional techniques

The emulation using traditional techniques was implemented by a graduate student in Spring 1975. This microprogram was written in TRANSLANG, the assembly language for the D-machine. He did not attempt to use the techniques of structured programming. He debugged the microprogram directly on the D-machine by running HP-2115 programs and examining the registers at each microstep. As we indicated above, this primitive approach is unfortunately typical of the way most microprograms are developed. This student had ideal conditions for using this approach in creating the emulation:

(1) He was thoroughly familiar with the HP-2115. He had spent two years as an M.I.T. undergraduate using this computer.
(2) He was thoroughly familiar with the D-machine. This student was in charge of maintaining the D-machine and the implementing enhancements to it.
(3) He was the sole user of the D-machine during that period. Usually a microprogrammer must compete with other users for access to the machine.
(4) The hardware was fixed and operational. With computer manufacturers the computer is usually being built and debugged while the microprogram is being debugged.† It is often difficult to distinguish between an error in the microprogram and an error in the hardware. With formal microprogram verification, the hardware is not needed until after the microprogram is verified, i.e., much later in the development cycle.
(5) There was software available to test his program. When a new instruction set is created, there is usually no program available to test the microprogram.

After he was satisfied that his microprogram worked, we tried running diagnostic programs for the HP-2115 on the emulation. Diagnostic programs are used to test if the hardware is working properly. This is a widely used technique to test accuracy of emulation. The argument is that if the diagnostics believed that the HP-2115 "hardware" was working correctly, the emulation of the HP-2115 must be working correctly. Running the diagnostics uncovered two errors in this emulation.

Subsequently we discovered that one of the unassigned opcodes performed a useful function. This opcode was obviously not tested by the diagnostics, but its use was apparently so widespread by users of the HP-2115 that they defined this opcode in a later programming manual. We were also surprised that the diagnostics did not test some apparently unusual combinations of options in the I/O instructions. The student left this out of his emulation because he doubted that it would ever be used. (In March 1976 he completed the emulation of all unusual I/O instruction options.) In writing the specification for the STRUM HP-2115 emulation, another error was discovered. Memory reference instructions can use the current page address to supply a portion of the operand address. When an interrupt occurs the program address register is not modified but the computer selects and executes an instruction from the first 64

TABLE I.—A Comparison of Size and Speed of Microassembly, Unoptimized Strum, and Optimized Strum Emulations of the HP-2115 Computer

	Microassembly	Unoptimized Strum	Optimized Strum
Number of Micro-instructions*	946	1124	940
Number of Nano-instructions*	162	123	161
Size in bits*	25504	25856	25344
Average number of cycles executed per instruction**	72.9	66.4	58.6

* The Burroughs D-machine has two levels of control memory so the size should be compared either in bits or number of microinstructions.
** The Burrough D-machine comes in several microcycle times from 50 to 500 nanoseconds.

* The selection of which computer to emulate was made by the person who made the emulation using traditional techniques, not by the author. It should also be mentioned that the language was designed before the computer was selected.

† A referee mentioned that usually a microprogram simulator is available while the hardware is under construction. Our experience is that the simulator and its corresponding hardware quickly diverge. While the simulator is useful this divergence combined with time constraints often force the microprogrammers to have access to the computer before the hardware is debugged.

locations in memory. It was not clear from Hewlett-Packard documentation whether a memory reference instruction that requested address modification from the current page would get the information from the program address register or from the current page of the instruction (page 0). This emulation used the program address register but a test of another Hewlett-Packard computer revealed that the address bits always came from page 0. These three examples show the danger in relying on diagnostic programs as the only method of verifying an emulation. This emulation used 946 microinstructions which required 162 unique nanoinstructions. The execution speed is shown in Table I. The values in these tables are given in terms of D-machine microcycles. The D-machine at UCLA runs at 800 nanoseconds per microcycle although Burroughs has developed versions that run as fast as 50 nanoseconds per microcycle.

Strum HP-2115 emulation

The second emulation of the HP-2115 using a high level language, structured programming and formal program verification was implemented in Spring 1976 by the author. We had serious reservations about this experiment, mainly because this microprogram would be the first microprogram that used the STRUM system. A simpler test case to catch any bugs in the STRUM compiler and program verification system was planned, but lack of time ruled this out. The result of the output from the optimized code is shown in Table I.

Testing the HP-2115 emulation

The testing of the STRUM HP-2115 emulation was performed on November 11, 1976 by the creator of the other emulation and the author. The test consisted of executing the HP-2115 diagnostic routines. These routines exhaustively test all opcodes and most register values for the memory reference, alter skip, shift rotate and overflow instructions. We did not know what to expect, because this was the first test of the STRUM compiler, and the first large-scale test of the STRUM verification system. The verification process uncovered 30 errors in the emulator divided equally between the executable microprogram, the specifications, and the assertions. The program and verification formulae were corrected by hand. Although one large (about 2000 lines of NUCLEUS code) program has been verified,[10] this program was never executed. We were in the uncomfortable position of using untested software tools to verify a program that would immediately be subjected to exhaustive testing.

Surprisingly no errors in the STRUM emulation were uncovered by the HP-2115 diagnostic programs. Four errors were found in the code generated by the compiler, but had we run a simple compiler test program beforehand, all these

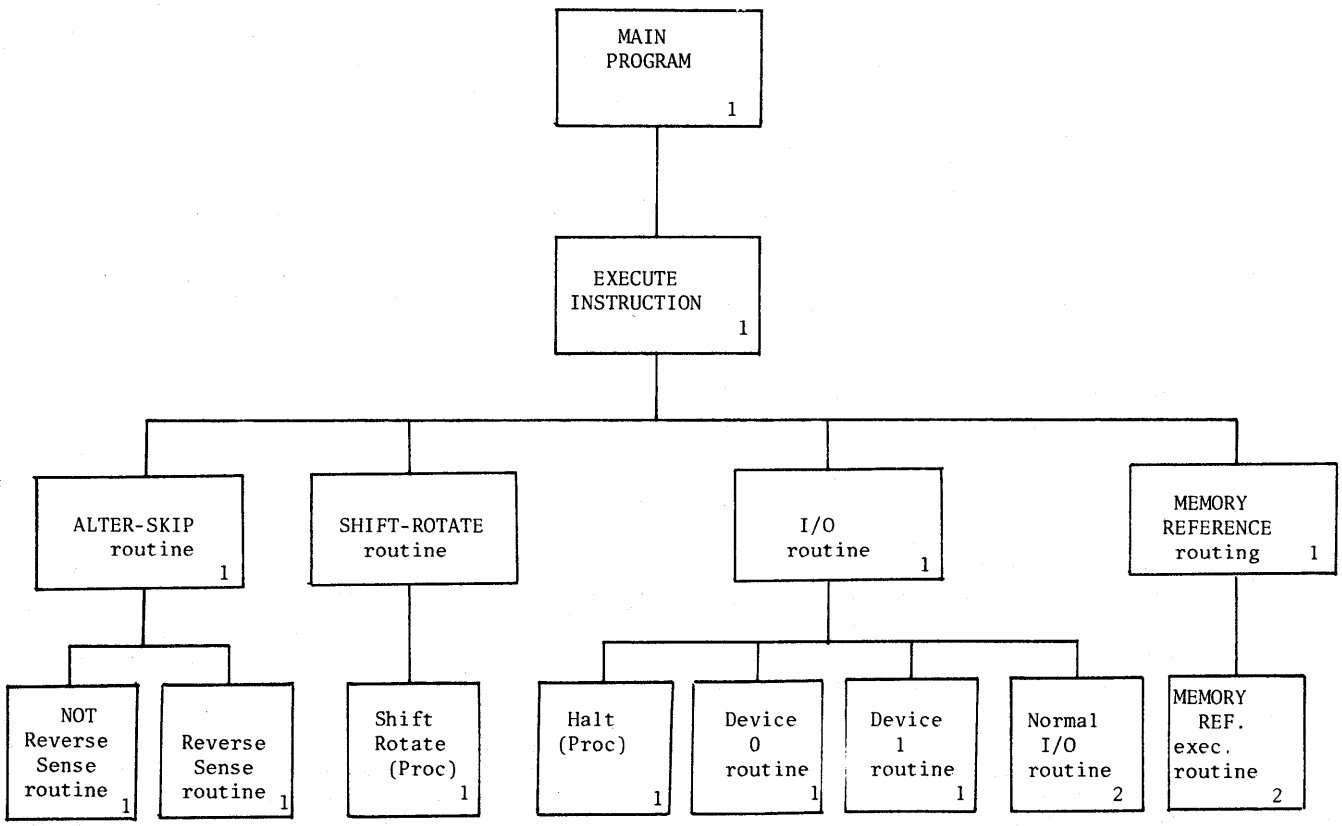

Figure 2—STRUM HP-2115 microprogram hierarchy (1 means one page in listing; 2 means 2 pages in listing)

errors would have been detected. This was indeed a gratifying result. To the best of our knowledge the STRUM emulator is the largest formally verified and tested program.

Summary and results

Although all the results were gratifying, we did not expect the STRUM version of the emulator to be faster than the TRANSLANG version. Many believe that high level language microprogramming is too inefficient to be useful.[3] Possibly an explanation for the unexpected result is the difference between "microprogramming-in-the-small" and "microprogramming-in-the-large." For small examples (10 to 20 microinstructions) it is feasible for a microprogrammer to spend hours optimizing microcode. However, with a 1000 instruction microprogram, it is extremely difficult to consistently convolute one's thinking to write efficient microcode. Also, high level languages and hierarchical structure make it easier to perform the global optimizations that may save more time or code than any instruction-by-instruction optimization. Perhaps the most exciting result was the success of the verification of microprogram. Although working with only a prototype system, we were able to verify a complete emulation of a real computer on a real microprogrammable computer. Moreover, although the exhaustive testing performed by the diagnostic programs did find four bugs in compiler, it did not reveal any errors in the STRUM emulation. Not only did the verification uncover program errors, it uncovered errors in the specification and assertions. No matter how practical testing may seem, it will not uncover errors in documentation (specification) nor in the comments (assertions). The microprogramming language STRUM proved to be very easy to use. The use of macros and good control structures resulted in a well-structured microprogram. Figure 2 shows the structure of the HP-2115 emulation. Each of the 14 boxes corresponds to a functional section of the emulator. Only two sections occupied more than one page of the listing and 12 of the 14 boxes are macros rather than procedures. STRUM object code and the original microassembly emulation contained many more jumps, labels and called statements than the STRUM source program (see Figure 3). The STRUM source program also contained fewer loops because the "handshaking" firmware used to access memory includes loops that are generated by the STRUM compiler.

HP-2115 EMULATIONS

	STRUM SOURCE	STRUM OBJECT CODE	ORIGINAL TRANSLANG EMULATION
LOOP'S	2	42	11
GO TO'S	0	144	144
LABELS	0	166	123
CALLS	16	37	104

Figure 3—Frequency of use of statements which make programs more complex

CONCLUSION

With respect to the microprogramming field we believe this experiment has demonstrated the validity of the use of each facet of the STRUM approach: use of a high-level microprogramming language, structured microprogramming, and formal microprogram verification. While we believe it is most effective to use all facets of the STRUM approach, the reader should be forewarned that the development of such system is a tremendous undertaking. The development of production versions of an efficient optimizing compiler and verification system is probably a five to ten man year effort. Hopefully tools will be created which will simplify this task.

Readers interested in a more detailed analysis should see References 4, 8, 11 and 12.

Code optimization techniques for micro-code compilers

by C. J. TAN
IBM T. J. Watson Research Center
Computer Sciences Department
Yorktown Heights, N.Y.

INTRODUCTION

With the ever expanding volume of system functions directly implemented in microcode and the growth of microprocessor applications, it has become necessary to design high level language compilers for these machines to achieve high programming productivity. However, because of the very low level architecture of many of these machines, compilers that generate efficient code for these machines have not been produced.

An optimizing compiler, called PL/MP, has been designed which is capable of supporting a variety of microprocessors such as the Motorola M6800 as well as machines like the IBM 370 model 145, and several microprocessors designed and used internally at IBM.[1] PL/MP uses a set of novel, machine dependent, and the more conventional high level, machine independent optimization techniques to achieve high object code quality. Experimental results have indicated that the machine dependent optimizations play a very significant role in enhancing the quality of the object code produced by the compiler. The most effective of these optimizations are

1. Register allocation: optimized binding of compiler source and temporary variables to fast machine registers.
2. Low level addressing code optimization: code motion and common expression elimination for addressing code.
3. Code consolidation: combining a set of scattered simple instructions into a single more complex instruction supported by the object machine.

Basic to all of these optimization techniques are the algorithms for obtaining information concerning the use of variables throughout the program. These data flow analysis algorithms,[2,4,5] are used throughout the compiler for both machine independent and machine dependent optimizations. In this paper we will describe the code consolidation process, the environment in which it is carried out, and its dependence upon global data flow analysis. Algorithms for register allocation, code motion and hoisting have been published elsewhere,[2,3,6] and will not be discussed in this paper.

THE PL/MP COMPILER

The PL/MP compiler accepts a high level language such as PL/I and generates efficient object code for a micro-machine. The compiling process takes the source code through several levels of internal text as shown in Figure 1.[1] Note that the front end of the compiler is concerned with the machine independent transformations and optimizations, while the back end is concerned with the machine dependent transformations. The interface between them is the A-text. Operands in A-text are generic, symbolic registers of arbitrary length.

Frequently, micro-machines have a large number of fast registers. Even though these registers often have inhomogeneous usage constraints, it is important to optimize the use of these resources. Hence an inherent design philosophy in PL/MP is to assume, early in the front end, a machine with an indefinite set of registers. Source level variables are loaded into the register space and kept there. Their values as well as those for the compiler generated temporaries are stored into memory only if absolutely necessary. The traffic between memory and register space is thus kept to a minimum.

The internal A-text[7] is basically a register transfer language. However, it is general enough to support a large class of high level languages and low level micro-machines. It consists of primitive and complex operations, which may or may not be all supported by a given object machine.

Operands in A-text are constants, labels or generic registers. All computational operations are register-to-register. The only operations addressing memory space are loads and stores. Thus all addressing code has been exposed at this level. A sample list of primitive and complex A-text units is shown below.

Note that the complex A-text operations, such as add indirect, load indirect, etc., can all be replaced by a sequence of equivalent primitive operations. For most ma-

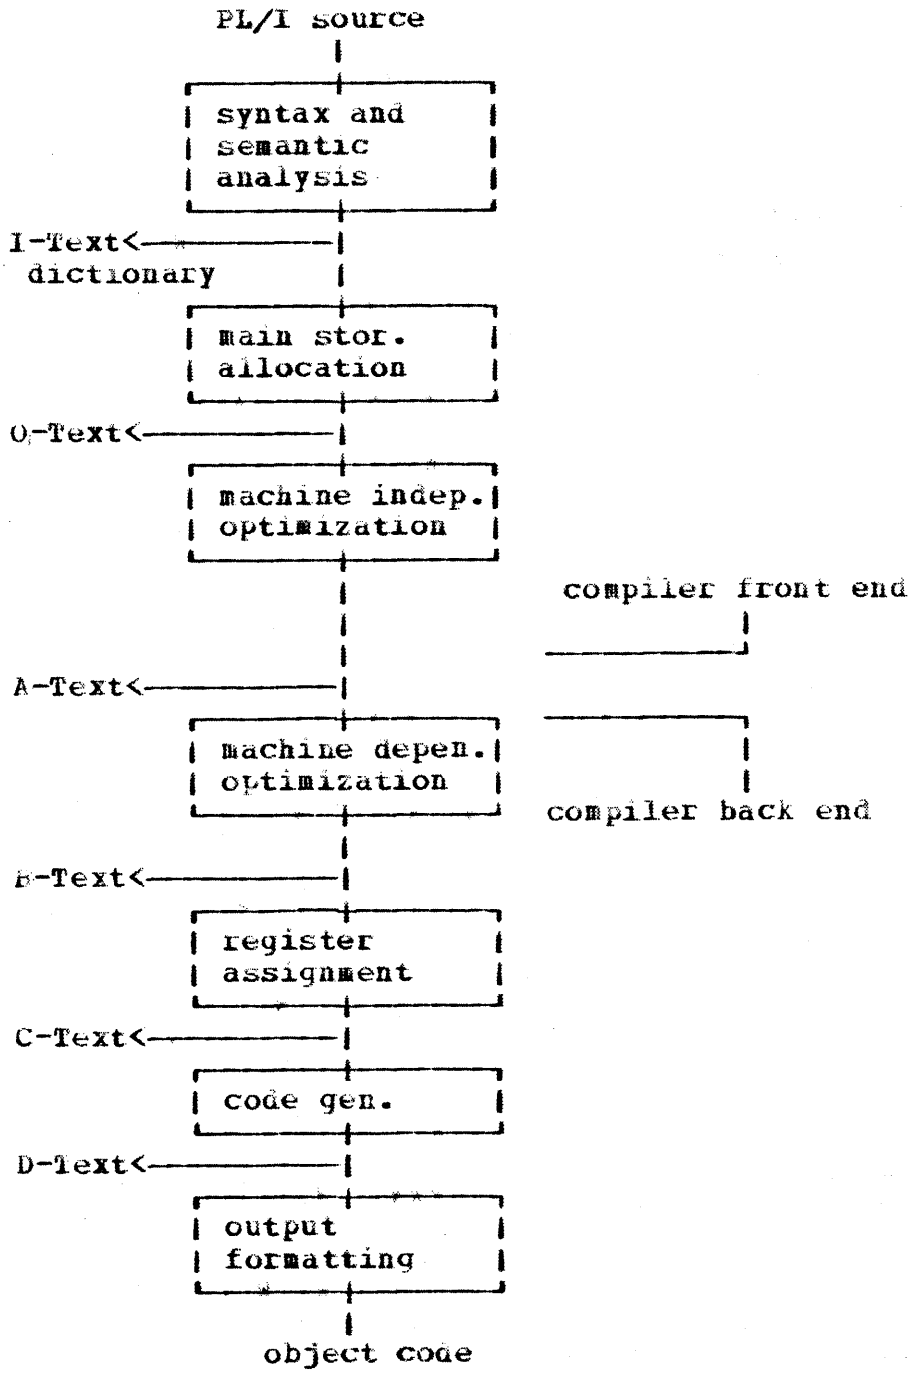

Figure 1—PL/MP structure

chines an add-indirect-with-offset, for instance, will be more cost effective than the equivalent set of primitive instructions. However, if the variables are used at several places in the program then under certain conditions many primitive addressing instructions can be optimized out by code motion or hoisting.[2]

THE ENVIRONMENT FOR CODE CONSOLIDATION

Assume that we have a machine with a set of general registers R_1 through R_{16} such that only R_1 through R_4 can be used as memory address registers. We further assume that the machine supports indirect addressing with and without

TABLE I.—Primitive and Complex A-text Operations

Operator	Operand	Comments
Primitive Operations		
ADD	R_1,R_2,R_3	add registers 2 and 3 and store result in 1
ADDC	R_1,R_2,R_3	add with carry
BLE	L,R_1,R_2	branch to L if R_1 less than or equal to R_2
LOAD	R_1,p	load into R_1 from location p
NOT	R_1,R_2	store into R_1 one's complement of R_2
CALL	L	call subroutine L
.		
.		
.		
Complex Operations		
LOADO	R_1,p,n	load with offset n[R_1<-MEM(p+n)]
LOADIO	R_1,R_2,n	load with offset indirect[R_1<-MEM((R_2)+n)]
LOADI	R_1,R_2	load indirect
ADDI	R_1,R_2,R_3	add indirect
ADDIM	R_1,p,k	add immediate[R_1<-p+constant k]
ADDIO	R_1,R_2,R_3,n	add indirect with offset

offsets. Thus, in this respect the target machine is at a higher semantic level than that of the primitive A-text.

Figure 2 shows a segment of an example in which we want to add a variable v to an array A of length 100 bytes. Both A and v are stored in a data area whose origin is at address p. The array's first element coincides with the area's origin and variable v is stored at an address 100 bytes beyond this origin. Thus, as shown in the figure, we first load into a register @a the address of array A. At program point p4 the array element is then loaded into register x through the load indirect instruction. The variable v is similarly loaded into register y, and it is added to x and stored in register z. Finally, the contents of z is stored back into the array, and the array element address @a is incremented by one to get to the next element. After iterating through the loop 100 times the program branches to point p7 where we proceed to other parts of the overall program. Figure 3 shows, in primitive A-text, the program after addressing code optimization by code commoning and moving the addressing code outside of the loop.

Notice that the sequence of code (p2,p3) which loads the variable v into the symbolic register y can be combined into the single instruction 'load indirect with offset', i.e.,

LOADIO y,@b,100 [R_y<-MEM((@b)+100)]

Once the above consolidation is performed the code sequence (p2,p3,p5) can be combined, so resulting, at p5, in a single add-indirect-with-offset instruction

ADDIO z,x,@b,100

Figure 4 shows the sample program after code consolidations at p2, p3, p5, and p7.

Notice that in the above consolidation process we have eliminated the register y containing the value of the variable v. Hence these consolidations are effective only because the symbolic register y, itself, is not referenced elsewhere in the program. Consider a slightly different situation, shown in Figure 5, where the register y is used at point p8. The subtract immediate instruction involves the register y and cannot be consolidated with the addressing code for y. This implies that we must keep the value of v in this registery.

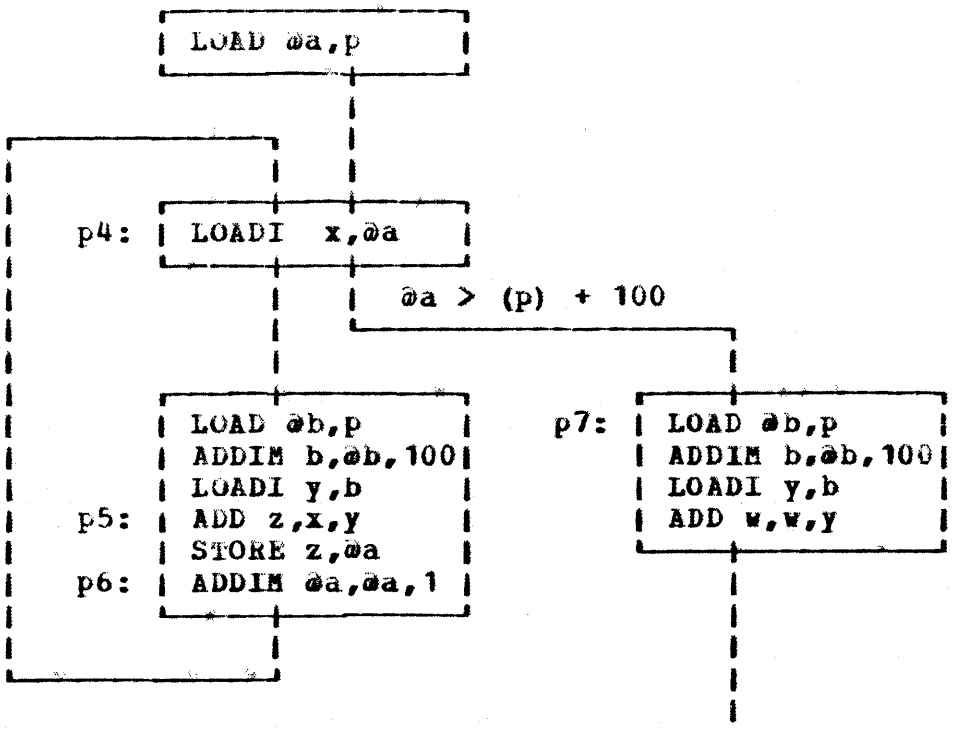

Figure 2—Sample program before addressing code optimization

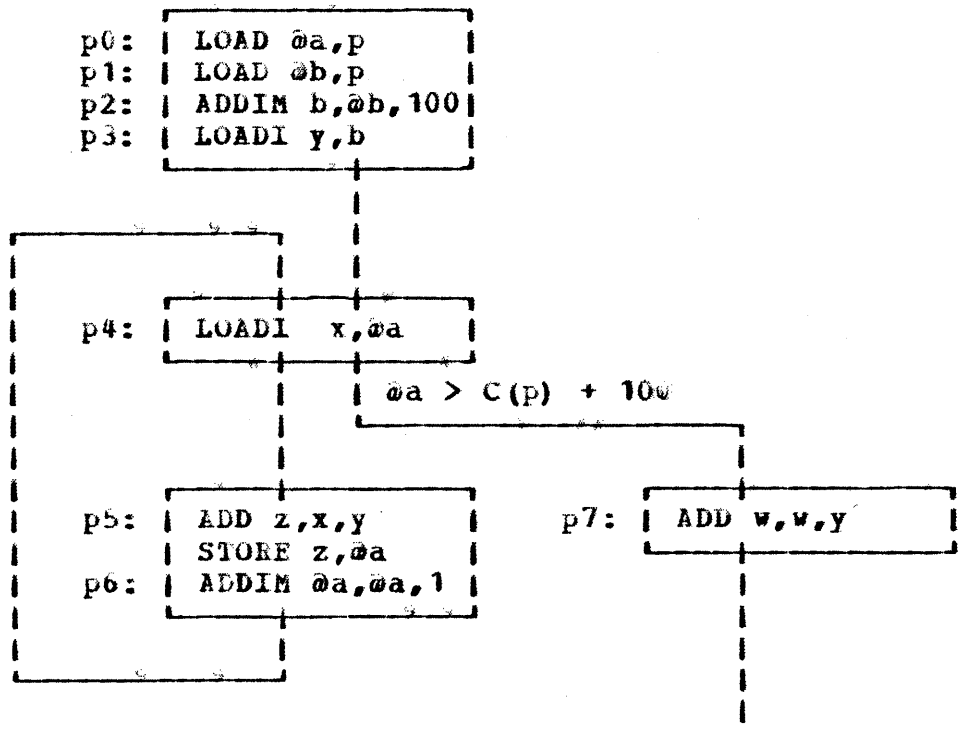

Figure 3—Sample program in A-text

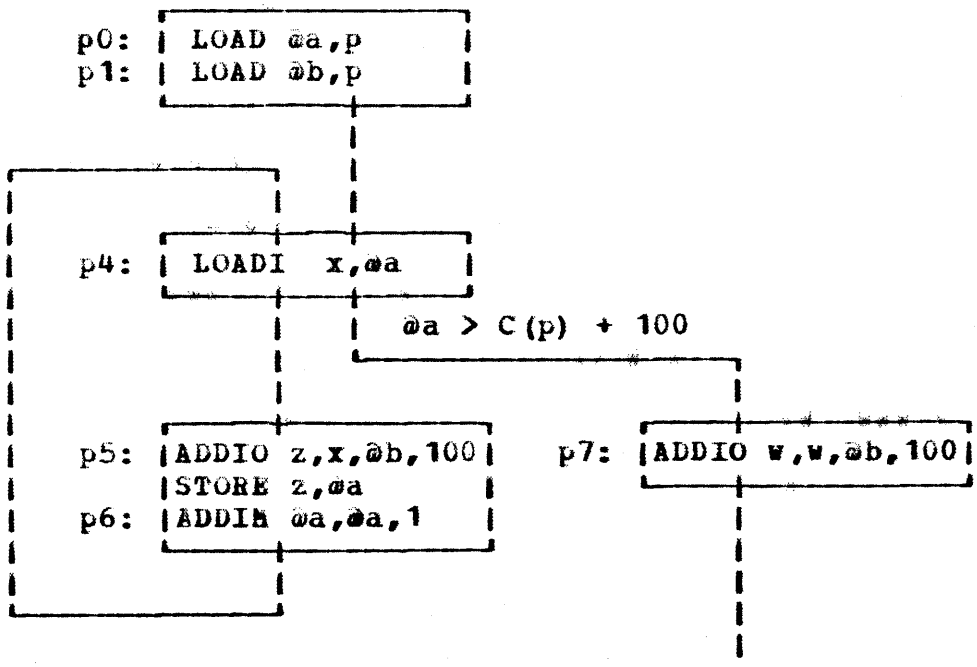

Figure 4—Sample program after code consolidation

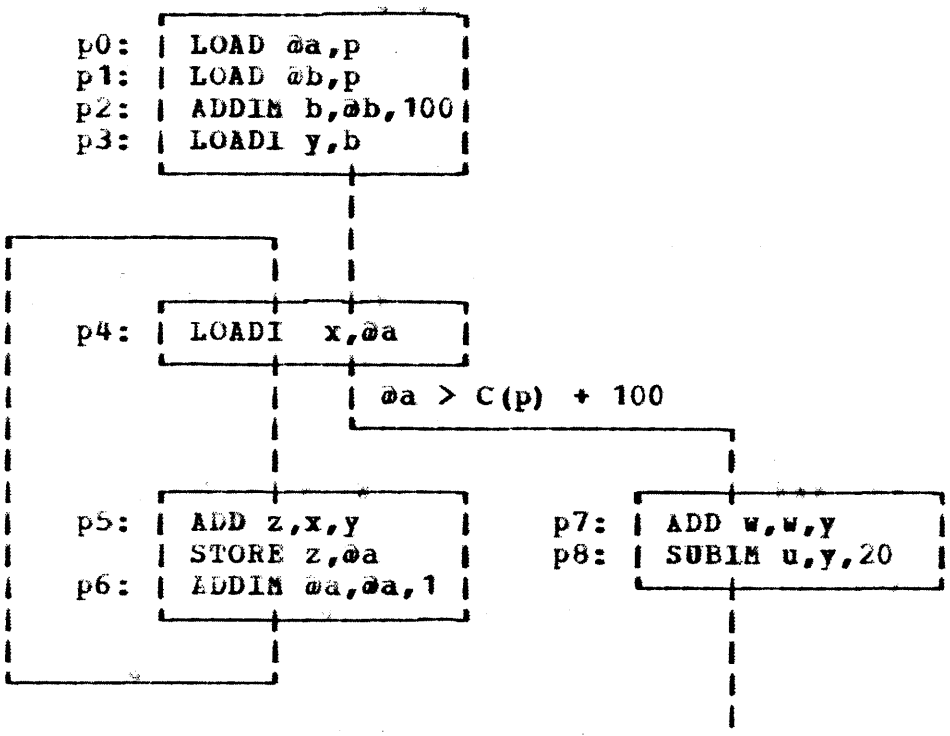

Figure 5—Sample program in A-text

Therefore, the instruction first consolidated from the sequence at (p2,p3), i.e.,

LOADIO y,b,100

cannot be deleted in the next consolidation iteration. Hence, for this case, replacing the code at p5 and p7 with the more complex instructions would actually increase the object code size.

It is clear from the above example that the decision to perform code consolidation can be made intelligently only after examining the global usages of the variables in question. It is not surprising, therefore, that the compiler strategy is to first generate A-text with only primitive instructions. The primitive A-text, with addressing code fully exposed, is then subjected to global code optimizations such as commoning and code motion. Finally, the possibility of code consolidation is explored to generate an equivalent A-text using complex instructions where advantageous.

CODE CONSOLIDATION ALGORITHM

We have seen, in the previous section, instances where scattered code sequences can be consolidated. We will now describe the procedure for performing code consolidations. The procedure involves: (1) recognizing a possible consolidation candidate, and (2) performing the actual consolidation if it is profitable to do so.

Code pattern classification

For many representative machines, the primitive A-text code patterns that correspond to complex instructions consist of an addressing code sequence followed by a computational operator, which we will call the terminal operator. Furthermore, it is often possible to find a set of terminal operators that share an identical addressing code sequence. Sequences having this commonality are grouped together to form a pattern class. For instance, the code sequence p2, p3 in Figure 3 is a member of the class that contains indirect-with-offset operations such as LOADIO, STOREIO, and so forth. Similarly, the sequence at p3, p5 is a member of the indirect operations class.

For many machines there exists a partial ordering among the code pattern classes. For example the code sequence (p2,p3,p5) corresponds to the complex operation ADDIO. Notice that the sequence (p2,p3) forms the complex operation LOADIO, and similarly (p3,p5) forms the operation ADDI. Hence the arith-indirect-with-offset(AIO) class is greater than the class containing LOADIO as well as the class containing ADDI.

The patterns for our fictitious machine may be classified as below, where the first instruction in the sequence is called the 'token', and the primitive instructions are divided into arithmetic, memory-register classes, and so forth.

From this classification we can derive the substitution rules for these patterns as shown in TABLE III.

TABLE II.—Pattern Classes

Class	Instructions	Token	Terminal code
C1	⟨mem-reg-ind-off⟩= {LOADIO,..}	ADDIM	⟨mem-reg-ind⟩= {LOADI,STOREI,..}
C2	⟨arith-ind⟩= {ADDI,SUBI,..}	LOADI	⟨arithmetic⟩= {ADD,SUB,..}
C3	⟨arith-ind-off⟩= {ADDIO,...}	LOADIO ADDIM	⟨arithmetic⟩= ⟨C2⟩
.			
.			
.			

That is, the instruction in C3 (e.g., ADDIO) replaces either the sequence consisting of LOADIO followed by the corresponding arithmetic instruction (e.g., ADD) or the sequence of ADDIM and a sequence from C2 (e.g., ADDI). Notice that all tokens are specific instructions either primitive or complex. Furthermore, a code sequence in a secondary pattern class, such as C3, can always be formed from sequences of a smaller class. It is obvious that if no code pattern in C1 or C2 can be profitably consolidated, for instance, then no pattern in C3 can be profitably consolidated either. Hence it suffices to perform consolidation starting from the smallest element in the partial ordering defined by the pattern classes.

Code sequence recognition

Before we can make a judicious consolidation decision based on relative costs, for a given A-text and a specific pattern class C, we must first find a valid code sequence in that class. This involves (1) finding a sequence of code satisfying the substitution rules, and (2) checking that the operands in this sequence satisfy certain data flow constraints.

Notice that, starting from the token of a code sequence, each operation defines a new symbolic register. This defined value, unaltered, must be used in the immediate successor operation in the sequence. Furthermore, the target variable at the token, called the substitution variable, must not be altered along the path containing the code sequence so that it can be substituted at the terminal operation.

Since the elements of a sequence may be scattered throughout the program, it is a difficult task to check for these conditions. Fortunately, very efficient global data flow techniques have been developed[5] that enable us to generate certain global relations among program variables. We will now introduce some of these data flow concepts, and then show how they can be used to find a valid code sequence for a given class.

TABLE III—Substitution Rules for Pattern Classes

⟨C3⟩::=LOADIO⟨Arith⟩|ADDIM⟨C2⟩
⟨C2⟩::=LOADI⟨Arith⟩
⟨C1⟩::=ADDIM⟨Mem-reg-ind⟩

Let (v,p) denote a variable v defined at program point p. We say (v,p) *reaches* point q if there is a path from p to q such that v is not redefined along that path. If q is a program point with two or more predecessor statements then we say (v,p) is *available* at q if (v,p) reaches q through every one of its predecessor statements. Availability implies that if v is also defined at another point, say r, then (v,r) cannot also *reach* q. Since the reach and availability information can be determined efficiently for any program, we can state the following

Variable Flow Condition: if p_i and p_j are two consecutive code points in a code sequence then the variable defined at p_i, as well as the substitution variable for the sequence, must be available at p_j.

We have already mentioned that every substitution sequence starts with a known token. Hence having found a token for a given class we must start scanning the text to find the next code point in the sequence that satisfies the variable flow condition. The following constraints allow us to search through the program rather efficiently. First we will introduce two additional data flow concepts.

The first concept we need is the so called *variable liveness*. If a variable v defined at p reaches a point q and is such that there is a subsequent use of (v,p) in a path starting at q then we say (v,p) is *live* at q, otherwise we say (v,p) is *dead* at q. Thus we need not search along a path where the variable being searched is either dead or not available.

The second concept we need is that of *node dominance*. (For the following discussions we use the term node to denote a block of straight line code in a program. Hence p0,p1,p2,p3 in Figure 5 constitute a node. Similarly, p5,p6 is a node.) We say a node d in a program flow graph *dominates* another node n if every path from the program entry node to node n goes through node d. For a given program a dominator tree can be obtained such that there is an edge connecting nodes d and n if and only if d dominates n. For the program in Figure 3 the dominator tree is simply the graph minus the loop edge from p6 to p4.

Notice that if $(p_1,p_2,p_3, \ldots ,p_i)$ is a substitution sequence then in order to replace this sequence at point p_i by a more complex instruction, the node containing p_1 must dominate that containing p_2, and so forth. Therefore, starting from the token at p_1 we need only follow the path defined by the dominator tree. Fortunately, for any flow graph a dominator tree can be obtained very efficiently as a part of the general data flow analysis.[2,5]

The overall algorithm

Once we have found a valid substitution sequence the next question is whether or not it is advantageous to actually consolidate the code. Notice that if $(p_1, p_2, \ldots, p_l)$ is a substitution sequence, then we can always replace the operation at p_l by the complex operation that is logically equivalent to the function of the sequence. However, since the replacement operation is usually more complex than the original operation at p_l, we presume it is advantageous to consolidate only if all the code at the other points in the sequence can be deleted. This is possible only if the intermediate variables are all used by terminal operations of the same class and found to be valid for consolidation. Otherwise, we cannot delete them, and hence there may be no advantage in replacing the original operation at p_l by a more complex one.

Starting with the token we search for all possible substitution sequences of the given class. If a code sequence is found to violate either the variable flow condition, or one of the intermediate variables is used in a statement not allowed by the sequence substitution rules, then the intermediate addressing code cannot be deleted. Hence no code consolidation will take place and the process terminates.

Note that if a code pattern is greater than another pattern in the pattern class ordering, as is the case with C3>C2 and C3>C1 in our previous example, then in searching for a sequence for C3 we must encounter a consolidated text unit in either class C1 or C2. Otherwise, since we always start the consolidation process for the smaller class first, this implies that no code can be advantageously consolidated for the patterns in C1 and C2. Hence no code pattern in class C3 can be consolidated either. In fact, the substitution rules for C3, as shown in Table III, clearly indicate that a valid sequence in that class must contain either a C1 or a C2 operation.

The above discussion can be summarized by the following:

Algorithm C

Input: Program expressed in A-text, program flow graph, variable liveness, availability, and dominator tree, pattern classes and substitution roles.

Output: Consolidated A-text.

Method:

1. Starting from the smallest pattern class C that has not been previously processed, perform the following steps. If no unprocessed class is left then terminate.
2. If consolidation failed for all lesser classes of C then go to step 1, otherwise proceed to step 3.
3. Starting from the root of the dominator tree, look for a previously unprocessed token of the given class. If a token is found then proceed to step 4, otherwise go to step 1.
4. Search for substitution sequences in class C along the paths defined by the dominator tree.
5. If no substitution sequence is found or if the variable flow condition is violated then return to step 1.
6. If a use of an intermediate variable is made by an operation not part of a code sequence then go to step 1.
7. Replace terminal operations found by appropriate operations in class C, and delete the intermediate addressing code. Return to step 3.

CONCLUSIONS

We have discussed some of the techniques used for machine dependent code optimizations for a micro-program compiler. One of these techniques, namely code consolidation, has been discussed in detail. It should be obvious that the compile-time efficiency of these optimizations is heavily dependent upon the efficiency of the global data flow analysis package used by the compiler.

The code consolidation process, as described, may seem to be rather complex. However, for typical real machines, the number of pattern classes turns out to be rather small, and the substitution sequence length is also usually short. Hence with the use of a high-powered data flow package, the algorithm indeed can produce very efficient code with reasonable computation.

Experiments conducted for one of the commercially available micro-processors, namely the M6800, have shown that code consolidation together with addressing code optimization have contributed a 30-40 percent improvement of the object code produced by the PL/MP compiler.

ACKNOWLEDGMENT

It is a great pleasure to thank Hans Schlaeppi, manager of the PL/MP compiler development group, for providing the environment under which the research reported in this paper was carried out. Thanks are also due to many of my colleagues in the compiler group, without whose assistance this work would have been impossible.

Microprogram verification considered necessary

by W. C. CARTER, W. H. JOYNER, JR. and D. BRAND
IBM Thomas J. Watson Research Center
Yorktown Heights, New York

INTRODUCTION

Microprograms have been around for some time now, and so have errors in them. Therefore techniques have been developed for finding the errors. We review these existing techniques and explain why we are working on a new one. The main advantage of our method is its ability not only to detect errors, but (if there are no errors) to give a formal proof that the microprogram does perform according to specifications. Using our approach we are working on actual machines and actual microcode. We discuss our experience with such proofs of correctness and what kinds of errors we are finding. The reader will also find a comparison of problems in microprogramming with problems of general software reliability.

WHY IS MICROPROGRAM VERIFICATION CONSIDERED NECESSARY?

"Microprogramming Trend Considered Dangerous" is the title of a letter in the ACM Forum.[1] The letter continues, "Thus the development and maintenance process for microcode will increasingly resemble that of systems and applications programs. And therein lies mortal danger." This paper will briefly trace the history of microprogramming and microprogramming support systems. As microprogramming has developed, better support systems have evolved so that microprogramming has been a useful tool. Now, with the widespread development of microprocessors on a chip, and use of read/write control stores, new ideas for support systems must be developed. This paper then describes one such idea, symbolic simulation for microprogram verification, and indicates its necessity. The goal of this symbolic simulation of microprograms is to find all errors in the microcode (and correct them) while proving that the final code is correct. To do this, the Language for Symbolic Simulation (LSS) is used to prepare an APL-like executable description of the architecture (or program) specifications. The same language is used to prepare a description of the microprocessor. Then it is proved mathematically that the microprocessor when controlled by the actual microcode simulates the specifications, using symbols for data instead of bits. This language and procedures are described, together with an automated set of program aids, the Microprogram Certification System (MCS). Some results are given of applying these techniques and MCS to real programs and computers. These results indicate that microprogram verification by symbolic simulation is feasible, and micro code maintenance problems indicate that verification is necessary.

WHAT ARE PREVIOUS TECHNIQUES?

When Wilkes first proposed microprogramming in 1953 and built the EDSAC II,[2] computers were built entirely of discrete components. The store holding the microprogram was also built of discrete components and the microprogram was debugged like the rest of the computer—by graduate students. When hardware components were available so that microprograms became commercially feasible (in the late 1950's), read-only storage was preferred because of its speed and low cost.[3,4] Fixing errors in the microprogram then became slow and awkward, so special simulators were written to help debugging. Unfortunately every data flow or control flow change necessitated changes in both the simulation program and the microcode. A race developed—would the simulator or the computer be running first?

However, computers controlled by microprograms have many convenient features. An architecture for a family of computers is desirable, but needs a complex instruction set for the top of the line and for ease of programming.[5] A rich instruction set costs very little more than a spartan set, if the computer is microprogrammed.[6] Rewriting application programs for new machines is expensive. But emulation of the previous computer instruction set by a new computer using the facilities of microprogramming allows the old program to run.[7] Maintenance of many distinct computers in a family is difficult, since the hardware for each computer is different. Again, using a microprogram allowed special maintenance techniques—microdiagnostics, scan-in, scan-out, log-out, instruction retry, etc. to be designed.[8]

This microprogram complexity doomed the individually written simulator, and more complex design automation systems were written. One, the Controls Automation System,[9] was written for the S/360 design effort. The computer hardware at the register transfer level was described by a Fortran-like programming language, including bit string handling. Design changes meant only a recompilation to produce an input for the simulator. The microprogram was written

at an assembly level, but with mnemonics for the microinstructions chosen by the design engineers. The assembled input to the simulator was kept in a program file, in which any single subroutine could be changed. The event driven simulator could be instructed to set up desired starting and ending for the simulation, to select the desired microcode for simulation, to produce snapshots of the registers at variable breakpoints, to dump in emergencies, to trace with or without timing checking, etc. This and similar systems[10] were a definite advance, but problems remained.

WHAT WAS WRONG WITH THEM?

Another litany on the difficulties of program testing in the middle 1960's is hardly needed. Anyone who has written a program to be used extensively by other people knows the problems. "Testing detects the presence of bugs, but never their absence"[11] is the well-known refrain. "Enough" test cases can never be generated in our limited time on earth. How is a good selection to be made? The coverage depends upon the skill and dedication of the individual who wrote the microprogram. But even if all paths are traversed by test cases, faults which are data dependent can still remain. Moreover, simulation in any guise is slow and expensive.

Thus the systems did reach the field with faults in their control. Diagnosis of the computers themselves was difficult. Most faults occurred many levels deep—a particular combination of instructions and data turned them into observable errors. The best routines for exposing these faults were the higher level language compilers. (The diagnostics run, but the compiler doesn't.) Therefore capturing the environment so the fault could be discovered and fixed was difficult. A knowledge of many different design levels became necessary—from circuits (were race conditions triggered?) to logic design (did that decoder work correctly?) to microcode (was that transfer necessary?) to machine code (what series of instructions was traversed?) to the compiler (what statement is being compiled?). The well-known technique of trying a fix to see how it worked could not be applied to microcode in read only storage.

WHAT HAPPENED?

Human ingenuity and perseverance triumphed again. Microprogramming was—and is—a great success. The computers worked well, and the new facilities made available more answers per dollar spent.

Hardware test support equipment[12] came into use—expensive but necessary. Special computers, equipped with read/write control stores were built. Facilities for rapidly changing the control store contents were added, and fixes were performed in minutes. Changes could now be tried rapidly, and if they seemed to work all system and test programs could be run against the microprogram change before final commitment. Also, automatic data test generators were built, and millions of pseudo-random data patterns could be processed.

Now the bandwagon effect began and is still continuing. SIGMICRO (ACM) and the Technical Committee on Microprogramming (IEEE CS) were formed and began to hold their yearly workshops, presenting new ideas. If microprogramming is good for central processors it must be good for I/O equipment.[13] Look at all the new functions which can be performed! Need reliability/availability? Add special progressive scan test routines.[14] Need help with communications? Provide independent computing power.[15] Does the operating system take too much time and space? Put part of it in microcode.[16,17] Would you like a slightly different computer, or direct execution of higher level languages? Just provide the correct microcode.[18] Does your terminal take too much of your CPU time? Provide an intelligent terminal. All of these advances were fostered by improving hardware technology which provided more and more logic facilities in less and less space. Now (in the 1970's) we have various types of microprocessors on a chip—CPU's of various types,[19] I/O processors,[20] standard busses, and everyone (almost) can build his own distributed system.

Help to do this is provided in abundance. Do you think that the use of higher level languages (Pascal, Algol, Fortran, etc.) will help your programming problems? Just provide the correct environment and the standard language can be used. Do you think that structured programming will help? Courses are readily available. Are you using your system for control? You can buy hardware test equipment which will simulate the environment in which your micro will run.[12] Many advances in program testing are now available. Do you want a system which will analyze your program, and produce test inputs so that all paths will be traced at least once, and all instructions executed (if possible)? Such systems are available.[21] Would you like to learn more about selecting test cases, devising adequate test procedures, applying support systems to your own problems? Help is available.

So what's the problem? Once again in our enthusiasm we are building faster and faster—and reliability is falling behind. Letters to the editor such as Lehman's "Microprogramming Trend Considered Harmful"[1] point out the dangers in this. All of the techniques listed so far test specific cases—and the untested cases can still be erroneous. Microprograms are hidden from all but the designer. Should we explain to the checker at the local supermarket that the buttons on the cash register send data to a computer which then uses this information to get a "correct" answer? Most of the time everything works correctly—but when errors occur rectifying them is expensive—and fixing the system is even more expensive. (Have you bought a very cheap pocket calculator recently?)

WHAT ELSE IS AVAILABLE?

The problems that microcode poses are also posed by ordinary programming systems when such systems are written to be used extensively by people distinct from the originators. Ten years ago a formal, mathematically oriented approach, called program verification, was formulated.[22,23] In this approach a series of assertions, written in first order

predicate calculus, are provided for the program input, output, and various intermediate points in the program. In particular every loop must satisfy an assertion called a "loop invariant" specified by the user. Devising these invariant assertions is not easy, even though many papers have been written, each proposing a procedure which is effective in various special cases.[24] Various simple program modules (written in high level languages) have been proved correct, and more informal proofs have been given for larger examples.[25] However, as with all proofs, the proofs are only as good as the hypotheses and the number of people who have actively checked them.[26] A difficulty with the pure form of this standard approach is that by starting from an externally given program text it necessarily loses sight of the program's genetic origins. This deficiency has been recognized;[27,28] and proposals made to cure it. In general the idea has been to recreate, or use, a formal expression of the generating steps by which programmers construct programs in the first place. These proposals are still in the research stage.

Another approach has been studied by King[29] and Clarke[30] and experimental program aids have been constructed. They use as a major part of program validation the execution of the parts of the program between assertions using symbols, not the actual data values. The difficulty here (which is one of the difficulties in automatic program verification also) is defining and implementing the execution semantics for the symbols and the operators used in the programming language.

Symbolic execution can be seen to have several deficiencies. Symbol manipulation is costly and slow. Again the question of coverage arises. The data paths are represented symbolically, but which paths can be covered? Mostly main lines? What is the total cost? Will all errors be found? In Howden's experiments[31] neither ordinary good testing techniques nor symbolic execution found all known errors in a Fortran program. In addition there are the real world problems of the actual computer representation of data, with overflow, interrupts, etc. Another difficulty is that symbolic execution also ignores the knowledge that the programmer has about the specifications, and it does not check the specifications. Recent studies have shown that wrong or inadequate specifications account for 50 percent of program errors, and these errors are the most expensive to find.[32]

WHY DO THESE TECHNIQUES HAVE PROMISE FOR VERIFYING MICROCODE?

The techniques of program verification have been applied for the most part to higher level language programs and have met with limited success. Fully automatic methods are almost nonexistent—often a fairly detailed human analysis of the data structures and control structures used is necessary before automated aids can be applied. Also, such proof of necessity deals with some abstraction of what actually happens in a computer when the compiled code produced from these programs is executed. Errors can therefore result because the actual running program is not the program which was verified. Why should program verification techniques have any more promise when applied to microprograms, especially to actual microcoded implementations, than they have in other applications?

As is described in the next section, our approach requires a complete formal description of the computer on which the microcode is to be run, and the actual microcode—the array of bit patterns—is used with a symbolic interpreter. Though this makes necessary a more complex description, because overflow, invalid array indexing, etc. must all be explicitly described, errors which would go undetected if these factors were ignored can be detected.

The use of a single data structure—a two-dimensional array of bits—simplifies both the symbolic execution and the specification of the Floyd-type assertions or their counterparts. The registers, memory, I/O channels, switches, etc. of the computer are all represented as arrays. Also, the operations on these arrays are limited to storing and retrieving strings of bits addressed by indices, concatenation, reshaping to other dimensions, and certain arithmetic and logical operations. Problems with program verification often arise when more complicated data structures are involved; if there are such structures in a microprogram, they are explicitly implemented in terms of the more primitive notions, and verification takes place over that more restricted domain.

The fact that microprogrammers are not constrained to write in a "structured" way (and often do not in order to increase time or space efficiency) probably increases the difficulty of formulating and placing correctness assertions in microcode. However, once that is done, the control structure of a machine description which interprets microcode is simple, and symbolic execution can proceed in a straightforward manner.

The way in which we use symbolic execution to prove microcode correct is another factor which improves our chances for success. As described in the next section, we do not place assertions at various points in the microcode which relate values of machine components to previous values, or describe a state (e.g., sorted, permuted, etc.) which the computer must satisfy. Rather, we equate the machine components with components of a higher level description, a description of the architectural specifications which the microcode is supposed to implement. In this way we can partially avoid the necessity for quantifiers, single-program inductive invariants, and references to initial or previous values of machine components.[33]

The most compelling argument for the feasibility of microprogram certification is our experience. We have designed and implemented an automated system to aid in verifying microprograms, and have used it to detect and correct errors in "real" code.

WHAT ARE THE DIFFERENCES BETWEEN VERIFYING MICROCODE AND VERIFYING HIGHER LEVEL PROGRAMS?

A microprogram is just a special kind of program. The main difference between firmware and software is in the semantics of the programming language and the emphasis on the speed of execution for firmware. Microcode is inter-

preted by hardware, whereas higher level programs can easily have their semantics defined in terms of another program—an interpreter. This makes a difference because a verifier must be given the semantics of the programming language. Thus for verifying microcode it is necessary to describe a piece of hardware as an interpreter. An interpreter for a higher level programming language presents an idealized view of the environment (this is the whole idea of higher level languages). The lower we go towards the physical realities the more we have to face to them; here are some of the realities we are faced with.

Hardware has the inherent capability of operating in parallel. Parallelism in software is certainly very common, but software can use the cushions provided by the lower layers of software. For example, memory interlocks prevent two processes from accessing a shared variable at the same time. Nobody will provide such interlocks for hardware, where shared variables are physical wires; therefore we have to watch for the possibility of races. Cooperating processes in software can take advantage of synchronizing primitives, which shield the software designer from the idiosyncrasies of hardware. No such shield is available for a microprogram, which is the shield for others. The microcode itself must handle such things as I/O, interrupts because of external causes, program-caused overflows, and other exceptions, which are "hidden" from the high level language programmer and which most program verification techniques ignore.

At the specification level, there are parts of the description which are left intentionally ambiguous, so that different models of a simple architecture (such as the 360 series) may implement them in different ways. In verifying a particular implementation, we must handle this ambiguity in such a way that it does not "lock in" the specification to a particular implementation technique.

On the other hand there are aspects of microprogramming, which make verification easier. Microprograms operate on one fixed data structure—bit vectors. Further, these operations are not very sophisticated, in the sense that the bit vectors are not supposed to represent notions very different from themselves (at least as far as the architecture is concerned)—a bit vector typically represents a number. Thus the statement of correctness is usually close to what the microcode does, but the results are expressed in terms of numbers rather than bits.

All these characteristics of microprograms make them good subjects of mechanical verification. They are so concerned with small details that it is difficult for people to examine them carefully. At the same time they are not sufficiently intellectually challenging for a person. But these are exactly the characteristics which machines find easy to handle, and therefore computers have a better chance in competition with people when verifying microcode than when verifying higher level programs.

HOW SHOULD MICROCODE BE VERIFIED?

Testing techniques are based on the ability to recognize an erroneous procedure. Verification proves that a program written at a level above machine code is correct. What is needed is a system which will find all errors in a given program as it runs on a computer in a reasonable length of time. To do this three capabilities are necessary: formal specifications which are natural and easy to produce; coverage determination, i.e., the ability to recognize a correct procedure; and the ability to execute the code as existing in the microprocessor so that analysis of the results will determine the fault.

Figure 1

To formalize specifications we model all facets of system operation using the APL-like Language for Symbolic Simulation (LSS).[34] This description is an abstract machine whose state consists of a facility vector describing the machine (or storage) components and a control structure which permits parallel asynchronous operation. The facility vector components, two-dimensional arrays of bits, are described by dimension statements, as in Figure 1. These facilities are an 8 bit wide Main Storage with 2^{24} locations, sixteen 32 bit General Purpose Registers and a 33 bit Accumulator. Operations upon the facility vector are specified by a library of macro routines written using APL-like operators, as in Figure 2.

This macro models a S/370 add register instruction. The 2's complement addition is modeled by decoding ($\perp$) the contents of the registers from bit strings to integers, adding the integers, then encoding ($\top$) the result in 33 bits ($(33\rho 2)$). This value is assigned (:=) to a. SETCOND is called, which sets the S/370 condition code. The low order 32 bits of a (bits 1 to 32, 0 origin) are put in GPR[R1;].

The macro SETCOND is shown in Figure 3. SETCOND shows the conditional structure of the LSS macros. OVERFLO is a predicate from the predicate library. If it is true, then bits 34 and 35 of the Program Status Word are both set to 1. Otherwise, if the result is zero, the condition code is $\langle 0\ 0\rangle$, or positive $\langle 1\ 0\rangle$, or finally negative $\langle 0\ 1\rangle$.

The last example is OVERFLO, which shows some of the logic operations available. Here, z is the 32-bit result of adding the 32-bit quantities X and Y (Figure 4).

The LSS language is carefully defined in Reference 34. Only two kinds of objects are necessary for LSS, integers and two dimensional matrices of bits (truth values are one bit matrices).

Modeling computing systems by describing their state vectors and the state transformations is intuitively plausible. LSS specifications are executable, i.e. given a state vector

```
ADDREG (R1, R2)=
      a:=(33,ρ2)⊤(2⊥GPR[R1;])+2⊥GPR[R2;]
      SETCOND (a,GPR[R1;],GPR[R2;])
      GPR[R1;]:=a[1+ι32]
```

Figure 2

```
SETCOND(X,Y,Z)=
    OVERFLO(X,Y,Z)→PSW[34+ι2]:=⟨1 1⟩
    ELSE          →X[1]=0→
                      (X=32ρ0)→PSW[34+ι2]:=⟨0 0⟩
                      ELSE→PSW[34+ι2]:=⟨1 0⟩
                  →X[1]=1→PSW[34+ι2]:=⟨0 1⟩
```

Figure 3

value as input, a symbolic output state vector value may be obtained by symbolic execution. A symbolic value is an expression built from the operators of the LSS language and symbols representing the initial values of the variables, after appropriate simplification. For example, if A has the value ⟨11110000⟩ and B has a symbolic value $B, then the assignment statement A:=A&B becomes A:=⟨11110000⟩&$B; A is given the new value $B[4],⟨0000⟩ (the "," here is catenation). The adequacy of the system model may be tested by executing cases of special interest. The model acts as a special purpose machine, i.e., it carries out one set of specifications.

LSS is also used to describe the hardware attributes of the computer on which the specified architecture or program is to be implemented by code. This implementation description acts like a general purpose computer. When the assembled code to be verified (a matrix of bits) is inserted in memory, and a set of symbolic inputs is given, symbolic execution and simplification will determine the outputs.

To determine if the desired action is identical to the action of the code, we use symbolic simulation. Heuristically speaking, the execution of the machine description and actual code simulate the execution of the specifications if everything the specifications can do the machine and code can do, though possibly in a different way. Because the two facility vectors (specification and implementation) may have different components, to carry out the simulation it is first necessary to specify a set of relations between them. These simulation relation components specify, for selected pairs of specification and implementation control points, relations between the state vector quantities which must hold at these points. See Reference 35 for a complete and formal description.

To carry out the verification a symbolic execution tree, or proof tree, must be constructed.[36] An automated, interactive system, MCS (Microprogram Certification System), has been designed and implemented to aid in this verification (see Figure 5). A node, or goal, in the tree represents a class of states of the system at one point in time. In general, a node will consist of

(a) two state vectors—an assignment of symbolic values to facility variables;
(b) two control points—positions on the control trees;
(c) a predicate list—a list of conditions that the initial values must satisfy in order that the states represented by this node can be reached.

```
OVERFLO(X,Y,Z)=(X[0]≠X[1])&(Y[0]=Z[0])
```

Figure 4

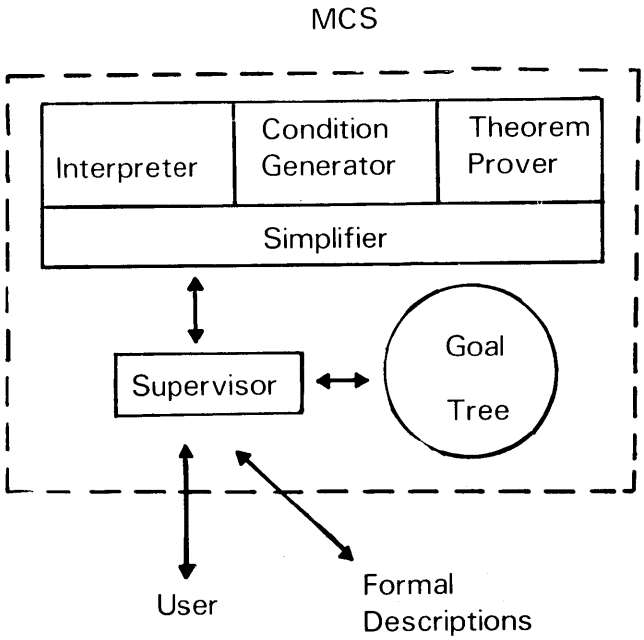

Figure 5—Parts of the microprogram certification system

The root of the tree (which represents the entire problem of proving the simulation) has a son, called a simulation relation node, for each of the simulation relation components. The state vector, control, and predicate lists of these nodes correspond to points at which the specified relations must hold. The values of the elements of the facility vectors in these simulation relation nodes satisfy the relationships necessary so that the implemented machine, under the control of the program, will simulate the specification machine. A branch in the proof tree represents a computation path. The leaves of the proof tree represent all possible final states.

The following process is used to build the proof tree. First, the simulation relation nodes are generated. In these nodes the most general symbolic values such that the conditions of the corresponding simulation relation component hold are given to the variables of the state vector. Any conditions which cannot be asserted in this way are placed on the predicate list. The next step is to run each abstract machine, performing symbolic computation until another corresponding pair of control points in the simulation relation is reached.

One machine is arbitrarily chosen to be run first. At this initial point variables have as values either symbolic constants (symbols representing unknown but fixed values) or values determined from the simulation relation. Control proceeds as in normal execution. When symbolic constants are encountered in expressions being computed in assignment statements, the value assigned is a simplified combination involving operators and symbolic constants.

When symbolic constants occur in predicates evaluated to determine possible branches, a single flow of control may not be able to be determined. The predicate may evaluate to a Boolean expression involving symbolic constants, such

as "$X=0," which cannot be evaluated to "true" or "false." In such a case all possible logically independent results of evaluating the predicate must be considered; in the previous case $X=0 and $X≠0. The program doing the symbolic evaluation will generate a node (subgoal) for each independent result, add a predicate expressing the truth of the result to the predicate list, and simplify the result. In the case being considered, two subgoals will be generated. For $X=0, 0 will be substituted everywhere for $X; for $X≠0, this predicate will be put on the predicate list. The user then chooses the path he wishes to follow (the program is interactive) and begins again. The remaining paths will be traversed later. If the predicate involving symbolic constants evaluates to true or false, no path branching occurs.

After generating a series of nodes and branches, the control corresponding to a simulation relation component is reached. Then the other abstract machine is run until a simulation control point for that level is reached.

Now the system verifies that the pair of control points reached defines the control component of a simulation relation node. The values of the two facility vectors are substituted into the simulation conditions of this component, and a goal is generated for each simulation condition. Using the predicate list, a proof is attempted for each simulation condition. The process is repeated for each node of the tree which is not a final node. In the process a complete goal tree is formed.

Newly created expressions are simplified at once to prevent the propagation of unsimplified forms. At present MCS has over 400 rules for the simplification of APL and logical expressions. If a theorem simplifies to "true," then the goal is achieved (and theorems are the only goals generated in proving simulation that can be achieved directly, without generation of subgoals). If the theorem cannot be proved by the theorem prover, its simplified form is the theorem of the pattern in a single generated subgoal so that analysis by the user is facilitated. It may occur that a theorem cannot be proved, or that a pair of stopping points not corresponding to a simulation relation component is reached, or that a stopping point is not reached. Then an error must be sought in the code or in one of the descriptions. In addition the occurrence of an unexplained branch will signal the presence of an error.[37]

In MCS, theorem proving, which is simplification of APL-like expressions, occurs at a number of places and forms an important part of the system.

This general process becomes more complicated when the asynchronous parallel operation of the system must be considered. Our method of modelling parallelism involves considering the processes as composed of K≥2 separate subprocesses running sequentially, but interleaving arbitrarily. No notion of time is built in. How the subprocesses interleave is immaterial as long as no shared variables are used, since these subprocesses are and remain independent. When shared variables are used, we have to consider which subprocesses can be executed between two references made by a single subprocess to a shared variable. We also must consider how the shared variables and the subprocesses interrelate in the process execution. To model this we provide LSS operators to express when interleaving may occur; when interleaving is not specified a subprocess runs without interruption.

A solution has been proposed by Brand and Joyner to consider the K separate subprocesses as each running with its own control tree and to add two statements to LSS, DELAY and WAIT, so that the shared variables can be correctly handled during the arbitrary interleaving of the subprocesses.[38]

EXPERIENCE USING SYMBOLIC SIMULATION

The MCS is now being applied to a version of a real computer, the NASA Standard Spaceborn Computer-2 (NSSC-2). This version is called the Hybrid Technology Computer (HTC). This version was produced at the IBM Federal Systems Division at Huntsville, Alabama.[39] Its architectural specifications require it to support the 86 System/360 Standard Instructions (no decimal or floating point operations). It has the usual sixteen 32 bit general purpose registers and 16 to 64K bytes of storage (with an extended protection mechanism). A single I/O channel supports three types of I/O: device initiated I/O, CPU initiated I/O and Direct Memory Access I/O. Device initiated I/O has two classes. Buffered I/O allows a device to transfer data to/from a table in main memory without knowing the location or size of the table. External interrupt permits a device to interrupt the normal program sequence. CPU initiated I/O also provides two types of services: command and 16 bit data transfers to or from I/O devices or CPU to I/O 16 bit control operations. Direct Memory Access is transparent to the NSSC-2 microprogram controlled hardware unless a hardware error occurs, when the microprogram is called. Each use of the I/O interface, whether CPU or device initiated, follows a certain protocol, depending on the I/O command.

Describing the NSSC-2 CPU was straightforward. The state vector facilities are essentially those listed in the S/360 programming manual. The basic CPU macros are all of the type (and approximate length) of those described earlier in this paper. This control, however, involves recursive calls, so that instructions will be fetched and executed indefinitely, or until some interrupt or other external signal intervenes. The basic idea is shown in Figure 6. The macro which handles the interaction between the CPU and the I/O is much more complicated because of the asynchronous parallel action of the CPU and I/O devices. This is carefully described in Reference 40. The description takes 25 double spaced pages of computer printout.

This architecture is implemented by a data flow that has a 16 bit wide data path, three working 16 bit registers, a 16

```
cpu=
    (SOFT-STOP=0)→DO-INSTRUCTION
                  SERVICE-INTERRUPT
                  CPU
    (SOFT-STOP=1) → Ω
```

Figure 6

bit wide store whose storage data register does double duty, a 64×16 bit scratchpad memory, and a 16 bit I/O register.[39] The data flow is controlled by a 1K read only memory of 64 bit wide horizontal micro-instructions, another 64×16 read only memory for computer instruction decoding, a 32 bit instruction register, and various sized registers and signals for speed of operation. The facility vector consists of the storage data flow registers and control signals. The macros describing the action of the 21 types of CPU oriented microcommands are again straightforward. The I/O protocols depend basically upon 2 other microcommands. These protocols require that certain acknowledgments be sent by the CPU, that the CPU wait until certain signals are received from devices, that interrupts not be ignored indefinitely, etc. Verification of these microprogram controlled protocols is an important part of microprogram certification (see Reference 40 for a complete description). This description takes 20 pages of computer printout.

One part of the HTC microcode, where the new treatment of I/O was heavily used, is system reset. This is code executed upon start of the HTC, and its job is mainly to initialize various data structures. It also initializes the I/O channel status; here it is important to ensure that the protocols are strictly observed. During system reset the microcode uses a certain piece of code that is used also for other purposes. For these other purposes the request line (which can be raised by the I/O interface) is sensed. The operation of system reset, however, depends on this line being down. To ensure this the computer must prevent any device from being serviced by the I/O interface. Therefore before entering the shared piece of code the microcode resets the interface. (That is, service of any device will be terminated). After resetting the interface the proper operation of reset is checked using this shared code. To prevent a device from getting service during this checking, the command line (under CPU control) is enabled. If these precautions were not taken, system reset would not be performed correctly when a device happens to request service at exactly the wrong moment. Needless to say, we could hardly expect this kind of error to be detected by testing.

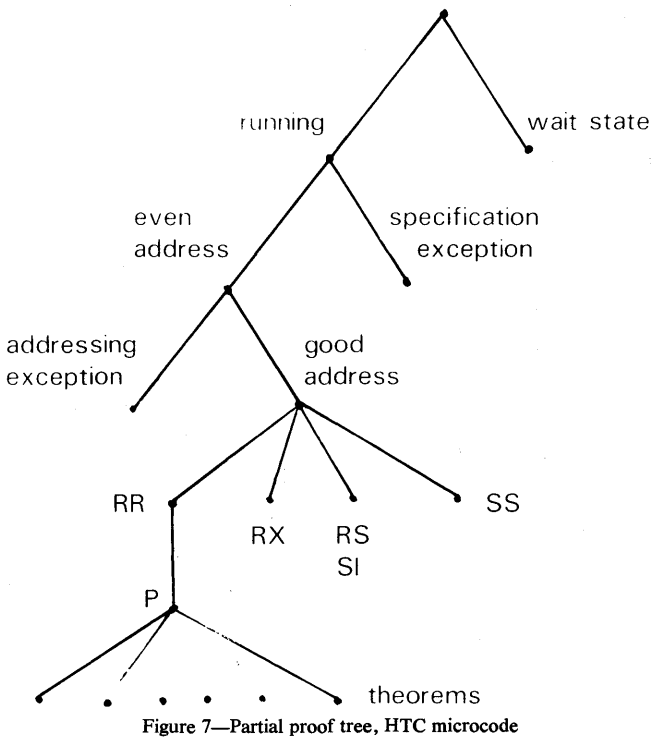

Figure 7—Partial proof tree, HTC microcode

In the course of trying to prove correctness of system reset we found that, after checking that the reset was valid, the microcode jumped to a routine which implemented part of the protocol for sending the storage data register information to an I/O device. This is not only a violation of specifications, but the information transmitted is random—whatever happens to be in the storage data register when the power is turned on. Moveover, in this routine the microcode sent an acknowledgment to the I/O interface without checking that the correct I/O routine had begun. If an unknown device were requesting service, it would receive the service acknowledgment even though no device input has been read. The device—and its input—would be actually unknown. After consulting with the author of the microcode it was determined that he used this feature for debugging purposes (indicating to Test Support Equipment that reset was finished) and had left it in the final product by error.

After eliminating this jump to the routine which violated the architectural specifications, we were able to verify system reset, following 5 paths and proving 28 theorems.

The next part of the microcode to be tested concerned the CPU IFETCH, 15 microinstructions, 3 paths and 45 theorems. Figure 7 gives an outline of the proof tree developed for this HTC microcode. In this part of the code we found that if a program overflow had been signaled, but upon return to the beginning of IFETCH an I/O interrupt was waiting, then the overflow would be ignored. We also found that no half-word instruction may reside in the last two bytes of memory. Since the memory contents are not available immediately, the first thing the IFETCH code does is fetch a word (16 bits) from memory, then immediately read the next word so 32 bits are read to fill the instruction register. If the instruction is 16 bits there is no slowdown, while if the instruction is 32 bits there is an increase in instruction speed. Unfortunately if the first 16 bits read are a 16 bit instruction in the last two bytes of memory, IFETCH tries to read the next two bytes, a memory overcapacity interrupt is given and IFETCH is never completed. This is an example of a bending of specifications, not a microprogram fault. A note in the programming manual would be better than slowing the HTC down.

Another 97 microinstructions were executed during symbolic execution of 10 S/360 RR instructions. Thirty-two paths were followed, and 480 theorems proved. In the Branch and Link instruction (BALR) the link address was stored before the branch address was accessed. Thus BALR R_i R_i became a NO-OP instead of a branch and link. This was not detected by being unable to prove a theorem; instead, it was detected by generation of an unexpected branch of the goal tree. (The error had been found by further testing

before we found it.) One other specification exception was found: bit 31 in the key word in the Set Storage Keys (SSK) instruction must be zero. This is counter to the instruction description, which says that bit 31 is ignored.

CONCLUSIONS

Some architectures, data flows, programs and microprograms have been described using LSS. Microcode has been symbolically simulated and errors found. Modelling systems and programs using LSS has been relatively straightforward, except when trying to describe very efficiently asynchronous parallel actions. MCS has run with reasonable speed during these verification runs, and it appears that MCS can be used to verify microprograms of moderate size. Thus, the approach of symbolic simulation does offer some hope for correct microcode before customer shipment, and automated methods have been successful in detecting errors in "real" microprograms, which would be very difficult or impossible to detect with program testing. Certification of microcode and machine level code may thus be the place where automated program verification techniques will reveal their applicability to actual software and firmware.

A panel session—Formal methods in programming—When will they be practical?

SESSION CHAIRMAN—KARL N. LEVITT
SRI International

Panel Members

Donald I. Good—University of Texas
Ellis Horowitz—University of Southern California
Barbara Liskov—Massachusetts Institute of Technology
Lawrence Robinson—SRI International

PANEL OVERVIEW—Karl N. Levitt

Formal methods, i.e., use of mathematical rigor, have been employed by research computer scientists in their attempt to develop general results for many aspects of computer science, e.g., computational complexity, undecidability, numerical analysis, programming language semantics. Much of this work has had little impact on those charged with producing working software systems. However, in recent years numerous researchers have suggested that by applying formal methods to the realization of systems, the quality of such systems could be significantly improved. Such formal methods could be applied in the structuring, specification, verification, and analysis of performance for systems. The position statements below explore the use of these techniques in the production of systems. The general opinion is that formal methods will ultimately assume a vital role, but for the present their use will be restricted to particular systems produced by skilled individuals. The use of the formal methods will gradually increase as the techniques are refined and applied to a larger variety of systems, as tools are developed to support their use, and as the general community becomes better educated in formal methods.

FORMALISM CAN HELP YOU—Lawrence Robinson

There is much resistance on the part of the programming community to the use of formalism in programming methods. However, there is also a problem in achieving reliable and maintainable software that meets its requirements. Despite the resistance, the application of formalism to programming techniques shows much promise in attaining a software product of high quality. At present, some advanced techniques are ready for limited use.

First it is useful to state exactly what formalism is. *Formalism* is a means for making logical and consistent arguments about a particular area. To formalize an area requires a set of definitions and axioms to characterize the area, and a set of rules of inference to validate or disprove logical arguments. Formalism can be used to understand, analyze, and reformulate both a problem and its proposed solution, and to verify that the proposed solution actually solves the problem at hand.

Other engineering disciplines make use of formalism to some extent (e.g., Laplace transforms in electrical engineering and partial differential equations in structural engineering). In fact, some aspects of software already make use of formal techniques, such as the exact specification of the syntax of a programming language. However, software engineering, because it is still a very young field, lags behind other engineering endeavors in the use of formal techniques.

In addition, the special problems inherent in software engineering require an even greater use of formalism than do the problems of other engineering endeavors. Two factors are responsible for software engineering's greater need for formalism:

- The complexity of large software systems exceeds that of other engineering systems by several orders of magnitude. Any engineering practices that are developed for software must place considerable emphasis on the management of this complexity. Current software engineering methods have not adquately done so. Formal mathematics has been the classical tool for managing complexity, by combining many cases into canonical groups, and by structuring complex concepts by the use of abstraction and formal definition.
- Software has a requirement for total exactness that is unique among engineering disciplines. Whereas the products in other fields are required to fall within continuous tolerances, the smallest error in a piece of software (a single bit) will sometimes result in the catastrophic failure of a system, rather than in degraded performance. Software engineering techniques must be able to guarantee the exact fulfillment of requirements. Formal techniques provide the only possibility of exactly stating the requirements of a piece of software, and for mathematically proving that the software meets its requirements.

Because software is so difficult an area, its development requires a great deal of attention to the analysis and planning that precede the coding. Current techniques underemphasize these early aspects of the software development process. Some new techniques require formal analyses of requirements and formal design specifications before coding can proceed. These techniques are ready for use by advanced systems programmers. A methodology developed at SRI International (HDM—the SRI Hierarchical Development Methodology) has been used for formally specifying the designs of several operating systems and many intermediate-sized systems; some of the systems have been implemented.

However, these techniques are not currently ready for everyone, and considerable training is required in order to use them. The major obstacle, however, is a resistance to change. But the education process (at universities, for example) is making these techniques available to people entering the software field. Gradually, programming will become closer to mathematics—more of a science than a black art. The changing process will be painful and fraught with resistance, but it hopefully will result in better and better software products.

SOFTWARE DESIGN BY ALGEBRAIC SPECIFICATION—Ellis Horowtiz

I'd like to adopt for the moment an extreme point of view so I can describe the range of application of algebraic specification to software design. A recent advance in software construction has been the recognition that one should begin by supplying a formal specification of the intended task. This notion applies both to programming systems as well as to individual programs. The debate now centers on the way such a specification will be phrased, and as with programming languages practitioners are developing strong biases for and against certain approaches. My own bias centers on algebraic specification.

Algebraic specification is not appropriate for specifying all possible tasks. For example, the technique does not seem natural for describing concurrency. What it does seem ideally suited for is the description of data types (data structures). Many computer applications can be conceived of as the transformation of data from one form into another. Then, the programming task becomes one in which the logical data structures must be precisely defined and then represented via other data structures which are available on a computer. The essential ingredient which makes the algebraic approach so successful for data type specification is the fact that a data type is composed of a set of related operations. These operations create, build-up or make smaller instances of the data type, they may decompose it into its constituent parts or answer questions about its form and content. All of these operations are best viewed together and algebraic specification naturally exposes these relationships.

The relationships between operations of a data type are given via a set of equations, usually called algebraic axioms. These equations show the effect that the operations have on instances of the data type. One important virtue of these equations is that they imply no representation. Thus the meaning of the operations of a data type is defined abstractly (i.e., without regard to the eventual representation), and the design process is broken into two logical phases: data type definition and implementation. My own experience leads me to conclude that an algebraic axiomatization is about as easy to compose for a data type as it is to describe the type in English.

The ease of specification might alone be sufficient to recommend algebraic axioms. But it turns out that there are other payoffs when one adheres to this software design scheme. In particular the testing and verification of the resulting software are all facilitated when one continues to design and implement all data types via the algebraic discipline. A software "environment" can be created which aids the programmer as he builds his system. At the USC/Information Sciences Institute several of us (D. Musser, J. Guttag) have created the Data Type Verification System (DTVS) which supports program creation by algebraic specification.

We begin by algebraically axiomatizing a single data type. Is our axiomatization correct? Before attempting a proof some testing would be desirable. DTVS will automatically synthesize an implementation from the axioms. This will permit testing at the level of the axiomatization without the trouble of implementation. Naturally such testing will be costly in terms of execution time, but experience indicates that only small cases are sufficient to turn up most errors.

When testing is completed, a representation for the data type in terms of other data types is devised. Then implementations of the operations in terms of the operations of the implementing data types are given. Once again testing is repeated, but this time DTVS will use the implementations as the semantics of the data type. Once we are satisfied, a proof of the correctness of the implementation is carried out semi-automatically by DTVS.

Specification is a process we continue to explore. It is possible to build a complex software system by strictly adhering to algebraic axioms. By doing so one gains both the virtues of a formal approach and the testing and verification environment. This offers much more than an ad hoc strategy. Finally, this approach is not inconsistent with the eventual use of a conventional programming language.

PRACTICAL BENEFITS OF RESEARCH IN PROGRAMMING METHODOLOGY—Barbara Liskov

In the past few years, considerable progress has been made in the area of programming methodology. Although all research in this area is interrelated, two main research directions can be distinguished. One direction is the study of software system structure, in particular study of desirable kinds of modules and module interconnections. The other direction is the study of the process of developing correct software having such desirable structure.

Study of software system structure has been particularly effective within the framework of research on programming

languages, especially the languages CLU[1] and Alphard.[2] This language work has succeeded in identifying new kinds of modules, and has provided precise rules governing the implementation and use of such modules. Each kind of module supports a kind of abstraction found to be useful in constructing software. The most important new kind of module is that supporting a *data abstraction*; however, there are other kinds of modules, and in addition rules governing the interaction of modules. These latter rules constrain and reduce the interconnections among modules.

Earlier work in structured programming[3] and stepwise refinement[4] made evident the advantages of top down development of software. Recent work has elaborated the top down development process, taking into account the work on software system structure discussed above, and clarifying the way that top down development proceeds. The most important contribution has been the recognition of the role played by *program specifications*. A program specification is a description of the behavior of a module, the behavior that will be depended on by any user, and that must be provided by any implementation. At any stage of design, the goal is to identify lower level abstractions useful in implementing the current level. As these abstractions are identified, their behavior is specified. The specification is given in advance of the implementation, and it provides a complete description of the interface of the module that will later implement the abstraction. The presence of the specification permits the question of how to implement the lower level modules to be deferred until a later stage of design.

As programming methodology has become better understood, there has been increasing interest in defining formal methods to support it. In particular, there has been much recent research in formal specification techniques,[5,6] which permit the specifications discussed above to be expressed in a formal language, i.e., one with a well-defined and unambiguous syntax and semantics. The advantages of such formal specifications are twofold: they are more precise and concise than informal specifications, and therefore may serve better the role of interface descriptions described above, and, in addition, given formal specifications, a formal proof that a module's implementation satisfies its specification is possible. However, formal specifications are more difficult to write than informal ones, and our current understanding of specification and verification techniques is insufficient to permit all useful abstractions to be described.

It is my belief that the present and near future construction of software systems can best be helped by popularizing the methodology. This can be done in a way that relies neither on a particular language, nor on the as yet incompletely understood specification and verification techniques. Instead, the following two ideas must be made clear to programmers:

1. What constitutes good modularity.
2. What constitutes good design practice.

Rules about good modularity are best explained by developing conventions, or better yet preprocessors, for existing languages in actual use; such conventions would permit a limited use of data abstractions and would prohibit current bad practices (such as non-local use of data). By expressing the rules in this way, they are explained in terms the programmers can understand, and furthermore, a tool is provided that helps in the development of a well-structured system. Good design practice then consists of top down decomposition into the kinds of modules that the programmers already understand, with emphasis on the role of (informal) specifications in the process, and especially on the necessity of specifications being given in advance of implementation. To aid programmers in understanding what specifications are, it is helpful to establish a specification standard which describes the kind of information that should be included in the specification, and gives a format for expressing that information. However, it is too early to require that specifications be given in a formal language. Formal methods in system design are not yet ready for practical use, but I believe use of the methods in an informal way can have considerable practical benefit.

BEYOND FACTORIAL—Donald I. Good

Factorial is probably the single most thoroughly verified program ever. It, and other small examples such as stacks, typically are used in the literature to illustrate formal program verification methods, and this tends to create the impression that these small examples define the limits of effectiveness of formal verification. We must be careful not to paint an overly optimistic picture, but the view that formal verification methods are effective only on small examples, such as stacks and factorials, is equally overly pessimistic. Formal verification methods have been applied successfully to a variety of programs in the 1000-lines-of-code range and strong verification clauses are now being written into some software development contracts with the U.S. Government. Although there is much yet to be done, formal verification methods show considerable promise of becoming an effective approach to building reliable software in actual practice.

Basic research over the last ten years has done much to develop formal methods of program verification. The prob-

lem of actually verifying a 2000- to 5000-line program, however, is much larger than just verification methods, and we must begin to focus some of our efforts on solving the "whole" verification problem if verification methods are to become effective in actual practice. The breadth and depth of the problem that is faced by a person charged with producing a substantial verified program is substantial. It encompasses the following issues: verification methods, specification methods, programming methods, specification language, verification language, programming language, specification tools, verification tools, programming tools, development strategies.

Verification methods are the central issue, but are by no means the only issue. A verification demonstrates the consistency of a program and a specification. Therefore, attaining a verification requires using specification and programming methods that are both compatible with the verification methods. (By "programming methods" we mean the use of program constructs that are verifiable, as opposed to program "development strategies".) We must know what kinds of things can and should be specified about various program constructs and we must know how to verify that the program construct meets the specification. We also must know how primitive verifiable program constructs can be put together to form large verifiable programs. Given the basic methods, precise languages for expressing the specifications, program, and verification are required. The specification and programming languages express the actual program and its desired properties, and the verifications are done in the verification language which normally is some variation of the predicate calculus. The development of suitable languages involves all of the well-known problems of language design. Given these languages, effective tools are required to apply these languages to an actual problem. Without adequate tools, the languages and the methods they embody become effectively inaccessible. Finally, these tools must be used according to some reasonable strategy for step-wise program development. Just as independent compilation is of major importance in developing a large program, independent verification is crucial even for a program of modest size; thus step-by-step verification must follow a sound program development strategy. Attaining a verified program of substantial size requires effective solutions to all of these problems and, just as importantly, it requires that these solutions be effectively integrated so that they can be used together in a systematic and coherent development of a verified program. In actual practice, an inadequate solution to any of these problems or an ineffective integration of individually effective solutions can completely defeat the verification of a 2000- to 5000-line program.

Automatic programming

The term Automatic Programming is ill-defined. It means many different things to many people. It has covered everything from Fortran Compilers in the mid-50's to futuristic visions of machines which completely program themselves to accomplish a given goal, or are even capable of generating those goals themselves.

The three Automatic Programming sessions in this conference clearly cannot cover such a broad spectrum. Instead, they are focused on a set of small research projects each attempting to expand the computer's involvement in the programming process. Surely, such continued expansion of computer involvement in the programming process is the central thrust of all the efforts in this field.

The current state of this field can best be accessed by noting that programming is still largely a manual process. Significant progress has been made over the years, but it has largely been concentrated in the final stages of the programming process (such as language translators, test case generators, and debugging tools). What facilities exist which help us formulate and design systems, study tradeoffs between alternative designs, foresee the implications of design and implementation decisions, understand the effects of modifications, predict system performance, foresee system bottlenecks, or even prevent the introduction of bugs during implementation?

Such tools basically do not exist. Instead, programmers and systems analysts deal with these issues in their own internal ways. These internal methods are not accessible for analysis by others, are error-prone, incomplete, and difficult to transfer from one individual to another.

This deficiency has been recognized and responded to by the development of a set (actually several competing sets) of techniques for MANAGING the programming process. These techniques attempt to control the complexity of programming by advocating certain practices and styles while proscribing others, and by developing languages which encourage and/or enforce such direction. Certainly such endeavors have significantly improved our ability to control and manage these design and formulation processes occuring within our heads.

Such manual techniques can only go so far. The regularized (structured) environment that they have created must be augmented by various tools which

record the stepwise development of these processes as they occur within our heads, expose the decisions we are making, and enable us to see the implications of those decisions.

The challenge for the field of Automatic Programming is to extend the programming environment by constructing such tools which expose this stepwise development process and enable each stage to be analyzed, as the basis for the next step, without impairing the formulators' design flexibility. To accomplish this, there must exist a clear separation between a decision of what step to take next, which the formulator must control, and the carrying out of that decision, which the tool must perform to ensure that it is being accurately accomplished. In this way the integrity of the system being formulated is maintained as it moves from stage to stage. These tools thus ensure system integrity between formulation stages by automating the "clerical" operations which transform one stage into the next after a decision has been reached. Since a very large number of decisions must be made in any formulation process and some of them are very detailed, there may well exist some portion which the formulator relegates to the Automatic Programming tool. These Automatic Programming tools must also provide some analysis capabilities which enable the formulator to determine which decision to make next and how to make that decision.

All of the prototype tools covered in these three Automatic Programming sessions match this paradigm. They differ in the portion of the formulation process they address, the analysis capabilities available at each stage, and the degree of control the formulator maintains over the decisions which get made.

The first session concentrates on tools which address the process of specifying a program, while the second is composed of those which address the implementation of such a specified system. These two sessions are not intended to present new research results (these have been reported in various specialized conferences and workshops), but rather, to bring together and highlight representative work in this field for the NCC audience.

The final session, a panel, will attempt to access the extent and timeframe of the impact of such work within the computing community.

Informality in program specifications[1]

by ROBERT BALZER, NEIL GOLDMAN and DAVID WILE

Information Sciences Institute
Marina del Rey, California

A critical step in the development of a software system occurs when its goal-oriented requirements specification is transformed into a process-oriented form that specifies how the requirements are to be achieved. Only after this transformation has occurred can the feasibility of the system be analyzed and the consistency of the process specification with the requirements be verified. The key to this transformation is expressing the process-oriented specification abstractly so that its functionality is completely determined while the class of possible implementations remains broad.

We believe that such abstract process-oriented specifications are the key to rationalizing the software development process. Such specifications are, in reality, programs written in a very high level abstract programming language. As such, they could provide an effective interface between the two major software concerns: functionality and efficiency. These concerns should be decoupled so that the functionality of a system can be addressed before its efficiency has been considered. Once functionality has been accepted, it can be preserved while the system is optimized. Thus, since the abstract process-oriented specification is a program, its consistency with the requirements could be formally verified, informally argued, or tested by actually executing the specification. Furthermore, the end user could be given hands-on experience exercising the specification to see if it behaved as intended. Deviations and/or inconsistencies could be corrected in the specification before any implementation occurred.

Once the system's functionality has been accepted by the user, the efficiency of the system in meeting its performance requirements remains an issue. Such efficiency must be gained without altering the system's accepted functionality. We have argued elsewhere[2] that a computer-based tool can be built which guarantees maintenance of functionality while a program is optimized without sacrificing the programmer's ingenuity or initiative in determining how best to achieve efficiency.

In this work we are concerned primarily with the procedure by which such process-oriented specifications are obtained and with computer-based tools for their construction. We will begin by determining some attributes of a suitable process-oriented specification language, then examine why specifications would still be difficult to write in such a language. We will argue that the key to overcoming these difficulties is the careful introduction of informality based on partial, rather than complete, descriptions and the use of a computer-based tool which utilizes context extensively to complete these descriptions during the process of constructing a well formed specification. We will then present some results obtained by a prototype of such a computer-based tool on a few informal example specifications. Finally, we will discuss some of the techniques used by this prototype system.

The PSI program synthesis system, 1978—An abstract

by CORDELL GREEN
Stanford University
Stanford, California

This abstract will cover the current status of the PSI program synthesis system. PSI is a computer program that acquires high-level descriptions of programs and produces efficient implementations of these programs. PSI allows program specification dialogues using a mix of natural language, traces, examples, and a very high-level language. These specifications are used to construct a well-defined high-level program description of the desired program. This description is called a program model. The model is then refined into an efficient implementation of the program. PSI consists of several modules including an English parser-interpreter, trace and examples inference expert, domain expert, explainer, dialogue moderator, program model builder, coder and efficiency expert. The class of programs synthesized are simple symbolic computation programs in either LISP or SAIL.

The system design has been a group effort with the individuals responsible for each module as follows: parser-interpreter, Jerrold M. Ginsparg; trace and example inference and domain experts, Jorge V. Phillips; moderator, Louis I. Steinberg; explainer, Richard P. Gabriel; model builder, Brian P. McCune; coder, David R. Barstow and Juan Ludlow; and efficiency expert, Elaine Kant. The interested reader should see the short summary paper[1] for a list of references on these components.

PSI's operation may be conveniently factored into an acquisition phase and a synthesis phase. The acquisition phase is concerned with acquiring the program specifications and producing a program model. The synthesis phase then finds an efficient implementation in the selected target language.

An assumption used in the design of the acquisition phase of PSI is that there is no one best method for specifying all programs. So a mix of methods is allowed, ranging from a "conventional" very high-level language through English and traces. The English sentences are first parsed, then interpreted into fragments. The parser limits search by incorporating considerable knowledge of English usage. The interpreter is more specific to automatic programming, using program description knowledge as well as knowledge of the last question asked and the current topic to facilitate the interpretation into fragments.

Fragments form a loose description of program and data structure. The model builder must then apply knowledge of correct high level programs to convert the fragments into the model. The program model includes complete, consistent and executable (but slowly) high-level algorithm and information structures. The model builder processes fragments, checking for completeness and correctness, fills in detail, corrects minor inconsistencies, and adds cross-references. It also generalizes the program description, converting it into a form that allows the coder to look for good implementations.

Another input specification method is partial traces mixed with input and output examples. Partial traces of states of internal and I/O variables allow the inductive inference of control structures. The trace and example inference module infers loose descriptions of programs in the form of fragments, rather than programs themselves. This technique allows domain support to disambiguate possible inferences, and also separates the issue of efficient implementation from the inference of the user's intention. Application domain specific knowledge (e.g., knowledge about learning programs) is concentrated in the domain expert, which supplies other acquisition modules with domain support for disambiguation and program model completion.

The moderator guides the dialogue with the user by selecting or repressing questions generated by various modules. It attempts to keep PSI and the user in agreement on the current topic, provides a review-preview on a topic change, helps the user that gets lost, and allows initiative to shift between PSI and the user. The explainer module generates questions about and descriptions of program models as they are acquired, in order to help verify that the inferred program description is the one desired.

After the acquisition phase is complete, the synthesis phase begins. This phase may be viewed as a series of program refinements or as a heuristic search for an efficient program that satisfies the program model. The coder has a body of program synthesis rules that gradually transform the program model from abstract into more detailed constructs until it is in the target language. Both algorithm and data structures are refined interdependently. The coder deals primarily with the notions of sets and correspondences and can synthesize programs involving sequences, loops, simple input and output, linked lists, arrays, and hash tables.

The refinement tree effectively forms a planning space that proposes only legal, but possibly inefficient, programs. The efficiency expert reduces the search of the tree by several heuristics and by estimating the time-space cost product of each proposed refinement and then using the

branch and bound method. It also factors the program into relatively independent parts so that all combinations of implementations are not considered. An analysis for bottlenecks can allocate synthesis effort to more critical parts of the program.

In summary, we have formulated a framework for an automatic programming system and have a start on the kinds of programming knowledge that must be embedded therein. PSI is moderately successful in that a research prototype is currently running and has synthesized many different programs including a graph traversal program, simple storage and retrieval programs and learning programs.

Protosystem I—An automatic programming system prototype

by GREGORY R. RUTH
Massachusetts Institute of Technology
Cambridge, Massachusetts

INTRODUCTION

Over the years people have come to understand certain functions of the programming process well enough to automate them—that is to replace those functions by programs. The most notable results were assemblers, compilers, and operating systems. Our knowledge and understanding of programming is once again reaching a level where a significant advance in automation is both necessary and possible. In particular, it is now possible (for certain simple application domains) to create a system that will take as input a specification for a user's application and will automatically design and code the desired data processing system. To demonstrate feasibility and gain insight into the issues and technology involved in creating such a system, a prototype automatic programming system (Protosystem I) for generating business data processing systems is currently being developed at MIT.

A MODEL OF THE PROGRAM WRITING PROCESS

The data processing system writing process may be conceived as a sequence of phases leading from the conception of a system to its implementation as executable machine code. A useful and plausible model for this sequence of phases is:

Phase 1: Problem Definition—The system specification is expressed in domain dependent terms in English that is understandable by the program developers.

Phase 2: General System Analysis and Design—The problem is reformulated in standard data processing terms and expressed as an instance of a known solvable problem class (in our case a subset of the class of all batch oriented dps's). Domain dependent policy and procedures are worked out in detail at this stage.

Phase 3: System Implementation—The system—the actual procedural steps and data representations and organizations—is constructed by intelligent selection from and adaptation of a number of standard implementation possibilities.

Phase 4: Code Generation—The design specifications are implemented in a high-level language (e.g., PL/I, COBOL) in a fairly straightforward, but not totally mechanical, way.

Phase 5: Compilation and Loading—A form is produced that can be "understood" and executed by the target computer.

These phases progress from a general notion of *what* is to be done by the desired system toward a detailed specification of *how* it can be accomplished. They also represent the classes of design and implementation problems involved in program writing, progressing from the most global and general considerations toward the most local and detailed issues.

Protosystem I seeks to automate the program writing process by automating and tying together the phases described in the model given above. That is, Protosystem I is designed in such a way that there are explicit parts or stages corresponding to each of the model phases. Each such stage embodies the knowledge and expertise of the human agent(s) for the corresponding phase, so that, given the same or similar input, it can intelligently produce comparable corresponding results.

The products of each stage should be sufficiently general and malleable so that further stages can have the maximum freedom in making their design contributions in the most effective and efficient ways. Consequently, we have chosen in Protosystem I to make the product of each stage a descriptive representation of the dps in terms of concepts and considerations appropriate for the next stage of development. In this way the programming process is conceived as the development of a succession of ever more precise system descriptions until, ultimately, a level is reached where every detail has been decided and the result is an executable computer program.

EFFICIENCY ENHANCEMENT IN SYSTEM DEVELOPMENT

To produce a credible and practical result an automatic programming system must perform a reasonable degree of

optimization. Current formal optimization methods pertain mainly to the compilation level; when the entire program development process is automated, new, additional types of optimization will have to be included.

The various possible types of optimizations fall quite naturally into categories that correspond to the program writing levels in our model. For instance, the combination of computations (for the sake of I/O efficiency) is something that should be considered during Stage 3 (system implementation) where the data and computational interrelationships among conceptual processing units are most evident. Problems involving efficient loop construction should be handled in a Stage 4.

THE DEVELOPMENT OF PROTOSYSTEM I

The Protosystem I effort began in 1971. Because of the difference in the natures of the technologies involved the work was divided into two parallel efforts: (1) a top-part-of-the-system effort (Phases 1 and 2), essentially of an Artificial Intelligence nature, concerned with natural language comprehension, model formation and problem solving, (2) a bottom-part-of-the-system-effort (Phases 3 and 4) addressing the problems of implementation and optimization of a program given an abstract relational specification (ultimately to be passed down from the top part of Protosystem I). The bottom part of Protosystem I has been completely implemented in the MACLISP language and is operational on the MIT LCS PDP-10. Research and development on the top part, being considerably more ambitious and novel, is not expected to cross the threshold of practical applicability for another five years, and so will not be discussed further in this article.

A structural diagram of the bottom part of Protosystem I is shown in Figure 1. The following sections give an explanation of its workings.

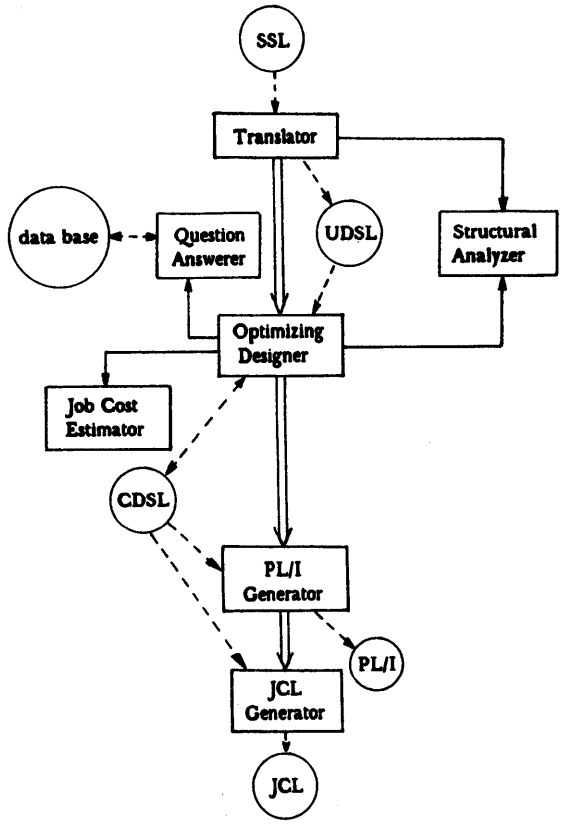

Figure 1—Protosystem I—Structure of the bottom part

THE PROTOSYSTEM I DATA PROCESSING SYSTEM MODEL AND THE SYSTEM SPECIFICATION LANGUAGE

Protosystem I handles a restricted but significant subset of all data processing applications: I/O intensive batch oriented systems. Such systems involve a sequence of runs or job steps that are to be performed at specified times. They are assumed to involve significant I/O activity due to repetitive processing of keyed records from large files of data. Systems such as inventory control, payroll, and employee or student record keeping systems are of this type.

A simple example of such a dps is a software system to perform the inventory and warehousing activities in the following case:

> The A&T Supermarket chain consists of 500 stores served by a centrally located warehouse. There are 4000 items, supplied by the warehouse, that these stores can carry.
>
> Every day the warehouse receives shipments from suppliers and updates its inventory level records accordingly.
>
> It also receives orders from the stores for various quantities of items. If for a particular item there is sufficient stock to fill all of the orders for that item, the warehouse simply fills the orders as made; but if there is insufficient stock it ships partial orders proportional to fraction of the total quantity ordered that is on hand.
>
> Inventory records are adjusted to reflect the decrease in levels.
>
> Finally, a daily check is made on the inventory levels of all items. If the level of an item is lower than 100 the warehouse orders 1000 more units of that item from the appropriate supplier.

In order for the bottom part of Protosystem I to implement such a data processing system application the basic aggregate data entities and their interrelationships must be determined. Consider the inventory updating activity of the second paragraph. There are three aggregate data entities involved: (1) the set of quantities received from suppliers, (2) the set of closing inventory levels for the previous day, and (3) the set of the updated inventory levels to be used for filling store orders. Such collections of similar data that are processed in a similar way are termed *data sets*. In

Protosystem I a data set is assumed to consist of fixed format *records* (e.g., one for the level of each inventory item). Associated with each record is a *data item* (e.g., the level of an inventory item) and *keys*. The key values of a record uniquely distinguish it (e.g., the inventory data set can be keyed by item since there is only one level [record] per item) and so can be used to select it.* If we call these data sets SHIPMENTS-RECEIVED, FINAL-INVENTORY and BEGINNING-INVENTORY, the relationship between BEGINNING-INVENTORY and the others may be described as:

For every item:

the beginning inventory level of that item
(i.e. the value of the data item for the record in BEGINNING-INVENTORY for that item)
is the closing inventory level of that item from the previous day
(i.e. the value of the data item in the record of FINAL-INVENTORY for the same item)
plus the quantity of that item received
(i.e. the value of the data item in the record of SHIPMENTS-RECEIVED for the item in question),
if any.

This relationship is expressed more succinctly in SSL (the System Specification Language):**

BEGINNING-INVENTORY IS FINAL-INVENTORY(1 DAY AGO) + SHIPMENTS-RECEIVED

The repetitive application of an operation to the members of a data set or sets such as this is termed a *computation*. The order of applications of the operation to the records of its input data sets by a computation is assumed to be unimportant to the user; in fact, he may think of them as being performed in parallel. However, every computation does, in fact, process its input serially, according to a particular ordering (chosen by Protosystem I) on their keys. Computations typically *match* records from different data sets by their keys (as above) and operate on the matching records to produce a corresponding output record. A computation may also *group* the members of a data set by common keys and operate on each group to produce a single corresponding output. Returning to our example, note that item orders can come from different sources (stores), so that both the item and the source of an order are needed (as keys) to distinguish it. To form the total of all orders for each item, a computation must group the orders by item and sum over the order amounts in each group. In SSL this would be expressed as:

TOTAL-ORDERS FOR EACH ITEM IS THE SUM OF THE QUANTITY-ORDERED-BY-STORE

Figure 2 shows the structure of the A&T inventory and warehousing data processing system in terms of computations (boxed) and data sets (unboxed). The complete SSL description of A&T dps is given in Figure 3. Note that in addition to the relational statements a list of data sets must be included to indicate the keys by which they are accessed.

THE TRANSLATOR AND THE DATA SET LANGUAGE

For the dps's which Protosystem I proposes to treat the calculations themselves are easily dealt with; the structuring and manipulation of the masses of data involved forms the major part of the Stage 3 implementation activity. Consequently, the development process at Stage 3 is data set oriented. Therefore, to facilitate the design process the SSL dps description is first analyzed from this point of view and re-expressed in a more appropriate medium, DSL (the Data Set Language). This reformulation is performed by the Translator module.

The determination of dps characteristics that can aid in the development of the dps design is made with the aid of the Structural Analyzer and included in the Translator's output description. This output is called the UDSL (Unconstrained Data Set Language) description, because most design details remain unbound (undecided) in it. As such it forms the skeleton of the dps description ultimately to be produced by Stage 3.

One useful piece of information determined by the Structural Analyzer is the set of *driving data set* candidates for each computation. A driving data set is an input data set that is guaranteed to have a data item for every tuple of key values for which the computation can produce an output. The computation, then, instead of having to loop over all possible combinations of values for the keys of the inputs, can be driven by the driving data set in that it only has to consider those key value combinations for which the driving data set contains records.

Another type of information the Structural Analyzer determines is directly related to our desire to specify data set organizations and orders and computation accessing methods and orders in such a way as to minimize the cost of operating the dps. Because a dps typically involves the repetitive application of *simple* calculations to large quantities of data we make the first-order approximation that the cost of operation is due entirely to data accessing (reading and writing). Our design, therefore, focuses on minimizing the total number of I/O events.

Accordingly, the Structural Analyzer also determines predicates that are the conditions under which a data item will be generated and under which a data item will be used by a computation. For example, a store will be shipped an item if (it is true that) that store ordered that item and there was sufficient inventory to fill the order; the order allocation step will use the inventory level for a particular item if some store ordered it. These predicates, together with basic information concerning the sizes of data sets in the dps, are used by the Question Answerer to determine the average and maximum sizes of files (proposed by the Optimizing Designer) and the average number of a file's records a computation will access.

* Thus, a data set is essentially the same as a Codd relation and its keys are what Codd calls primary keys.

** Implicit in this statement is that the addition operation is performed for each item and that if one of the operands is missing (e.g., if no chicken noodle soup was received today) it is treated as having a zero value.

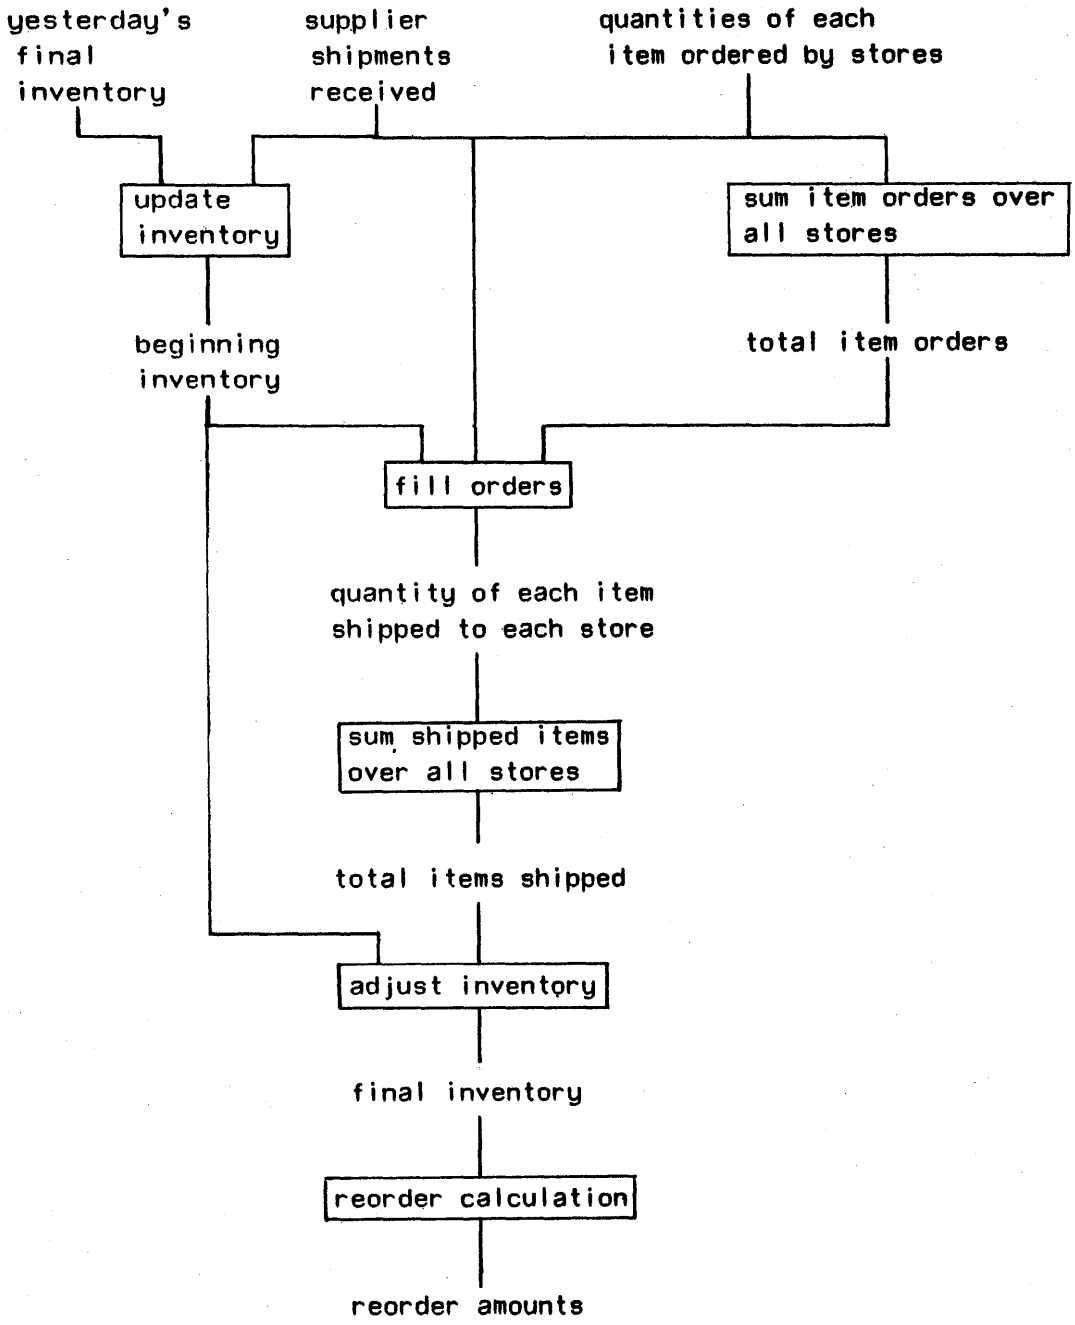

Figure 2—A&T inventory and warehousing system

THE DESIGN CRITERION AND THE JOB COST ESTIMATOR

The design criterion for Protosystem I is the minimization of the dollars and cents cost of running the final dps program on the target machine/operating system configuration. Because the dps's are assumed to be I/O intensive, as a first approximation, this can be equated with access minimization. An *access* in this sense is defined as the reading or writing of a single secondary storage block, which corresponds to a single operating system I/O event. In Protosystem I, for a particular data set a *block* consists of a fixed number of records.

With this approximation the relative costs of alternative dps design configurations can often be assessed without knowledge of the particular target configuration. But sometimes actual cost estimates, provided by the Job Cost Estimator, are necessary. This module must thus contain knowledge of the charging scheme and operating characteristics of the target configuration (in our case the OS/360 configuration). Optimization with respect to a different configura-

tion and/or charging scheme would require the substitution of a new appropriately tailored module.

THE QUESTION ANSWERER

The function of the Question Answerer is to supply answers to questions from the Optimizing Designer about the average sizes (in records) of abstract aggregate data entities. Two examples of such data aggregates are a file and the collection of records in a file that are accessed by a particular computation. Each "question" sent to the Question Answerer is in the form of a predicate describing the conditions under which a record will be in the data aggregate in question.

The Question Answerer maintains a data base of all of the event probability and size information given by the user. When asked a question it attempts to find the associated size or probability directly. Failing this, it will try to calculate the probability of the event in question happening from those of its sub-events and its knowledge of event independence and correlation within the dps. If the information on hand is insufficient to answer the question, the Question Answerer obtains enough additional information from the user (through a flexible line of questioning) to do so.

THE OPTIMIZING DESIGNER

The Optimizing Designer is the heart of Stage 3; all of the other modules in this stage exist merely to serve it. When the translation from SSL to UDSL has been completed, control passes to the Optimizing Designer. This module is responsible for constructing job steps to implement computations and files to implement data sets. In particular its job is to:

1. design each keyed file—in particular its
   a. contents (information contained)
   b. OS/360 organization (consecutive, index sequential, or regional(2))
   c. storage device
   d. associated sort ordering (by key values)
   e. blocking factor (number of records per block)
2. design each job step of the dps—namely
   a. which computations it includes
   b. its accessing method (sequential, random, core table)
   c. its driving data set(s)
   d. the order (by key values) in which it processes the records of its input data sets
3. determine whether sorts are necessary and where they should be performed
4. determine the sequence of the job steps

The Optimizing Designer performs dynamic analysis (analysis of the operating behavior) on the dps to propose and evaluate alternative design configurations. Occasionally, static analysis (analysis of system structure and interrelationships) of such tentative configurations is also necessary, and this is obtained through calls to the Structural Analyzer. When additional information is needed to make evaluations and decisions the Question Answerer and the Job Cost Estimator are called.

All design decisions are made in an effort to minimize the total number of accesses that must be performed in the execution of the dps. There are three major techniques that the Optimizing Designer uses toward this end:

1. *Designing files and job steps to take advantage of blocking*—Accesses can be reduced if files are given blocking factors greater than one and if processing and file organizations are designed in such a way that the records of each block can be used consecutively.
2. *Aggregating data sets*—If two or more data sets that are accessed by the same computation are combined into one file (whose records have multiple data items) and processing is arranged so that a single record of the aggregate can be accessed where more than one record from each of the otherwise unaggregated files would have been accessed, accesses can be saved.
3. *Aggregating computations*—When two or more computations access the same data set and the orders in which they process the records of that data set are the same, it may be advantageous to combine them into a single job step. Then each record of the shared data set can be accessed once for all, rather than once for each computation.

These access minimizations techniques require that the key order of processing agree in a special way with the organization of the data being processed. Because different computations accessing the same data set may have different preferences for its organization, optimization of the type performed is necessarily a problem in global compromise.

The straightforward solution of evaluating the cost of every possible combination of assignments of sort order, device, organization, and access method for data sets and computations in every possible aggregation configuration to determine the least expensive is ruled out by the sheer combinatorics involved. Even with mathematical and special purpose tricks it would be impossibly slow.

To make optimization tractable a heuristic approach must be taken. First different kinds of decisions (e.g., choice of driving data sets, which objects to aggregate) must be decoupled wherever possible. Further decoupling must be judiciously introduced where it is not strictly possible, for the sake of additional simplicity. Such forced decoupling does not mean, though, that decisions that are in fact coupled are treated as if they were independent. The decoupled decisions are still made with a certain awareness of their effects on other decisions. Finally, as a first order approximation, the optimizer does what is reasonable locally, and then adjusts somewhat for global realities. While we make no claim that this approach will lead to the true optimum, it does produce good and usually near-optimal solutions for real and honest problems.

STAGE 4: CODE GENERATION

Stage 4 of Protosystem I consists of the PL/I and JCL Generator modules. The PL/I Generator takes the fully specified output of Stage 3 (the CDSL or Constrained Data Set Language description) as input and produces PL/I code for each job step. This involves the determination and arrangement of PL/I I/O specifics, the construction of the data processing loops, and the programming of the necessary calculations. The JCL Generator then writes IBM OS/360 JCL and ASP instructions for the I/O, administration and

scheduling of the compilation and execution of the dps job and job steps.

CONCLUSION

A model of the data processing system implementation process has been presented and a blue-print, based on that model, for automating the entire process has been developed. Protosystem I is a project to exhibit the feasibility of these ideas. Already, two of the four heretofore manual phases of the software writing process have been automated and are capable of producing acceptable implementations. The automation of the remaining two phases should easily fall within the realm of presently developing technologies within the next decade.

INTRODUCTION

Program synthesis is the automatic construction of programs to meet given specifications. These specifications constitute a high-level description of the desired program which expresses the purpose of the program, without indicating the method by which that purpose is to be achieved.

The specifications are expressed in terms of many constructs which are endemic to the particular subject domain of the desired program (e.g., numbers, sets, lists). Because these constructs are only intended to describe the purpose of the program and need not be computed, they can be of a much higher level than the constructs of any programming language (e.g., they can include logical quantifiers, set constructors, and other noncomputable operations). The specification language can correspond closely with the concepts a programmer actually uses in thinking about the problem.

The techniques we are developing are independent of the choice of a target programming language. The particular language we use in our examples and in our experimental system is a simple LISP-like language containing only basic numerical and list-processing operations, conditional expressions, and recursion. In considering the formation of programs with side effects, we extend the language to include assignments to variables, array elements, and other data-structure components.

Our basic approach is to transform the specifications repeatedly according to certain rules; each rule replaces one segment of a program description by another, equivalent, segment. The process continues until a description is obtained that is entirely in terms of the primitive constructs of the target language; this description is the desired program. The entire sequence of descriptions leading from the specifications to the final program is called a *program derivation.*

The transformation rules are guided by certain strategic controls, which ensure that they are applied only at the appropriate time. Many of the transformation rules represent knowledge about the program's subject domain; some explicate the meaning of the constructs of the specification and target languages; a few rules correspond to basic programming principles, which are independent of the particular subject domain or programming language.

The programs constructed by these techniques are guaranteed to be correct and to terminate, and require no separate verification phase. Up to now, we have not been concerned with the efficiency of the target program.

The techniques we develop are tested in the implementation of an experimental system called DEDALUS (DEDuctive ALgorithm Ur-Synthesizer). This system is implemented in the QLISP programming language, an extension of INTERLISP that includes pattern-matching and backtracking facilities.

The identification of the basic programming principles, their codification as transformation rules, and their implementation in our experimental system have constituted a major component of our effort. Some of the principles we have identified so far are:

- *Conditional formation*—This principle causes a case analysis to be introduced into the derivation, yielding a conditional expression (or test) in the ultimate program.
- *Recursion formation*—This principle introduces a recursive call into the ultimate program by observing when a subgoal to be achieved is actually an instance of the desired top-level goal.
- *Well-founded ordering*—The termination of the recursive programs formed by the above technique is ensured by constructing a well-founded ordering with the property that the arguments of the program's recursive calls are all strictly less than the program's inputs.

* This research was supported in part by the National Science Foundation under Grants DCR72-03737 A01 and MCS76-83655, by the Office of Naval Research under Contracts N00014-76-C-0687 and N00014-75-C-0816, by the Advanced Research Projects Agency of the Department of Defense under Contract MDA903-76-C-0206, and a grant from the United States-Israel Binational Science Foundation.

- *Procedure formation*—A subsidiary procedure is formed when a subgoal is found to be an instance, not of the top-level goal, but of a previously generated subgoal.
- *Generalization*—A generalized procedure is formed when two subgoals are found to be an instance of a third expression, which is somewhat more general than both.
- *Simultaneous goals*—In constructing a program to achieve two or more goals simultaneously, we first construct a program to achieve one goal, then modify that program to achieve the others as well, while protecting the condition that was already achieved.

Some of these principles are fairly well understood and have been incorporated into the DEDALUS system; others require further study. In the next sections we examine in some more detail our basic program-synthesis techniques, indicating which areas have already been implemented. Our treatment of these techniques will be extremely brief; further discussion of the same topics, at a more leisurely pace, appears in the authors' Stanford University-SRI International report, "Synthesis: Dreams⇒Programs" (November 1977).

GENERAL FRAMEWORK

Specifications

In designing the specification language, we have incorporated many constructs (e.g., the set constructor and the logical quantifiers) that facilitate the description of a program but that may not be included in the target programming language. We present below examples of specifications for simple programs using some of these high-level constructs.

A program *lessall(x l)*, to test if a number x is less than every element of a list l of numbers, is specified as follows:

lessall(x l)⇐**compute** $x<all(l)$
where x is a number and
l is a list of numbers.

In general, the specification construct *P(all(l))* denotes that the property P holds for every element of the list l.

The specification for a program to compute the greatest common divisor $gcd(x\ y)$ of two nonnegative integers x and y is

$gcd(x\ y)$⇐**compute** $max\{z : z|x\ and\ z|y\}$
where x and y are nonnegative integers and
$x\neq 0$ or $y\neq 0$.

The set constructor $\{u: P(u)\}$ denotes the set of all elements u satisfying the property P.

The *all* construct $(P(all(l))$ and the set constructor $\{u: P(u)\}$ are specification constructs that are nonprimitive (i.e., they are not in the target programming language). The synthesis task is to transform a description of the desired program, such as the specifications presented above, into an equivalent description that employs only primitive constructs of the target language.

The specification language is not fixed: as we consider new subject domains, we introduce new specification constructs accordingly.

Transformation rules

We use the notation

$t \Rightarrow t'$ if P

to denote that a subexpression of form t may be replaced by the corresponding expression t', provided that the condition P is true.

For example, the rule

$Q\ and\ true \Rightarrow Q$

denotes the basic logical principle that an expression of form "Q *and true*" may be replaced by Q. This rule has no conditions; it can always be applied.

The rule

$P(all(l)) \Rightarrow P(head(l))\ and\ P(all(tail(l)))$ if $not\ empty(l)$

expresses the fact that a property P holds for every element of a nonempty list l if it holds for the first element *head(l)* and for every element of the list *tail(l)* of the other elements. This rule imposes the condition that the list l be nonempty.

In the DEDALUS system, transformation rules are represented as programs in the QLISP language. The full expressive power of the programming language may be brought to bear in representing each rule.

Derivation trees

In developing a program whose specifications are

$f(x)$⇐**compute** $P(x)$
where $Q(x)$,

we establish the output description as a goal to be achieved, viz.,

Goal: **compute** $P(x)$.

Subgoals are derived from this goal by application of the relevant transformation rules. For example, in deriving the *gcd* program, we form the top-level goal

Goal 1: **compute** $max\{z: z|x\ and\ z|y\}$

By applying a transformation rule

$u|v\ and\ u|w \Rightarrow u|v\ and\ u|w-v$

we obtain the subgoal

Goal 2: **compute** $max\{z: z|x\ and\ z|y-x\}$.

If a transformation rule imposes a condition P, which must be true if the rule is to be applied, a subgoal of the form

Goal: **prove** P

must be achieved before the rule can be applied. For example, in developing the program *lessall*(x l) to test if a number x is less than every element of a list l of numbers, we have the top-level goal

compute $x<all(l)$,

which is obtained directly from the specifications; in attempting to apply the rule

$P(all(l)) \Rightarrow true$ if $empty(l)$

to this goal, we derive the subgoal

Goal: **prove** $empty(l)$.

From each subgoal that is derived, we can generate further subgoals by the application of more transformation rules. We thus construct a tree of goals and subgoals, which we will call a *program derivation tree*.

A subgoal **compute** S is already achieved if S consists entirely of primitive constructs of the target language. A subgoal **prove** P is achieved if P is the logical constant *true*. Such goals are terminal nodes of the derivation tree.

Let us now discuss some of the basic programming principles used in developing the derivation tree.

BASIC PROGRAMMING PRINCIPLES

Conditional formation

Many of the transformation rules impose conditions (e.g., l is nonempty, x is nonnegative) that must be satisfied for the rule to be applied. Suppose that in attempting to apply a particular rule, we fail to prove or disprove a condition P, where P is expressed entirely in terms of the primitive constructs of the programming language; in such a situation, the conditional-formation rule is invoked. This rule allows us to introduce a case analysis, and consider separately the case in which P is true and P is false. Suppose we succeed in constructing a program segment S_1 that solves our problem under the assumption that P is true, and another program segment S_2 that solves the problem under the assumption that P is false. Then the conditional-formation principle puts these two program segments together into a conditional expression

if P *then* S_1 *else* S_2,

which solves our problem regardless of whether P is true or false.

If we happen to generate the program segment S_2, say, without using the case assumption that P is false, then S_2 solves our problem regardless of whether or not P is true. In this case, no conditional expression is formed, and the program constructed is simply S_2. Thus, conditional expressions are generated only for truly relevant conditions.

The conditional-formation rule is among the best-understood of our basic programming principles and was among the first to be incorporated into the DEDALUS implementation. Other program-synthesis systems that form conditional expressions by case analysis have been implemented by Buchanan[1] and Luckham and Warren.[2]

Recursion formation

Suppose, in constructing a program whose specifications are

$f(x)$⇐**compute** $P(x)$
where $Q(x)$

we encounter a subgoal

compute $P(t)$

which is an instance of our *output specification*, **compute** $P(x)$. Because the program $f(x)$ is intended to compute $P(x)$ for any x satisfying its *input specification* $Q(x)$, the recursion-formation rule proposes achieving the subgoal by computing $P(t)$ with a recursive call $f(t)$. For this step to be valid, it must ensure that the *input condition* $Q(t)$ holds when the proposed recursive call is executed. To ensure that the new recursive call will not cause the program to loop indefinitely, the rule must also establish a *termination condition*, showing that the argument t is strictly less than the input x in some well-founded ordering. (A *well-founded ordering* is one in which no infinite strictly decreasing sequences can exist.) This condition precludes the possibility that an infinite sequence of recursive calls might occur during the execution of the program.

For example, the DEDALUS system derived the program *lessall* (x l), which tests whether a given number x is less than every element of a given list l of numbers. The specifications for this program are

lessall (x l)⇐**compute** $x<all(l)$
where x is a number and
l is a list of numbers.

In deriving this program, we develop a subgoal

compute $x<all(tail(l))$

in the case that l is nonempty. This subgoal is an instance of our output specification, with the input l replaced by *tail*(l); therefore, the recursion-formation principle proposes that we achieve the subgoal by introducing a recursive call *lessall* (x *tail* (l)). To ensure that this step is valid, the rule establishes an input condition, that

x is a number and
tail(l) is a list of numbers,

and a termination-condition that the argument pair (x *tail* (l)) is less than the input pair (x l) in a well-founded ordering. This termination condition holds because *tail* (l) is a proper sublist of l.

The final program we obtain is

lessall (x l)⇐*if empty* (l)
then true
else $x<head(l)$ *and lessall* (x *tail* (l)).

The recursion-formation principle is well-understood and is included in the DEDALUS implementation. The principle is the same as the "folding rule" of the Burstall and Darlington[3] program transformation system.

Procedure formation

Suppose in developing a program whose specifications are of the form

$f(x) \Leftarrow$ **compute** $P(x)$
where $Q(x)$

we encounter a subgoal

Goal B: **compute** $R(t)$,

which is an instance, not of the output specification **compute** $P(x)$, but of some previously generated subgoal

Goal A: **compute** $R(x)$.

The procedure-formation principle proposes that we introduce a new procedure $g(x)$ whose output specification is

$g(x) \Leftarrow$ **compute** $R(x)$.

In this way, we can achieve both Goals A and B by calls $g(x)$ and $g(t)$ to a single procedure. In the case that Goal B has been derived from Goal A, the call to $g(t)$ will be a recursive call; otherwise, both calls will be simple procedure calls.

For example, in constructing a program *cart* $(s\ t)$ to compute the Cartesian product s and t), of two sets, we are given the specification

cart $(s\ t) \Leftarrow$ **compute** $\{(x\ y): x \in s \text{ and } y \in t\}$
where s and t are finite sets.

In deriving the program, we obtain a subgoal

Goal A: **compute** $\{(x\ y): x = head(s) \text{ and } y \in t\}$

in the case that s is nonempty. Developing Goal A further, we derive the subgoal

Goal B: **compute** $\{(x\ y): x = head(s) \text{ and } y \in tail(t)\}$

in the case that t is nonempty. Goal B is an instance of Goal A; therefore, the procedure-formation rule proposes introducing a new procedure *carthead* $(s\ t)$ whose output specification is

carthead $(s\ t) \Leftarrow$ **compute** $\{(x\ y): x = head(s) \text{ and } y \in t\}$

so that we can achieve Goal A with a procedure call *carthead* $(s\ t)$ and Goal B with a (recursive) call *carthead* $(s\ tail(t))$.

The *carthead* procedure is constructed by the techniques we have already introduced. The final system of programs we obtain is

cart $(s\ t) \Leftarrow$ *if empty* (s)
then $\{\}$
else carthead $(s\ t) \cup$
cart $(tail(s)\ t)$,

where

carthead $(s\ t) \Leftarrow$ *if empty* (t)
then $\{\}$
else $\{(head(s)\ head(t))\} \cup$
carthead $(s\ tail(t))$.

The basic procedure-formation principle has been implemented, and the DEDALUS system can carry out this and other such derivations. However, our method for proving the termination of ordinary recursive calls does not always extend to the multiple-procedure case.

Generalization

Suppose in deriving a program we obtain two subgoals

Goal A: **compute** $R(a(x))$

and

Goal B: **compute** $R(b(x))$,

neither of which is an instance of the other but both of which are instances of the more general expression

compute $R(y)$.

Then the extended procedure-formation rule proposes that we introduce a new procedure, whose output specification is

$g(y) \Leftarrow$ **compute** $R(y)$,

so that we will be able to satisfy Goal A by a procedure call $g(a(x))$ and Goal B by a procedure call $g(b(x))$.

For example, in constructing a program *reverse* (l) to reverse a list l, we derive two subgoals

Goal A: **compute** *append*(*reverse*(*tail*(l))
cons(*head*(l)
nil))

and

Goal B: **compute** *append*(*reverse*(*tail*(*tail*(l)))
cons(*head*(*tail*(l))
cons(*head*(l) *nil*))).

Each of these goals is an instance of the more general expression

compute *append*(*reverse*(*tail*(l))
cons(*head*(l)
m));

therefore, the extended procedure-formation rule proposes introducing a new procedure *reversegen* $(l\ m)$, whose output specification is

reversegen $(l\ m) \Leftarrow$ **compute** *append*(*reverse*(*tail*(l))
cons(*head*(l)
m)).

This procedure reverses a nonempty list l and appends the result to m. Although the procedure solves a more general problem than the *reverse* program we actually require,

it turns out that the *reversegen* procedure is actually easier to construct. The final system of programs we obtain is

reverse (*l*)⇐*if empty* (*l*)
then nil
else reversegen (*l nil*)

where

reversegen (*l m*)⇐if *empty*(*tail* (*l*))
then cons(*head* (*l*) *m*)
else reversegen(*tail* (*l*)
cons(*head* (*l*) *m*)).

The generalization mechanism and the extended procedure-formation principle are just beginning to be formulated; the elaboration of these concepts is an important part of our projected effort. Generalization was proposed as a program-synthesis technique by Siklossy,[4] and is routinely performed by theorem-proving systems for proofs by induction (e.g., see Boyer and Moore[5]).

STRUCTURE-CHANGING PROGRAMS

In the discussion so far, we have been concerned with *structure-maintaining* (i.e., "side-effect-free") *programs,* which produce an output but effect no permanent change in the data objects of the programming environment. To produce *structure-changing programs,* which can effect such changes, we introduce structure-changing primitives, such as assignment statements, into our target language. To specify such programs, we admit new constructs into our specification language. Most notably, we employ **achieve** P to denote a program intended to make the condition P true.

All the principles we have applied to construct structure-maintaining programs may be adapted to construct structure-changing programs as well. However, certain new problems arise in the synthesis of structure-changing programs; among these is the *simultaneous-goal problem.*

In constructing a program to achieve two conditions P_1 and P_2, it is not sufficient to decompose the problem by constructing two independent programs to achieve P_1 and P_2 respectively. The program that achieves P_2 may in the process make P_1 false, and vice versa. Thus, the concatenation of the two programs will not achieve both conditions.

For example, suppose we want to construct a program to sort the values of three variables x, y, and z; in other words, we want to permute the values of the variables to achieve the two conditions $x \leq y$ and $y \leq z$ simultaneously. Assume that we are given the primitive instruction *sort*2(u v), which sorts the values of its input variables u and v. Then we can achieve each of our desired conditions independently by executing the program segment *sort*2(x y) and *sort*2(y z) respectively. However, the concatenation

*sort*2(x y)
*sort*2(y z)

of these two segments will not achieve both conditions simultaneously; in sorting y and z, the second segment *sort*2(y z) may make the first condition $x \leq y$ false.

To circumvent difficulties of this sort, we have introduced the following *simultaneous-goal principle*: To satisfy a goal of form

achieve P_1 *and* P_2,

first construct a program F to achieve P_1, then modify F to achieve P_2 while protecting P_1 at the end of F. The program-modification technique we employ is based on the "weakest-precondition operator" (Dijkstra[6]). A special "protection mechanism" (cf. Sussman[7]) ensures that no modification is permitted that destroys the truth of the protected condition P_1 at the end of the program.

To apply this principle to the goal

achieve $x \leq y$ *and* $y \leq z$

in the sorting problem, we first construct the program segment *sort*2(x y) that achieves the first condition. We then modify this program to achieve the second condition $y \leq z$. We cannot achieve this condition by inserting the instruction *sort*2(y z) at the end of the program, because (as we have seen) this modification violates the condition $x \leq y$, which we must protect.

However, our program-modification technique allows us to achieve a goal by inserting modifications at any point in the program, not merely at the end. In this case, the technique causes us to introduce the two instructions

if $y < x$ *then sort*2(x z)

and

if $x \leq y$ *then sort*2(y z)

at the beginning of the program segment. The modified program,

if $y < x$ *then sort*2(x z)
if $x \leq y$ *then sort*2(y z)
*sort*2(x y),

will achieve both conditions $x \leq y$ and $y \leq z$ simultaneously.

Similar techniques are employed by the system of Warren.[17]

The derivation of straight-line programs with simple side-effects is now fairly well understood; much work needs to be done on the derivation of structure-changing programs with conditional expressions and loops, and the derivation of programs that alter list structures and other complex data objects.

APPLICATIONS TO PROGRAMMING METHODOLOGY

Although the development of a practical program-synthesis system requires considerable research effort, certain applications of program-synthesis techniques to more restricted problems will be of more immediate practical value.

Various programming disciplines have been evolving that attempt to make the programming process simpler or more reliable. Let us consider several of these disciplines, to see where program-synthesis techniques may be applicable.

- *Structured Programming*—Like program synthesis, structured programming (cf. Dijkstra[8]) presents principles for deriving a program systematically from given specifications. However, the principles of structured programming are intended to guide a human programmer, whereas the principles of program synthesis are meant to direct a computer system. Nevertheless, we have found that some of the techniques we have developed for a program-synthesis system could well be employed by a human programmer. In particular, the recursion-formation principle is a better motivated guide for introducing a loop than the conventional structured-programming method for the same task.
- *Program Transformation*—In this approach (cf. Burstall and Darlington[3]), the programmer constructs a transparent program for his task, which is likely to be correct but which may be inefficient. This program is then transformed into an efficient equivalent program, which may be more difficult to understand. This transformation process is guaranteed to produce a program equivalent to the original. Program transformation may be regarded as a synthesis task in which the specifications are given in the form of a clear program in the target language. All the program synthesis techniques we have developed can be applied to program transformation as well.
- *Data Abstraction*—In this approach, the programmer expresses his program in terms of *abstract data types*, objects such as sets, queues, or graphs whose properties are well-defined but whose precise machine representation is left unspecified. When this program is complete, representations for its abstract data types are chosen and the program is transformed to replace the operations on the abstract data types by the corresponding concrete operations on the chosen representation (cf. Guttag et al.[9]).
- *Program Modification*—It is often observed that programmers spend more of their time extending programs that already perform some task correctly than they do in developing new programs. This process is particularly fraught with error, because in modifying a program, the programmer is likely to make some change that interferes with the program's original functioning. We have remarked that a program-modification technique was developed to support the simultaneous-goal principle. This technique can also be applied to perform independent program-modification tasks. The protection mechanism ensures that the modified program must still perform the task for which it was originally intended.

IMPLEMENTATION

It is difficult to develop or evaluate heuristic techniques without experimenting with an implementation. The DEDALUS system is a laboratory tool rather than a practical product. The system is implemented in QLISP (Wilber[10]), an extension of INTERLISP (Teitelman[11]) that includes pattern-matching and backtracking facilities. In this section, we will describe some of the special characteristics of our implementation without going into very much detail.

The specifications are expressed in a LISP-like notation. Thus, the output specification for the *lessall* program, which we wrote as

$$x<all(l),$$

is represented in the DEDALUS system as

```
(LESS X (ALL L)).
```

The output specification for the *gcd* program, which we wrote as

$$max\{z: z|x \text{ and } z|y\},$$

is represented as

```
(MAX (SETOF Z (AND (DIVIDES Z X)
                   (DIVIDES Z Y)))).
```

The target program is also expressed in LISP syntax.

The transformation rules are expressed as programs in the QLISP programming language. For example, the rule that we denoted by

$$Q \text{ and } true \Rightarrow Q$$

is represented by the QLISP program

```
(QLAMBDA (AND ←Q TRUE) $Q).
```

The rule

$$u|v \Rightarrow true \quad \text{if } u \text{ is an integer and } v=0$$

is expressed in QLISP as

```
(QLAMBDA (DIVIDES ←U ←V)
         (INSIST (PROVE ('(INTEGER $U))))
         (INSIST (PROVE ('(EQUAL $V 0))))
         TRUE).
```

Although the reader who is unfamiliar with the QLISP language may not understand all the details of the above programs, he may still observe that they are similar in form to the rules that they represent; the features of the QLISP language make this representation fairly direct. Because rules are represented as programs, we are allowed the full power of the programming language in expressing each rule.

The DEDALUS system currently contains more than a hundred such transformation rules. In expanding the system to handle a new subject domain, we simply introduce new rules.

The rules of the system are classified according to their *pattern*, their left-hand side. This pattern describes the class of subgoals to which the rule can be applied. Thus, the rules

$$u|v \Rightarrow true \quad \text{if } \ldots$$

and

$$u|v \Rightarrow u|v-u \quad \text{if } \ldots$$

both have pattern $u|v$, and can be applied to goals such as

compute $x|y+z$.

When a new goal is generated, the QLISP system retrieves those rules whose patterns match the form of the goal. This retrieval is facilitated by arranging the rules in a classification tree according to their patterns; thus the two rules above would be classified on the same branch of the tree. This mechanism allows us to avoid matching every rule in the system against each newly-generated goal.

If no rule matches the entire expression of a goal, its subexpressions are established as subgoals. If no rule matches any subexpression of a given goal, a *failure* occurs, and backtracking is invoked; the system attempts to find an alternate transformation that applies to a previous subgoal.

The QLISP pattern-matcher has special provisions for matching commutative functions. Thus, because the *and* operation is commutative, the rule

Q and true ⇒ *Q*,

represented as the QLISP program

(QLAMBDA (AND ←Q TRUE) $Q),

can be applied to goals of form "*true and Q*" as well as "*Q and true*". For this reason, commutativity rules such as

P *and* Q ⇒ Q *and* P

are not necessary in the DEDALUS system.

This kind of matching also occurs in the recursion-formation rule, in determining whether a new goal is an instance of some earlier goal. For example, in the actual synthesis of the *gcd* program, the top-level goal

compute $max\{z: z|x \text{ and } z|y\}$

is regarded as an instance of itself with the roles of x and y reversed, because the *and* function is commutative. The recursion-formation rule, therefore, is able to propose the recursive call $gcd(y\ x)$.

The final *gcd* program we obtain is

$gcd(x\ y) \Leftarrow$ *if* $y<x$
then $gcd(y\ x)$
else if $x \neq 0$
then $gcd(x\ y-x)$
else y.

Currently, the DEDALUS implementation incorporates the principles of conditional formation, recursion formation (including the termination proofs), and procedure formation, but not generalization or the formation of structure-changing programs. The techniques for deriving straight-line structure-changing programs were implemented in a separate system (see Waldinger[12]).

Representative samples of the programs constructed by the current DEDALUS system are the following.

Numerical Programs:

- the subtractive *gcd* algorithm
- the Euclidean *gcd* algorithm
- the binary *gcd* algorithm
- the remainder of dividing two integers

List Programs:

- finding the maximum element of a list
- testing if a list is sorted
- testing if a number is less than every element of a list of numbers (*lessall*))
- testing if every element of one list of numbers is less than every element of another

Set Programs:

- computing the union or intersection of two sets
- testing if an element belongs to a set
- testing if one set is a subset of another
- computing the Cartesian product of two sets (*cart*).

COMPARISONS WITH AUTOMATIC PROGRAMMING

It has been claimed (e.g., see Balzer[13]) that, for a complex programming task, it is unrealistic to expect the user to formulate complete, correct specifications for the desired program. In specifying an airline-reservation system, an operating system, or a spacecraft-guidance system, for example, we are unlikely to anticipate the desired behavior of the system in every possible situation. In some systems, the specifications for the program are formulated gradually through an extended dialogue between the user and the system. (See, e.g., Green[14] and Balzer et al.,[15] or the survey of Heidorn[16].) The dialogue is continued during the program-construction process, so that the user can aid in the design of the algorithm and resolve any ambiguities or inconsistencies the system might discover. Typically, these systems attempt to play the role of an expert programmer-consultant, and they tend to rely more on built-in or acquired knowledge of a particular subject domain than on deductive processes. By concentrating on basic programming principles, we have focused on general techniques that apply to any subject domain. The ultimate automatic programming system, of course, will combine specific subject knowledge with general deductive methods.

Automatic representation selection for associative data structures

by PAUL ROVNER
University of Rochester
Rochester, New York

INTRODUCTION

Motivation

One of the persistent hopes for rapid progress in Computer Science is that standard solutions to software design problems will be developed, analyzed, and used. In particular, the hope for high-level languages has always been that enough low-level detail could be left to "the system" to allow a mere human to develop solutions for enormously complex problems. An ideal high-level language would allow a programmer to concentrate on the conceptual development of a solution for his problem, rather than on the design of a representation for his solution once he can express it.

Although existing high-level languages insulate a user from many details, they still require him to do low-level design for many problems, especially for complex ones. Such cases arise either because the language provides only low-level storage structures (records, arrays, pointers, lists) with which the programmer must encode his algorithm, or because it provides a general-purpose data structure for which an arbitrary (and usually sub-optimal) representation design choice has been made a priori (LISP,[1] SAIL[2]). Any single representation choice for a general data structure is very badly matched to some problems; the user of a general data structure must often spend much time designing a way to avoid unacceptable inefficiencies. Furthermore, good storage structure design requires much clerical work, for which a person whose goal is to solve a problem will usually have little time or enthusiasm. An automatic system, on the other hand, is well suited to the job of systematically comparing the cost and applicability of the many representations that are available for program data. In addition, an automatic system is less likely than a person to overlook possible representation candidates.

The problem

This paper explores one aspect of the representation selection problem: storage structure selection for associative data structures. By "associative data structure," we mean a collection of associations between abstract items. We express associations as ordered lists ("tuples") of items. Thus, an association between n given items is (conceptually) an n element list of them, called an "n-tuple". The role of each item in an association is identified by its position in the n-tuple.

Before going into specific detail about representation selection, we present a simple example which will be used to illustrate technical details as they arise. The example data base is a collection of relations among family members, their genders, and their places of residence. For the most part, we will be concerned with three-part associations (triples) such as:

```
Sexof·Abby=Female
Parentof·Eric=Roberta
```

or abstractly A·O=V. The A,O,V notation comes from considering the association as:

```
Attributeof·Object=Value
```

We view a collection of associations in the computer as a software "associative memory."[3] That is, one could retrieve any (3-part) association by specifying any one or two of its positions. Figure 1 describes these possibilities.

An associative language will contain operations like:

```
Make Parentof·Eric=Paul
```

and

```
Erase Homeof·ANY=Valhalla
```

which add or delete associations or sets of associations from the collection. There will also be operations to retrieve and make use of associative information like:

```
Print (Sexof·Peggy)
```

and

```
Foreach PERSON such that
  Homeof·PERSON=Rochester do
    Print (PERSON, "lives in Rochester").
```

Form	Example	Interpretation
A·O=V	Homeof·Paul=Valhalla	The association itself, if present
A·O=X	Parentof·Eric=PARENT	Parents of Eric
A·X=V	Parentof·CHILD=Paul	Children of Paul
X·O=V	RELATION·Eric=Rochester	Attributes linking Eric to Rochester
A·X=Z	Parentof·CHILD=PARENT	Child-Parent pairs present
X·Z=V	RELATION·PERSON=Male	All pairs of attributes and objects yielding Male
X·O=Z	RELATION·Abby=VALUE	All attributes of Abby and their values

Figure 1

In the latter case, PERSON is a variable that is repeatedly "bound" to the middle (Object) position of associations matching the pattern.

We are interested in how to implement a programming system that can do such operations efficiently. The difficulty, of course, is that each program is different and one cannot expect a single implementation to be best for all programs. What is required is an "intelligent compiler" which selects a different collection of storage structures for each program. The first such effort[4] was concerned primarily with sets and lists, which are simpler to deal with than associations. This paper explores the automatic selection problem for associations, and describes an experimental system (called the "selection system") which embodies our ideas. The discussion centers around associative data structures which fit into some "main" memory. (The problem for structures in several different kinds of memory is more complex.)

The following discussion illustrates the behavior of the system using the following simple program as an example:

```
BEGIN
   Attributes Parentof, Sexof, Homeof
   Item Constant Male, Female, Peggy, Abby, Rochester,...
   Item Variable CHILD, PARENT
     Make Parentof·Abby=Paul
     Make Parentof·Abby=Roberta
     Make Sexof·Abby=Female
     Make Homeof·Abby=Rochester
     Make Homeof·Thor=Valhalla
                .
                .
                .
(1)  Foreach CHILD, PARENT such that
        Sexof·CHILD=Male
         and Parentof·CHILD=PARENT do
         Print ("Sonof" PARENT "is" CHILD)
(2)  Foreach CHILD, PARENT such that
        Parentof·CHILD=PARENT
         and Homeof·PARENT=Rochester do
         Print (CHILD "writes home to Rochester for
         money")
END
```

Figure 2

First let us consider the even simpler program with the part in the box omitted. The program builds a collection of associations involving the three attributes. The "Foreach" part computes (parent,son) relationships in two steps. First it chooses an association of the form

Sexof·O=Male

and binds CHILD to the value of "O" in the association. It then uses that value to match an association of the form

Parentof·CHILD=V

and assigns the matching V to Parent, and prints. This is repeated until there are no more matching associations. We will see how the system chooses storage structures for this simple program.

A MODEL OF ASSOCIATIONS AND HOW THEY ARE USED

How should a program (in an associative language) be described for the purpose of designing a storage structure for its associative data structures? The first thing to note is that a program usually deals with more than one class of association. A class of associations is a group which will be represented the same way internally. In the example, there are two classes: one based on the Parentof relation and one on the Sexof relation. Since there are no searches on the Homeof relation (with the boxed statement omitted), the selection system would not include those associations at all. For each class of associations, the system will characterize the operations performed on that class and the possible values for unbound variables. In our simple case, each class has several MAKE operations and one SEARCH.

The differences among classes of associations are often reflected in the ways that the program accesses and modifies them. That is, a program often uses different parameter patterns for associative operations on different classes of associations. For example, the simple program includes a search for male children, i.e.,

⟨given: Sexof⟩·⟨variable to be bound⟩=⟨given: Male⟩

but not for the sex of a given child, i.e.,

⟨given: Sexof⟩·⟨given: Eric⟩=⟨variable to be bound⟩

For the "Parentof" association, on the other hand, there are two SEARCH parameter patterns (with the statement in the box included):

⟨given: Parentof⟩·⟨given: a child⟩=⟨variable⟩

and

⟨given⟩·⟨variable⟩=⟨variable⟩

In another case, a program may require access to attributes that relate two items, for example spatial relations between two objects in a 3-D scene: above, below, behind, or in-front-of.

Other reflections of the differences in associations are to be found in properties of the associations themselves. For example, the sex of a person has only one value, but a parent may have several children.

Often, the conceptual differences in the associations with which a program deals provide information that is useful for making low-level representation decisions. For example, a representation that immediately comes to mind for the Sexof attribute is a pre-defined (at compile-time) field of every PERSON record, to hold a code (one bit is enough) which specifies Male or Female.

If the program used only searches for the sex of a given child, such a representation would be just fine. But the program does not use the Sexof relation this way, but instead asks that people who are Male be enumerated. The above representation would require that all PERSON records (both male and female) be scanned for ones that are marked "Male". For this purpose, a list of male people might be a better representation. This example points out that classes of associations should be characterized both in terms of the operations of the program and the properties of the data.

Now that we have an intuitive understanding of what "class of associations" means, we will define it more precisely, and sketch how the automatic selection system determines the different classes of associations that a given program uses.

The process begins with a flow analysis phase, in which the system determines the possible run-time values of item variables at their points of use in the program, and the possible associations that could exist at run-time. The first approximation to the collection of classes of associations is one class for each MAKE statement, representing those associations that the MAKE statement would create (at run-time). For our simple example, each such class would contain one triple.

The next phase causes two classes to merge if any single SEARCH or ERASE operation could access associations from both classes. The basic idea is that each SEARCH or ERASE operation divides the store of triples into two subsets: those triples which could match the parameter pattern of the operation (subset A) and those triples which could not (subset B). If the A subsets for two operations intersect, the algorithm merges the subsets, and associates both operations with the result. This continues until there are no more mergers to perform. The result is a model of the (disjoint) sets of triples (called "classes of triples") that will exist when the program is run. Each class has an associated set of operations which access only the triples of the class. The use of this algorithm reflects an implicit assumption about computation cost: a representation that would require access to more than one storage structure to service a single associative retrieval operation is assumed a priori to be too expensive. For our simple example (with the statement in the box included), the algorithm would yield three classes of associations: one for each of the three attributes.

A LIBRARY OF REPRESENTATIONS

The automatic selection system knows how to deal with roughly twenty different storage structure representations, but these are all based on a few fundamental concepts. One representation of a set of triples is simply to store triples in a vector of entries three items wide and to search all entries for the answers to the questions in Figure 1. There are a variety of record techniques in which a fixed location in a block of storage is associated with an attribute, e.g., one could have records for people with a Sexof field, etc. Another common technique is to form a linked list of attribute-value pairs for a given object (a "property-list"). Other useful ideas include inverted lists (a link through all tuples which contain a given item), hash-coding,[5] and using one-bit fields to represent the presence or absence of a property.

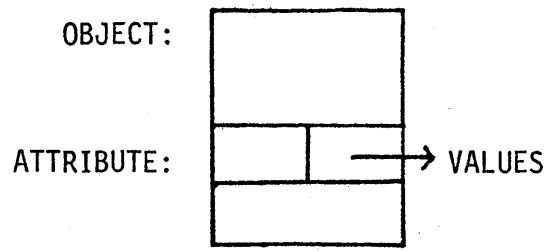
The selection system has a built-in library of representations for associations. The library is organized in two parts: "associative retrieval techniques" for servicing individual associative operations, and "associative representations" for common combinations of operations. The following discussion introduces the retrieval techniques and storage structures that provide access to triples, and describes the ways in which the storage structures can be varied and combined to synthesize "representations." This two-level organization is useful for proposing candidate representations: The analysis of which retrieval techniques are applicable to each associative operation on a class of triples need not be re-done for each (composite) representation that is considered. For example, once hash-coding is eliminated as a possible retrieval technique for an operation, no representations which would use hash-coding for the operation will be tried. Such methods for avoiding duplication of analysis effort are crucial for controlling combinatorial explosion in the selection process.

We have chosen four basic retrieval techniques upon which to base the example representations in the library: field selection records, property lists, inverted files, and hash tables. The diagrams in Figure 3 illustrate simple storage structures which implement these retrieval techniques.

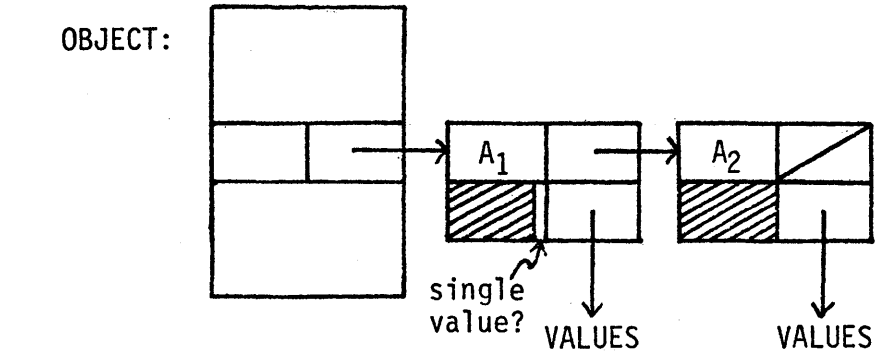
The library consists of twenty-three prototype representations which are based on these simple storage structures. We sketch these below: for a complete discussion, see Reference 6.

For the purpose of the discussion below, we will assume

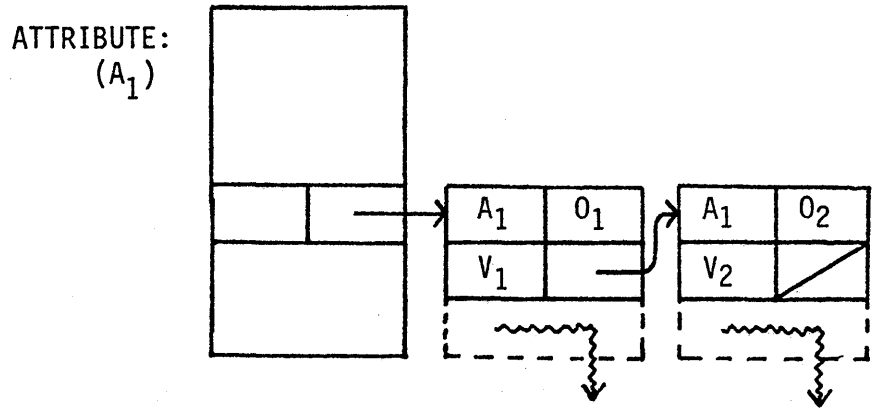
1. FIELD SELECTION RECORD



2. PROPERTY LIST SEARCH



3. INVERTED FILE SEARCH



4. HASH TABLE LOOK-UP

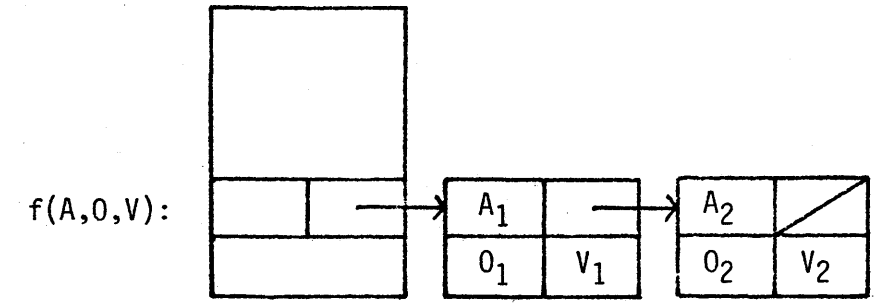


Figure 3

that each item has a unique (integer) "internal name." We will discuss using this integer as a hash-code operand, or as a key to various useful information about the item. Specifically, we will assume that the internal name of an item is a pointer to a block of contiguous storage cells, and refer to such blocks as "item descriptors." A typical item descriptor contains space for bit vectors and pointers to various lists that the selection system might allocate for triples that contain the item.

Field selection records

There are three variations, corresponding to the cases where the value field of the triple is binary (one bit), single-valued (e.g., the Homeof attribute), and multiple-valued.

Complex inverted list

This representation provides one sequential block of storage cells in memory for each triple (called "triple block"), with one field for each item. Each block can be threaded on either one, two, or three lists: one list for each item in the triple. The head of each such list is contained in an item descriptor.

P-List

A P-list is a list of (attribute-value) pairs. The head of each list is contained in the item descriptor for each object. There may be more than one value for each (attribute,object) pair.

Two argument hash-table

Two items (internal values of the attribute and object) are hash-coded (using a bucket hash) to locate a cell in a hash-table; the cell contains the attribute, the object, and a list of values. The cell can be threaded in either one or two lists: one list for each hash operand. The header for each such list resides in the item descriptor for the item which is the hash-operand. This variation is effectively a combination of a hash-coding retrieval technique and either one or two P-list retrieval techniques.

Another variation of the hash-table representation is to thread each value in an inverted list (of triples which have that value). Each of these representations combines a hash-coding retrieval technique with an inverted file retrieval technique.

A third variation is to use entries in the hash table to point to triple blocks, which can be threaded in a complex inverted list.

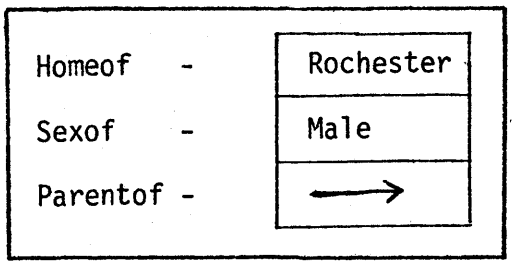
Three argument hash-table

The three item internal names are used as hash-coding operands. Each cell in the hash table represents one triple either by storing the three items, or by pointing to a triple block (which can be threaded as above). In addition, each cell can be threaded in one, two, or three inverted lists.

The above representations allow great flexibility in combining property-list, inverted list, and hash-coding retrieval techniques. This flexibility is most useful for dealing with ERASE operations, which must delete all paths to a triple in a complex representation when the triple is erased. In particular, certain of the above representations support back-pointers in their internal lists. The selection system makes use of this information. A more thorough discussion of the details is beyond the scope of this paper; the reader is referred to Reference 6.

Each retrieval technique in the library is associated with an "applicability" rule. This is an heuristic which is used to determine whether the access structure should be used to realize a given ERASE or SEARCH operation. Applicability rules usually reflect "common sense" (to a storage structure designer) rules, and are employed to limit combinatorial explosion in the selection process. These are useful constraints that represent pre-canned cost analysis decisions, like "blind search should be avoided whenever possible". Applicability rules are also used to detect relatively common special cases for which an unusual representation is particularly well suited.

For example, let us consider the basic record-style representation of a triple. A typical choice for the sample universe described above would be to have a record for each person with fields for his Sex, Home, and Parents. Since there may be two parents, the Parentof field might point to a set of parents, yielding something like the following structure for Eric:



There are additional complications, such as how to represent the set of parents. More to the point, this representation will not support an associative search such as:

Parentof·CHILD=Paul

without exhaustive search. The applicability rule for the record-style access structure would eliminate it as a candidate for the Sexof association because of the need for exhaustive search. Figure 4 contains a partial list of the computation cost tradeoff assumptions that underlie the heuristic applicability rules.

It is the nature of heuristic search that it is always possible to concoct situations in which a path that would turn out to yield an optimal solution is left untried. As for any heuristic method, the use of applicability rules is meant to achieve a

1. It is cost effective to maintain ordered lists of VALUE items in instances of the following access structures:
   Field Selection Records
   Property lists
   Two Operand Hash Tables
2. It is not worthwhile to consider an associative retrieval algorithm which requires that all items that could appear in a given operand position for a given class of triples be enumerated and tested.
3. The bookkeeping overhead for dealing with storage blocks for Field Selection Records whose lengths might vary at run-time is not cost effective.
4. It is cost effective to maintain an ordering relation on the elements of a property list access structure.
5. It is not worthwhile to consider an associative retrieval algorithm which requires the examination of all triples in a property list access structure for a given item.
6. It is cost effective to maintain an ordering relation on the elements of an inverted list access structure.
7. It is not worthwhile to consider an associative retrieval algorithm which requires the examination of all triples in an inverted list access structure for a given item.
8. It is cost effective to use the necessary storage space and execution time to maintain explicit "back pointers" in an inverted list access structure if it would otherwise be necessary to search the list from its beginning to find the list element which precedes a given one.
9. A hash coding scheme which uses chaining for collisions is as good as any other hash coding scheme.
10. It is not worthwhile to consider an associative retrieval algorithm which requires preliminary searching to locate the buckets in a hash table which might contain answers.

Figure 4

compromise between optimal solutions at tremendous expense and poor solutions that are easy to find.

STRATEGIES FOR PROPOSING REPRESENTATIONS FOR THE TRIPLES OF A GIVEN PROGRAM

Proposing non-redundant representations

This section describes how the selection system uses the model of a class of triples and the information in the library of representations to propose storage structures to represent the class. Proposal proceeds in two phases. First, each operation is analyzed to determine a set of applicable techniques. Next, an attempt is made to find representations which provide an applicable technique for each operation of the class. Heuristic rules are used to eliminate inefficient representations.

For each operation on the class, each technique in the library is examined. If its applicability criterion is satisfied for the operation, it is added to the set of techniques that are applicable to that operation. A technique may apply to an operation in more than one way. For example, suppose we had a SEARCH operation of the form:

⟨given⟩·⟨given⟩=⟨variable⟩

(like Parentof·⟨given child⟩=⟨variable to bind⟩)

and we were considering the inverted file technique. We could either keep a list of triples for each item which appears as ATTRIBUTE (e.g., Parentof), or we could keep a list of triples for each item which appears as OBJECT (e.g., child). In the first case, we would use the given ATTRIBUTE to locate the list, and then search it for triples which have the given OBJECT. In the second case, we would use the OBJECT to locate the list, and then search it for triples which have the given ATTRIBUTE. Locating such an inverted list of triples is a simple computation: the pointer to the list would be contained in a known field of the ATTRIBUTE's (OBJECT's) item descriptor. The internal name of an item is a pointer to its item descriptor; the selection system would assign one field of the descriptor to contain the pointer to the inverted list.

In the above example, the two options are represented by the selection system as a set of permutations of the triple operand pattern, as follows:

{(AOV),(OAV)}

The convention for denoting variations of the inverted file technique is that the first letter in a permutation indicates the position by which the list is accessed, and the second indicates the position by which the list is ordered. The two options here are "the list is accessed by A (i.e., ATTRIBUTE), and ordered by O (i.e., OBJECT)," and "the list is accessed by O, and ordered by A." For our simple example, these correspond to keeping a single list of all (child,parent) pairs, ordered by the internal name of the child, and keeping an unordered list for each child of his parents.

After each operation in a class is associated with all techniques that can be used to realize it, the second phase of proposal occurs: finding candidate storage structures that provide techniques for all operations of a class. In our example (with the statement in the box included), the Parentof class has two search operations, with the following forms:

⟨given⟩·⟨given⟩=⟨variable⟩

and

⟨given⟩·⟨variable⟩=⟨variable⟩

A slightly more complex case is a class with several operations where all operations have the same set of applicable techniques, and for each of these techniques the same set of permutations. This will occur, for example, if all operations of the class have the same form (i.e., the same pattern of ⟨given⟩,⟨variable⟩, or ANY parameter descriptions). In such a case we treat the set of operations as a single operation, and the task is the same as described above. All operations of the class will use the same associative retrieval technique.

In the general case, there are several forms of SEARCH operations which retrieve associations, and the sets of applicable techniques are not the same for all operations. Even in such a case, the intersection of these sets may not be empty. That is, there may be at least one technique which is applicable to more than one operation. The general prob-

lem is to find ways to decompose a set of operations into subsets each of which can be serviced by one associative retrieval technique.

Each representation in the library is cross referenced by the retrieval techniques that it provides. The algorithm for proposing representations for a decomposition is sketched below:

> Each representation which provides the required number of techniques is considered. Each applicable technique of each subset of operations in the decomposition is examined. If it is a technique provided by one of the representations, then the applicability rule for each such representation is evaluated. The evaluation yields a (perhaps empty) set of "candidate representations" to be proposed.

Each such "candidate representation" is a data structure which instantiates one of the representations in the library. That is, it specifies which retrieval techniques are to service which (subsets of) operations, and how (i.e., the operand permutation). In other words, an applicability rule for a representation specifies acceptable matches between the techniques that are provided by the representation and the techniques that are applicable to the given operations.

To avoid duplication of effort, the selection system treats similar candidate representations as a unit whenever possible. Specifically, candidate representations which differ only in their operand permutations are usually treated as a unit. For instance, the inverted file representation for the example above has two permutations which would be treated as a unit until final cost analysis is done.

The system cannot always treat representations which differ only in their operand permutations as a unit. Aside from a few such special cases, however, differences in operand permutations are ignored until cost analysis is done, thus saving both space and time in the early phases of automatic selection.

Proposing redundant representations

The discussion above describes a method for proposing candidate representations for a class of triples where each triple in the class is stored in memory only once. In such a representation, each triple will be represented by either one triple record (with perhaps several threads), or one VALUE cell (perhaps in a list of them), or one field of an item record.

The selection system also considers representations in which triples are stored more than once. The advantage of keeping multiple copies is that each copy can serve a special purpose for which its storage structure can be custom designed. In a case where there is no single representation which will service all the operations on the class efficiently, there may be a way to decompose the set of operations into subsets for which efficient special purpose representations can be found. It is more likely that an efficient storage structure can be found for a small set of associative operations than for a large set. Depending on the cost tradeoff between storage space and execution time, such a decomposition might be "cheaper" than a monolithic representation, even though more storage space is required. For example, a membership relation ("Memberof·Set=Element") between sets and their elements might be represented both as a list for each set of its elements and as a list for each element of the sets to which it belongs. Such a representation would provide speedy access both for queries about the elements of a given set:

Memberof·⟨given⟩=⟨variable to bind⟩

and for queries about the sets to which a given element belongs:

Memberof·⟨variable to bind⟩=⟨given⟩

To propose redundant representations, the selection system uses the method for proposing non-redundant representations as a subroutine. The problem is to discover decompositions for which efficient redundant representations can be found. The method is based on enumerating the ways of partitioning the set of ERASE and SEARCH operations on a class of triples. Roughly, we look for ways to decompose the set of operations on a class into a collection of subclasses, each of which can be analyzed for applicable storage structure representations (using the methods described above) as if it contained the only operations on the class. The idea is to capture in the notion of "subclass" a way to identify groups of operations for which efficient storage structures exist. The result of the analysis of a given class of triples is a collection of candidate redundant representations, each having one "efficient" (see below) storage structure for each subclass in one partition. Thus, for a particular partition (i.e., set of n subclasses), each proposed representation requires n copies of each triple: one copy in each of n storage structures. Each MAKE operation for the class of triples must create its triple in each of the n storage structures, and each ERASE operation must remove triples which match its operand pattern from all n storage structures (problems of critical races and deadlock do not arise).

In our example of a redundant representation for a set membership relation, each association would be stored twice: once as an entry on the list of elements in the given set, and once as an entry on the list of sets which contain the given element.

In any representation, each execution of a SEARCH operation must find all triples which satisfy the operand pattern of the SEARCH. We assume that each SEARCH operation is associated with exactly one subclass. That is, it will find all its answers from one storage structure. Thus, each subclass must service all MAKE operations for the class. For consistency, each storage structure will contain all the triples of the class (one could imagine clever ways to relax this requirement, but we do not consider them here).

Unless the rules for acceptable redundant representations are more restrictive than the rules for non-redundant representations, the number of candidate representations will be very large, and the cost of the overall analysis will be huge. There is always a way of using our library and

applicability rules to design a storage structure to service a given set of associative operations. If everything else fails, a complex inverted list representation could be used, with a separate thread for each operation. Thus, every possible subclass would be acceptable, and each partition of the class of triples would be plausible. If several representations were applicable to each subclass, things get worse. If we consider the fact that the number of applicable redundant representations for a partition is the product of the numbers of representations for its subclasses, we can begin to see that unless the applicability rules are tightened for subclasses, there could be very many candidate redundant representations indeed.

To limit the combinatorial explosion of candidate representations that use multiple copies of the store of triples, we have chosen a specific notion of efficiency and an heuristic rule to decide when to propose such representations. In general, we consider a storage structure to be inefficient for an operation if significant searching is required to service the operation. Many of the cost tradeoff assumptions that are used by the selection system are based on this idea, and they provide (crude) thresholds for early detection of representations that are likely to be eliminated eventually in the detailed cost analysis. The most expensive kind of searching is "unrestricted" searching; it is this sort that the applicability rules disallow. For example, we do not even consider a record technique for a SEARCH operation which has only the ATTRIBUTE given; a search through all possible items which could be the OBJECT of a triple would be required to perform the SEARCH. It is convenient to distinguish four types of search:

1. unrestricted
2. loosely restricted
3. tightly restricted
4. fully restricted

An example of "unrestricted" search is given above. By "loosely restricted" search, we mean (for example) search for elements which have a given attribute in a list of (attribute-value) pairs. By "tightly restricted" search, we mean (for example) search for a given item in a set of them (e.g., is Paul a Parentof Eric?). By "fully restricted" search, we mean access to answers via computation rather than search, e.g., selection of a given field of a given record, or hash-table look-up.

The cost tradeoff assumptions used in proposing non-redundant representations lead to applicability rules which eliminate representations that require unrestricted search. Loosely restricted search is allowed for non-redundant candidate representations, but not for redundant ones. In other words,

> We assume redundant representations which require loosely restricted search to be inefficient enough to be eliminated a priori as candidates for final selection. Intuitively, it is only worth the price of multiple representations if searching can be tightly (or fully) restricted.

As redundant representations are synthesized for a class of triples, they are tested for loosely restricted search requirements. If such search is required, the representation is not proposed as a candidate.

Now we consider the problem of proposing candidate redundant representations. The crude way to do it is to generate all possible ways of partitioning the set of SEARCH and ERASE operations of the class of triples. For each partition, each subclass would then be analyzed to determine applicable non-redundant representations. The cross product of the sets of representations for the subclasses of a partition would be the applicable redundant representations. The partition with one subclass (i.e., non-redundant) would fall out.

The inherent symmetry of the problem leads to combinatorial duplication of effort; early detection of situations that have already been analyzed is important.

The analysis deals with subclasses, which are sets of SEARCH, ERASE, and MAKE operations, and partitions, which are (initially disjoint) sets of subclasses. Each associative operation corresponds to an expression in the source program, and is represented by the corresponding expression node in the syntax tree of the program.

The selection system uses a central data structure to keep track of the subclasses and partitions which it analyzes. This data structure (called the "set dictionary") is similar in motivation to the "discrimination net" of QLISP:[7] it associates a unique descriptor with each set that is entered.

The set dictionary is used by the selection system to avoid duplicating:

1. The computation of applicable non-redundant representations for each unique subclass (i.e., set of operations).
2. The computation of redundant representations for each unique partition.

Whenever a new subclass or partition is analyzed, it is entered into a set dictionary and the result of the analysis is recorded with the entry. A sketch of the method for proposing candidate redundant representations is presented below:

> A recursive function in the selection system generates the partitions of a set of operations, using another recursive function to generate the subsets (subclasses) of the given set. Each subset that is generated is looked up in the set dictionary. If not found, it is assigned a (new) descriptor, entered, and tested to determine whether applicable representations exist (this test considers cost tradeoff assumptions for redundant representations. The new descriptor is associated with the result of the test. If it is found in the set dictionary, then it has already been tested. If the result of the test indicates no applicable representations exist, then the next subset is generated and the process continues. Thus, no subset is considered further unless it has applicable representations; i.e., once a subclass is analyzed and found to fail, no partition which contains the subclass will be considered. Furthermore,

because of the structure of the library, if a subclass fails, any subclass that contains it will fail. In other words, if there is no efficient representation for a given set of n operations, there will not be one for any larger set that contains the n operations. Thus, supersets of failed classes can be eliminated automatically.

A method similar to the one described above for subclasses is used for avoiding duplication of analysis effort for partitions. A partition is a set of subclasses. Each such set has a unique entry in the set dictionary. Thus, there are two kinds of entries in the set dictionary: sets of operations (subclasses) and sets of subclasses (partitions). After a partition is analyzed the first time, its descriptor is marked, and subsequent attempts to analyze it are short-circuited.

The cost of avoiding duplication of analysis effort is the set dictionary look-up time; the large relative cost of analyzing a subclass makes this overhead worthwhile. Another advantage of using the set dictionary is that storage space is conserved: only one copy of each unique set is kept, and only one copy of the analysis results is kept.

HOW TO SELECT A GOOD REPRESENTATION FROM THE CANDIDATES

In this section we show how to estimate the cost of each candidate representation and choose the cheapest one. We consider two components of computation cost: execution times (in micro-seconds) and storage space (in 36-bit words). For a given program, we are interested both in the execution time required to service its associative operations, and the storage space required for its associative data structures. We use three kinds of parameters to characterize each class of triples in a given program:

1. the average sizes of substructures of the class of triples (e.g., For a given A and O, how many V's will there be on average?).
2. probabilities of occurrence of searches that fail and changes that are redundant.
3. relative frequencies of statement executions.

The computations for estimating the space and time costs of a given candidate representation for a given class of triples are based on evaluating formulas which are expressed in terms of these parameters. Each representation in the library is supplied with two functions: one for estimating storage space cost, and one for estimating execution time cost. The arguments to a space function specify a set of associative operations and for each operation the associative retrieval technique that will be used to realize it if the given representation is chosen. This information is used by the space function to identify the parameters for estimating storage space cost.

A function for estimating time cost is a little more complicated. The arguments are the same, but the time function must sum the estimated contributions to total execution time of each of the operations. For each operation, this estimate is the product of two terms: the number of times the operation was executed in the sample execution and the estimated cost of one execution of the operation for the candidate representation. The estimated time cost of one execution of the operation is determined by a formula that is specific to the use of the indicated associative retrieval technique in the indicated representation. Each representation in the library is provided with formulas for each of its associative retrieval techniques. There is one such formula for each associative operation to which a technique applies. Thus, for each operation, the arguments to the time function are used to select a formula and to identify necessary parameters.

For our example, the space cost formula for a record representation for Parentof and the time cost formula for a search operation of the form

$$A \cdot O = X$$

are shown in Figure 5. The space formula represents the requirement that there be a field of each record (0.5 cells) for each set-valued attribute (e.g., Parentof), and that space for the set of values is needed. In our example, there is only one attribute (Parentof), hence NA=1. NO (number of objects) represents the number of people. NVALS(A,O) represents the average number of parents per person.

The flow chart for the search algorithm is also shown in Figure 5. The time cost formula represents the cost of the algorithm. C1, C2, and C3 are constant terms; to a good

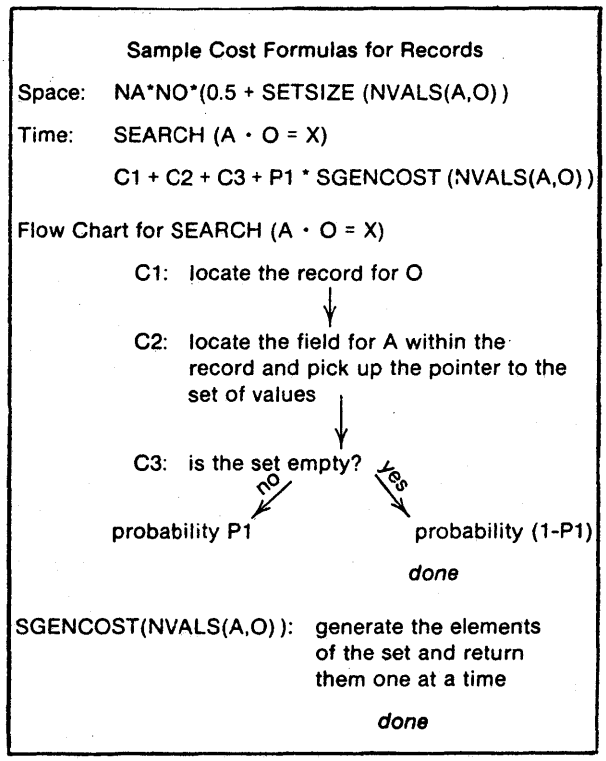


Figure 5

approximation they depend only on the machine and on basic design decisions and can be determined a priori. P1 represents the probability that the search succeeds. The call on the SGENCOST function represents the execution time required to generate the elements of a set of a specified size (NVALS(A,O)). The values of P1, NO, and NVALS(A,O) are determined from answers to questions that the system asks. The choice of which questions to ask is based on which cost formulas are being used in a given run of the selection system.

Parameters that depend only on the representations in the library (e.g., C1, C2, C3) are determined once when the library is defined, and built into the library. Their values are always available. Parameters that depend on the program are determined from information supplied by the programmer in response to questions that the selection system asks.

For example, the selection system asks three questions about the use of the Sexof relationship in our simple example. They are:

1. How many males are there likely to be? Sample answer: 5.
2. How often will the Sexof search fail to match? Sample answer: Never.
3. How often will a redundant MAKE occur? Sample answer: Never.

Not all parameters are needed: only ones required to evaluate formulas that are relevant to the representation candidates for a class of triples. Moreover, some parameters can be computed from others. For example, if the answers to

"For a given A, how many O's (AVG) will have at least one V?"

and

"For a given A and O, what is the average number of V's?"

are known, then the selection system can deduce the average number of triples, since it can determine (by asking a question, if necessary) the average number of items that can appear in a triple of the class in a given position. Thus, any two of the above three answers determine the third. The system makes use of such dependencies to derive needed parameters from available ones if it can. If it can't, it will ask a question.

We should say a word here about our assumptions regarding parameters. In any system that does automatic representation selection, a model of the expected behavior of the program is necessary. To make the analysis tractable, we made many intuitive decisions about the appropriate level of detail for cost formulas and their parameters. Two major assumptions about program behavior characterize our model and underlie our work on cost analysis:

1. It is in general impossible to tell for an arbitrary program precisely how it will behave when it is executed. Instead, we depend on the relative frequencies of statement executions in one example execution, and on estimates given by the programmer about program behavior and data structure size. We assume that the programmer has good enough intuitions about his program to provide a good general characterization. After all, he would have to use such intuitions if he were to design a representation without the help of an automatic system.
2. To really do an optimal selection, we would need to use distributions of the values of the relevant parameters both over time within a run and between runs. We assume here that use of the average values of parameters (i.e., scalars) over the entire execution of the program provides enough information for good decisions about representation choice.

In other words, we are using a crude estimate of computation cost. This estimate should be useful for gross distinctions, but not fine ones. A human storage structure designer works much the same way: he often uses rough estimates of relative frequencies of operations and of relative sizes of data structure components to guide the choice of a storage structure.

Because we are not making precise distinctions for estimating cost, it is not necessary to formulate precise characterizations of the associative search techniques and storage structures in the library. It is adequate to outline each algorithm and compose a cost formula for it in terms of the costs of its primitive steps, the parameters that describe average data structure size, and the parameters that describe expected program behavior. After enough experience with automatic selection systems like this one, we will learn where (heuristics, libraries, formulas, parameters, etc.) additional effort should go.

After both space and time costs are estimated, if a representation is at least as expensive in both time and space as one already analyzed, it is eliminated as a candidate. Otherwise, its estimated overall computation cost is computed (see the discussion below), and it is added to an ordered list of candidates that have already been analyzed. The list is ordered by estimated overall computation cost. The final step in the current selection system is to print out detailed descriptions of the top few candidate representations on the list.

The choice for real programs of an appropriate overall measure of computation cost is a good research problem. Attempts at a solution might well lead to the development of new ways of describing programs and their behavior, and to new ideas and standards for the systems in which programs function. Such a study is certainly worthwhile, but although we could make use of the results, it is outside the scope of this work and is left for future research. Instead (following Reference 4), we have provided in the selection system a function which defines the overall computation cost of a candidate representation to be the product of its storage space and execution time requirements. It would be easy to define a new function of space and time to replace

the one provided, or to experiment with several in the context of the selection system.

Once cost estimates are derived for all candidates, we rely on the methods of Reference 4 to choose the best representation for the class of triples in the context of the entire program. In particular, we refer the reader to Low's book for a discussion of the following problems:

1. estimating and considering the cost of the non-associative operations of the program.
2. defining an "overall" cost function of space and time.
3. considering the interaction between representation choices for separate data structures whose life-times overlap.

RESULTS FOR THE SIMPLE EXAMPLE (Figure 2)

Based on its analysis and on the answers to questions, the system proposes and evaluates several possible storage structures for the Sexof relation. The best of these is a record having one field which points to the set of MALES (this set is represented as a linked list). Based on the cost formulas, this has an expected size of 5.5 cells and an expected time of 457 instructions. Another alternative would be to list each association separately in a table. This has an expected size of 13.0 and an expected time of 935. The set representation is better than this (and all others) in both time and space, and is chosen. This is a very simplified (almost degenerate) case of the selection system's operation.

In selecting a storage representation for the class based on the Parentof relation, the system goes through a similar procedure. In this case, it selects to assign a record for each person, with a field of the record indicating the set of parents.

Now let us consider the more complex program including the statement in the box. Since the Homeof relation is used, there are now three classes of associations. In our tiny sample program, the only use of Homeof is to test if someone lives in Rochester. This, plus the fact that there is a small fixed number of people, causes the selection system to choose as the best structure a single word per person indicating whether he lives in Rochester. This representation is estimated to require one cell and 300 instructions.

A more interesting effect of adding the boxed statement is to change the choice for representing the class based on the Parentof relation. Now the program calls for enumerating all Child-Parent pairs as well as finding the PARENT of a given child. The selection system considers making two separate data structures or making one data structure which does both jobs. The best choice is to have a list of all children with each child indicating the set of his parents. This is estimated to require 16.5 cells and 1600 instructions.

SUMMARY

This paper explores some of the problems of automatic representation selection for associative data structures. In particular, it presents methods for selecting in-core storage structures for programs which use associative data and operations which are similar to the ones that the SAIL programming language provides.

A model of the associative data and operations of such a program is defined. We describe a library of storage structure representations for three-part associations (triples) that includes records, property lists, inverted lists and hash tables. We show how to use the model in conjunction with the library to find "efficient" candidate representations for the associative data of a given program. This choice of candidate representations is guided by heuristic rules that embody educated assumptions about computation cost tradeoffs. In addition to representations that provide a single method of access to associative data, we consider representations that provide multiple access paths to the data and ones that provide multiple copies of the data.

Finally, we discuss methods for estimating the computation cost of each candidate representation, and for selecting the "best" one.

Efficiency estimation—Controlling search in program synthesis

by ELAINE KANT
Stanford University
Stanford, California

People should be able to specify a program in a high level language and let the computer take care of finding an efficient target language implementation. One way to do this is by program synthesis. LIBRA is a system designed to guide the application of synthesis rules in the PSI program synthesis system. In the PSI system, there is a structured programming style of organization of programming knowledge. High level concepts such as sets may go through an arbitrary number of levels of refinement before target language concepts such as lists or arrays are produced. Refinement rules make the transformations between these concepts. If given such a set of refinement rules, LIBRA can guide the transformation of a high level program specification to a target language program. The target program is made efficient in two ways: by clever choice of refinements and by the application of optimizing transformations at any levels that are appropriate.

LIBRA uses the technique of efficiency estimation to guide a heuristic tree search of some of the possible refinement sequences. Efficiency estimation takes into consideration: a user-specified program cost evaluation function, resources allowed for program writing, data structure sizes, and conditional branching probabilities. An estimate of the cost of the program descriptions in the tree is maintained for comparison between alternatives, for identification of the most important decisions, and to trade off final program performance with the cost of writing the program. To simplify the decision making process, decisions are grouped into related sets or cost-independent blocks. Heuristic knowledge about efficient implementations for certain circumstances is also integrated into the system. A version of LIBRA has been written in INTERLISP; it has been used to guide the implementation of several LISP programs.

This work is described in more detail in *The Selection of Efficient Implementations for a High-Level Language* in **Proceedings of the Symposium on Artificial Intelligence and Programming Languages,** Rochester, New York, August 1977.

Transformational implementation

by DAVID WILE and ROBERT BALZER

Information Sciences Institute
Marina del Rey, California

Only modest gains in programming productivity have been produced in 25 years of software research, but the groundwork has been laid for major advances through rationalization and automated aids. This groundwork rests on two critical ideas: that specification must be separated from implementation, and that the separation between these two processes should be a formal operational abstract (i.e., very high level) program rather than a nonoperational requirements specification. Structured programming represents the first results of combining these ideas. It is a special case of a more general two-phase process, called Abstract Programming, in which an informal and imprecise specification is transformed into a formal abstract operational program, which is then transformed into a concrete (i.e., detailed low-level) program by optimization. Abstract Programming thus consists of a specification phase and an implementation (optimization) phase which share a formal abstract operational program as their common interface.

The concept of Abstract Programming is completed by adding the feedback loops required by Testing, Maintenance, and Tuning. In conventional programming where no abstract program exists, these feedback loops all operate on the optimized concrete program. On the other hand, in Abstract Programming, if an effective method can be found for guaranteeing the validity of an implementation (that is, the functional equivalence of the abstract and concrete programs), then the validation process can be shifted to the specification phase to show equivalence between the user requirements and the abstract program. Thus, validation could, and should, occur before any implementation. Furthermore, if the implementation process could be made inexpensive through computer aids, then maintenance could be performed by modifying the specification and reimplementing it rather than directly modifying the optimized concrete program, as is current practice. The importance of such an advance can be recognized when one realizes that optimization is the process of maximally spreading information (to remove redundant processing), and that modification requires information localization. Thus, the two processes are diametrically opposed; this fact explains much of the current problem with modifying and maintaining existing programs. The second major cause of this dilemma is that optimization obscures clarity and thus makes it difficult for maintainers even to understand how the concrete program operates.

It is therefore clear that major advances in programming will hinge on the ability to provide an inexpensive optimization process with guaranteed validity so that maintenance and validation can occur in the specification phase on the abstract program rather than in the implementation phase on the concrete program.

Several researchers have espoused an approach which we will call Transformational Implementation (TI), in which equivalence-preserving transformations are successively applied to the abstract program to effect such an optimization. The key to this approach is that while optimizing transformations are selected by the programmer, the program is transformed by the computer system. Hence, the programmer designs the optimization; the machine ensures its validity and transforms the program.

In addition to guaranteeing the validity of the implementation, drastically reducing the time and effort required to implement a system, and enabling maintenance to be performed at the conceptual level on the abstract program, this approach would also allow programmers to experiment with alternative implementations to widen their experience base and improve their capacity to design optimizations.

We have undertaken a study to discover: what facilities are necessary for the TI approach; what transformations are required; how are they expressed; what categories do they fall into; how can they be named; what kinds of applicability criteria are required; what processes are required to verify that these criteria are satisfied; what instrumentation facilities are required to test a transformation's selection criteria; what proof techniques are required to validate the transformation; etc. In short, the study will provide an experience base for the TI approach from which we can design and implement a prototype system.

A panel session—Whither automatic programming

SESSION CHAIRMAN—ROBERT BALZER
Information Sciences Institute

Panel Members

Thomas S. Standish—University of California
Michael Hammer—MIT Laboratory for Computer Science

PANEL OVERVIEW—Robert Balzer

The preceding sessions have displayed some current research into the area of Automatic Programming. These efforts are small laboratory prototypes which attempt to automate particular portions of the programming process. It is quite clear that to progress significantly beyond our current state of software development technology, increased automation, in some form, must occur.

The questions facing this panel, and addressed below, are when, in what form, and to what extent this automation will occur?

THE FUTURE OF AUTOMATIC PROGRAMMING—Thomas A. Standish

In *automatic programming,* we strive to build systems that will perform problem acquisition, algorithm and data representation synthesis, optimization, and concrete program generation—systems which automatically acquire specifications of the program behavior required and which will build programs to satisfy them.

I speculate that the attainment of technological capability to build such automatic programming systems flexibly across a spectrum of dissimilar, important problem domains is a long way off—perhaps centuries and most likely decades. Before we succeed, we shall likely have had to develop deep understanding of the interrelation between knowledge systems of many sorts—knowledge systems in which problems are posed and in whose terms solutions must be delivered (the so-called problem domains), knowledge systems describing the media in which problem solving computations must execute at the lowest levels (the so-called concrete solution domains), and knowledge systems that cooperate together to provide the scaffolding in which program synthesis can take place (the intermediate problem-solving knowledge systems, which offer systems of reasoning and representation).

The exploration required to develop an understanding of relationships between these several sorts of knowledge systems is likely to lead to a deep reorganization of the foundations of epistemology itself. For example, the *doctrine of reductionism*—which holds that phenomena at higher levels of science can be explained by reduction to laws and facts at lower levels—is a doctrine which is far too simplistic and inadequate to provide understanding of how to build program synthesizing systems. *Reductionism* may describe the end *product* of program synthesis—i.e., the already synthesized program—but it seems inadequate to describe the *process* of synthesis itself.

The doctrine of reductionism is important in programming. Every large software system is living testimony to the idea of reductionism. In such systems, we organize the data and operations at given levels to represent the information and problem solving processes required at higher levels. When we engage in "top-down programming" or "programming by stepwise refinement," we consciously organize the act of large system construction into a number of levels of reductionistic choice, each carefully selected to be intellectually manageable and to permit flexibility in future maintenance.

While every synthesized software system is an example of successful reductionism in which the external high-level behaviors of the system have been reduced to a composition of the lowest level behaviors of the underlying machine, there may be a *paradox.* The knowledge systems in the heads of programmers who build the overall system may not be similarly reducible. Rather, such knowledge systems may exhibit phenomena akin to the logical independence of the parallel postulate from the remaining axioms of Euclidean geometry.

The history of science teaches us that large increments in technological power are seldom purchased through cheap tricks or shallow understanding. Rather, deep basic understanding of a degree of indirectness scarcely imagined by original explorers seems more characteristic (recall here the history of the conquest of flight, or the history of the quest to transmute the elements).

It seems to me that basic understanding of how to represent knowledge systems, and how to use one knowledge system to represent and solve problems posed in another, is a basic requirement of the task of building program synthesis systems. Perhaps it is better to make an indirect assault

on deepening our knowledge in these areas before making direct assaults on the synthesis of particular categories of programs. After all, the Wright Brothers built a wind tunnel and studied properties of airfoils extensively before they conquered flight.

THE IMPACT OF AUTOMATIC PROGRAMMING RESEARCH—Michael Hammer

Contemporary automatic programming research encompasses a variety of approaches to the goal of transferring some of the programming function from human to machine and thereby alleviating the software problem. A very high level language system translates a program expressed in terms of nonprocedural, problem-oriented constructs into conventional algorithmic code; in so doing, it must perform global program transformations in order to achieve an efficient object program. A knowledge-based system uses the semantics of a particular problem domain to interpret a user's functional specifications for a program in that domain and to construct a system with the specified functionality. A program synthesis system utilizes formal theorem-proving techniques to transform non-functional program specifications (typically expressed in terms of a set of input-output pairs) into an executable program.

Although extensive research has been conducted in each of these areas, and significant advances have been made in addressing the technical problems that each presents, it is unlikely that any of this work will culminate in systems that will meet the ambitious goals that have been set for them. The very high level languages that have been developed so far are adequate for expressing the main body of a program in a nonprocedural way; however, they do not address issues related to deviations from the normal flow of the computation, such as special case recognition, exception handling, and coping with erroneous data or system failure. Furthermore, introducing a new language into an operational environment has in the past proven to be a major undertaking, one that raises serious managerial and technical problems. The principal problem facing the more advanced, artificial intelligence systems is one of scale. It is doubtful that the techniques that suffice for laboratory prototypes can be extended to cope with realistically rich problem domains and large, complex programs.

The difficulty underlying all of these problems is that the fundamental premise of automatic programming is simply false. This premise is that, after thirty years' experience in writing programs, we now know enough about the programming process to automate it. On the contrary, it appears that our understanding of the nature of programming is weak. The ad hoc attacks on the software problem that are currently feasible are not likely to produce major results.

Nonetheless, automatic programming research will have important consequences, both direct and indirect, for the future of software construction. In the near term, we should see limited systems that automate one part of the programming process or that are adequate for the synthesis of small programs; in either case, the context will be a simple problem domain that has a well-defined and understood semantic structure. Examples of such systems include an automatic data base design system and a facility for generating simulation studies. Another possibility is a system that uses knowledge of an application domain to assist a user in deriving a complete and consistent set of program specifications. In another vein, very high level language research should lead to the design of formal specification languages for effective and precise inter-personal communication.

However, the most significant benefit of automatic programming research should be a deeper understanding of programming by human programmers. It has often been the case that the attempt to automate an activity has forced its practitioners to understand and systematize their actions; automatic programming research should have the same effect on programming. In the attempt to computerize the software production process, it is uncovering important general programming principles and techniques. The structures and guidelines that derive from this work will enable and encourage programmers to be more disciplined and organized; in the long run, they can contribute to turning programming from mysticism into science. In other words, automatic programming research should benefit software engineering practice.

Data networks

In this area we explore the technology and development of information networks on a national and international basis. There are four sessions in this area and they deal with (1) "The Architecture and Application of Nationwide Packet Switching Networks," (2) "International Computer Communications," (3) "International Public Data Networks," and, (4) "Satellite Data Communications for Public Service."

The first session focuses upon the architectural similarities and differences of several packet-type networks and how the application of these networks influences network architecture which have recently become operational or are under development.

The first of two sessions on international computer networks will cover matching future international regulations against the continued growth of computer communications systems and technology utilizing all types of international transmission media. The concerns of this session include the non-homogeneous nature of national regulations as they apply to international computer communications systems, transborder data flow, and the need for new regulatory considerations for international satellite-oriented computer communications networks.

The second international session emphasizes the operational problems of international data networks with multiple organizations interconnecting dissimilar equipment rather than a single, coordinated, homogeneous network. This inhomogeneity creates special problems and requirements in order to create a viable service. This session will describe some aspects of the interconnection problem, potential solutions, and some internetworking field trials underway.

The final session will deal with the emerging question of information networks for public service users in the United States. These users consist of a small number of related communities—libraries, educational institutions, health centers, and local government agencies. Each of these communities has a need for data communication capabilities with certain common characteristics. Among these characteristics are a high degree of connectivity within a highly dispersed user community, the ability to distribute relatively small amounts of data with high economic or social value and a modular structure which can accommodate rapidly changing and diverse data rates within the same system. The key to

satisfying these data communication needs is the aggregation of the public service data communications market by means of communications satellites and the broadcast data communications architecture they make possible. In this session we describe the projected requirements of this aggregated market and discuss the status of current proposals to provide these data services.

Challenges in the planning of international communications

by DAVID J. HORTON
Hawaiian Telephone Company
Honolulu, Hawaii

It's difficult sometimes to realize how far international telecommunication has come in 20 short years. As recently as 1957, "Hawaii Calls" was broadcast using HF radio. After the program was switched to transpacific cable, simulated fade had to be added to recapture the flavor of "music from the isles." Today we've progressed to the point where we can provide a small store on Molokai with on-line data communications to a data base in Paris—at low cost and virtually error free.

I'd like to explore with you the environment under which all this achievement came about and to examine some real areas of concern which may inhibit continued progress. While some of my remarks may apply generally, my emphasis will be on data communications in the Pacific Basin.

I have a very simple definition of planning: A process which results in spending the right amount of money, on the right amount and right kind of equipment at the right time. The definition is simple; the process, alas, is always difficult and rarely perfect. Planning in the face of rapid technological change and everchanging market needs is particularly tricky. When the international dimension is added, the complexity reaches quite awesome proportions. Yet, decisions must be made or opportunities will be lost and/or needed services will not be provided.

Let's look at some of the elements that enter the picture when we go international:

- Apart from the obvious problems of language and cultural differences, we must recognize the different ways that telecommunication is viewed in different countries. In North America for example, we aim for the lowest possible cost consistent with good service and a fair rate of return. Most other countries are inclined to view telecommunication as a source of high profit with which to subsidize some of the weaker operations, most notably the postal service.
- Political considerations cannot be ignored. Here we must be concerned not only with political ambition, but with the opportunities of political progress. We can contemplate, for example, the phenomenal increase in communications which would accrue from full trade with the People's Republic of China.
- We must concern ourselves quite deeply with some of the reservations being expressed regarding the presence of data bases in foreign countries. Not only is this viewed as an unnecessary import, but there is very valid worry regarding what is left of our privacy.
- Markets are different as we travel around the world. We find different terminal types, different protocols, and different speeds—happily, however, major success is being achieved in the area of international standards. I can think of no area more deserving of our continued attention than this. We, as carriers, have a profound obligation to ensure a high degree of uniformity in the networks we design for Spaceship Earth. We have the skills, and we have the vehicle (CCITT)—we will have no excuses for failure.
- Geography differs widely, as is obvious when one compares the wide open spaces of Canada with the density of population in the Netherlands.
- In satisfying customer needs with new equipment, it is frequently not enough that it was invented "here", but it also must be designed here, developed here, manufactured here, sold here, and serviced here. And, often the customer must wait until these national objectives can be satisfied.
- And finally, planners must contend with all of the unpredictability inherent in the presence of extensive competition for international telecommunications.

But, complex as it may be, planning must continue. Good planning is essential and plans, once agreed, should meet time and cost targets or both carriers and customers will suffer. This is particularly true of international planning where the inability of planning members to fulfill their commitments can cause considerable difficulty for their correspondents.

International planning in telecommunications has had its problems to date but has nothing to be ashamed of. It is interesting to recall that the first major achievement was the laying of the telegraph cable between two countries which today provide the butt of many a joke; namely, Newfoundland and Ireland—and that this occurred in the year 1856, 20 years before the invention of the telephone.

Progress since then has been quite rapid (with most of it coming within the last 15-20 years) to the point where we now have extensive cable and satellite facilities encircling the globe.

At the 6th Annual International Conference on Planning, held last fall in Honolulu, we were treated to paper after

paper about the growth in the Pacific Basin with special emphasis on the emergence of Korea, Taiwan, Singapore, and Hong Kong as "new Japans" with all that it implies in terms of increased trade and thus, telecommunication traffic. It is obvious that good planning is essential if we are to meet the emerging needs of customers in these Pacific Rim countries.

Thus far, we've gone through a progression of complexity: fast moving technology; increased and changing market demands; and a high requirement for international cooperation. We must now add yet another challenge—international *data* communications.

The past few years have seen explosive growth in international data communications and with the advent of packet switching, this growth will continue at an ever-increasing pace. This latest technological wonder which has been with us a very short time finds its roots in the ARPA network but its branches now encircle the world. At last count, there were almost 20 such networks in service or about to be in service.

Packet switching respects no boundaries. It was internationally almost before it became domestically available. The Atlantic was the first pond to be hurdled, and we have today extensive access to North American data bases by European customers. Similar plans are already well under way in the Pacific area.

Technologically, packet switching is a hyperactive child, constantly exploring new possibilities—and now and again getting itself in a little trouble. The pace of technological change is higher than in any other area of telecommunications and with the introduction of microprocessors, we find ourselves using third generation technology within three years of the first network going into commercial service.

Data communications customers are a demanding breed—demanding that new technology be introduced fast, demanding shorter time frames than they have traditionally been promised, demanding the features that they need, and perhaps most importantly, attaching a very valid threat of taking their business elsewhere (or doing it themselves) if these demands are not met.

There is of course much to be done, and I've touched on some of the tasks:

- harnessing the right technology to meet real market needs
- standards
- international dialogue

One area, however, which could become a major stumbling block is not within the carriers' control. I'm speaking, of course, of regulation, or more precisely, the regulatory process.

Let me suggest that regulation is here to stay and that it will probably get worse before it gets better.

In a December 1977 Time magazine, President Carter was quoted as follows: "Regulations should be as simple and clear as possible. They should achieve legislative goals effectively and efficiently. They should not impose unnecessary burdens on the economy, on individuals, on public or private organizations, or on state and local governments."

How about that? That was in December 1977. You all notice the big improvement?

To be fair, the problems are not entirely the fault of the FCC. Once the decision is made to have controlled competition as opposed to a monopoly, it follows logically that there will be a greater workload. It is the FCC's inability to handle this workload that causes so much pain, not only domestically, but also with our partners in other lands. At a meeting of Pacific cable operators held in Honolulu at the Kahala Hilton Hotel in September 1977, all countries expressed dismay at the regulatory lag caused by the FCC. In one cited example, a submarine cable cut into service one and one-half years late and cost $40 million over budget as a result of this delay.

And, if I may use an example much closer to my own experience, let me tell you that from the start of the initial discussion with Telenet until the installation of a working node in Honolulu, less than three months expired. More specifically, from the placing of the order to the acceptance of installation was a mere six weeks, or more specifically, still, from the delivery of equipment to turn up (capable of providing service) five working days expired. By comparison, our request for approval to construct was filed on August 12th, 1977 and approved about December 15th with an effective date of January 3rd, 1978. I think you can imagine the disappointment that is caused to carrier and customer alike as a willing switch capable of earning revenue sits gathering dust as the paper flows around Washington. This is simply not adequate regardless of what the problems and what the excuses are.

The fact is that whether we like it or not (and I personally do) technology is moving fast and market demands are increasing daily, resulting in the need for fast response from carriers both domestically and internationally. The regulatory process must keep up.

How do we do this? I wish I knew.

I don't believe that simply increasing the staff at the FCC is the answer. So let me offer some suggestions which may be of help:

1. Establish guidelines and policies for international telecommunication.
2. Clarify the roles of individual carriers if in fact there are any valid reasons for segmenting the market among them.
3. Anticipate the effect of technological likelihoods, and
4. Based on carrier-provided information, anticipate the kind of action that market demands will require not only of the carrier, but of the regulatory process itself.

Let me give you an example:

We're now in the middle of an extremely costly exercise called Computer Inquiry II. There's a great deal at stake and some very vocal and widely different views are being expressed by various lobbies. What bothers me most about this is that it's only six years since we were presented with the wisdom we have come to know and love as *the* computer

inquiry. But it wasn't *the* computer inquiry—it lasted a mere six years. Why? Mainly because its authors failed to understand where technology and the demands of the market place were taking us. And at the very moment in history when everyone finally realized the line between communications and data processing was a broad blur, the FCC presents us with a definition which claims to draw a major distinction. It's thus difficult to be optimistic that CI2 will be a big improvement on its predecessor.

Let me stress again that we must have a thorough understanding of what technology can do, what the customer wants, and what the various vendors are trying to achieve. We must then produce regulations that are fair, of course, but which stimulate innovation and keep prices as low as possible. A difficult task, indeed, but one which must be undertaken. I believe the carriers themselves should play an active role in trying to streamline regulation. I would hope that both they and the FCC would welcome this.

The need for continuation of full-period transparent private-line service

by PHILLIP C. ONSTAD
Data Services, Control Data Corporation
Greenwich, Connecticut

During the past year several moves have been made by the international telecommunications industry which may threaten the continuation of the flexibility currently available to the user of telecommunications services for data transmission. The major problem now confronting the user of international telecommunications services for data transmission is the hinted or announced intention of the international and foreign carriers to offer "value added" services as a replacement rather than an alternative to full-period transparent private-line services. The availability of transparent private circuits permits technological innovation in signaling and in information processing network development to the benefit of all. Loss of transparent, flat-rate, private circuits would retard advances in distributed processing and shared data base developments. Furthermore, many existing teleprocessing systems would be degraded in effectiveness and in many cases their data services would be withdrawn.

With the advancement of computer technology during the fifties and sixties, it became evident that the full potential of data processing and information systems would not be forthcoming until a faster and more efficient means of transportation could be developed to move information in and out of the data processing systems. While data processing systems had the power to manipulate information at split second speeds and store vast amounts of data which could be retrieved in fractions of seconds, these capabilities were of little use unless the user was within close proximity to the data processing system. Transportation by means of mail or delivery services worked well for batch processing operations such as payroll, sales analysis, and other operations where there was no need for an immediate answer to a problem. However, these transportation methods could not satisfy the demands of applications such as reservation systems or production control systems where information was needed on an immediate basis.

The obvious solution to this problem lay in the use of the vast telecommunications networks covering the country and the world. Although these networks operated in an analog mode and were used for transmission of voice and low speed telegraph signals, equipment was developed for connection between the data processing systems and terminals and the telecommunications network which could convert the signals from digital to analog and then back to digital at the other end. Thus began the era of telecommunications dependent data processing systems.

In the early days of data transmission, the speed of transmission was limited by many factors and the reliability of the transmission was low. In addition, there was very little interest by the communications industry, whose major purpose was to provide voice and low speed message communications service, and not to provide methods for the high speed data transmission and high reliability factors required by the data processing systems. Thus, it was left to the data processing and related industries to develop the necessary equipment and procedures.

The telecommunications common carriers offer transparent telecommunications circuits on both the private-line and switched networks; these are available in various speeds. By utilizing these circuits, the data processing industry developed or perfected equipment and techniques which made the transparent communications facility a highly efficient and highly reliable method of transportation of information from remotely located input/output devices to and from the data processing system.

Once this means of transportation was proved feasible, the number of telecommunications-oriented data processing applications exploded. This demanded increasing technological development to obtain optimum performance of the transportation medium in order to maintain optimum performance of the overall data processing system.

The data processing industry has been and continues to be a highly competitive and highly complex industry with many companies manufacturing and marketing many different types of equipment and systems from the very small micro processors to huge information handling systems. To remain competitive in the marketplace each company has developed unique architecture, technologies, coding methods, circuit logic, storage methods, protocols, etc., in order to make their systems more reliable and faster than others. Each system has a specific balance of hardware and software control to maintain optimum performance from a specific system and specific application. In maintaining this balance, the user must also have control over all input and output functions, including remote terminal devices that carry information to and from the system.

When preparing a new application for a data processing

system, the programmer and system designer must have the flexibility to utilize the best combination of computer logic, storage media, input/output methods and devices. Further design must be made to the transportation system from remote terminal devices to the processor in such a way that information is received and released in a manner which meets the requirements of the application, such as formats for messages, etc. It must also meet the requirements of the data processing system to properly mesh these input/output operations with the multitude of other operations going on during the processing of a major application. The importance of the input/output operations increases as the complexity of the application increases. The effect of several low speed terminals coming into a system or application which is primarily batch oriented is minimal and does not require a great deal of control over the input/output method. However, a system operating a large reservation or time sharing application involving hundreds of terminals requires a highly complex input/output protocol with almost total control over the telecommunications activity in order to maintain optimum system performance.

The transparent nature of the telecommunications networks has given the application designer the flexibility to design the transmission protocol and utilize equipment which best meets the requirements of the overall system environment. The designer may choose the speed of transmission, the line protocol to be used, the coding structure, block lengths, error correction methods, retransmission methods, etc. He has the flexibility to utilize the usage-sensitive switched circuits of the public networks or full-period line service. He also has the flexibility to utilize asynchronous or synchronous transmission methods and may utilize various types of equipment such as multiplexors, concentrators etc., to obtain maximum utilization from the telecommunications service. This flexibility is extremely important to the operation of a major telecommunications dependent data processing application. Hundreds of data processing systems of this type are operating throughout the world today. Many of these systems require thousands of miles of private lines which are leased from the common carriers, both nationally and internationally. They also connect to the public-swtiched network for many applications.

Several years ago a new method of data transmission was introduced with the advent of the "value added" carriers. This group of regulated carriers lease full period private-line services from other carriers and, through the use of various types of telecommunications and data processing equipment and software in conjunction with the private line services, establish a stand alone data transmission network with a protocol *best suited to the operation of the network*. This "valued added" service then is offered to users who do not wish to establish and operate their own telecommunications networks but have some telecommunications requirements in their data processing applications.

Although these "value added" data transmission services do fulfill the telecommunications network requirements of many users operating data processing systems with small- or medium-scale remote terminal operations and further allow the user to share a network with other users, in most cases they are of little value to the user with a large telecommunications network requirement. This is because they have been designed with the optimum performance of the network rather than the optimum performance of any single application as the criterion. In utilizing these networks, the user must conform to the protocol requirements of the "value added network," therefore losing much of the flexibility available in the transparent network. This is not to say that the "value added networks" do not furnish a valuable service to the small- and medium-scale user on a national basis. Indeed, the savings in telecommunications cost available through use of this type of service is in many cases such that they provide the economic feasibility of performing some telecommunications functions in an application normally run in batch mode.

In the area of international data transmission, the value added services provide the only means of communications on a *usage sensitive basis* between the United States and foreign points. The only other alternatives available to the user are the very slow telex service at high cost or the use of full period international private-line service, which, because of its extremely high cost, is only economically feasible in the cases of very large requirements or with users needing an alternative voice data capability which might offset the high cost. In many cases even the large user will find it more feasible to utilize the value added type service to points having small transmission requirements even though response and/or system optimization may suffer somewhat when adapting to the protocol of the value added service.

To summarize, the intelligent networks provided by the value added services will fulfill the requirements of a great number of telecommunications-dependent data processing applications and systems. However, the large variety of data processing systems, each operating under a unique architecture and the various requirements of the large telecommunications dependent data processing applications, demand that the user have complete flexibility to utilize the best data transmission method possible. This is true whether those methods be transparent or value added service, private-line or switched network service, in order to design and operate the optimum environment for the data processing applications.

During the past year several moves have been made by the international telecommunications industry which may threaten the continuation of the flexibility currently available to the user of telecommunications services for data transmission.

As previously stated, the new value added type services make available a viable alternative to fulfill the needs of a significant number of telecommunications users. However, these type services have serious drawbacks and cannot be applied to all user requirements. They are also relatively new and have yet to be totally proven from economic as well as reliability standpoints. While the growth of these services has been somewhat slow within the United States with only three independent carriers currently offering the service, the international common carriers, as well as a number of foreign telecommunications administrations are

moving ahead at a substantial pace to have these value added services in place as soon as possible. This has led to additional problems to the users as the fast pace toward installation of these services has not allowed the proper consideration for much technical standardization among the various services, thus creating a number of potential problems for the user.

The technical problems leading toward some type of standardization of these networks is currently being handled by the Study Group VII of the Consultive Committee on International Telegraph and Telephone of the International Telecommunications Union. Although this group has made significant progress toward solving of the standardization of the protocols and other technical criteria which will allow for the eventual interconnection of these networks, much work must still be done before proper solutions are found to make these networks truly viable on an international basis.

The major problem now confronting the user of international telecommunications services for data transmission is the hinted or announced intention of the international and foreign carrier to offer these new services as a *replacement* rather than an alternative to full period transparent private line services.

The possible replacement of full period transparent private line services for international and foreign communications has been brought to the attention of users during the past year by:

- The introduction of a contribution by the Italian delegation to the CCITT Study Group III on Rates and Tariff Matters requesting the group to study the feasibility of replacing full-period private-line services with some method of usage-sensitive or volume-sensitive pricing for the service.
- The refusal of an internaional common carrier to furnish full-period private line service to the United States. The refusal is based on the availability of a new usage-sensitive service between that point and the United States which would now fulfill prospective customers' requirements.
- Articles now appearing in the Japanese press which indicate that Japan plans to have their new Venus Value Added Service operating within the next year or so to replace for private line services for data transmission.

Solutions to these problems which are of true benefit to the user are complex and difficult to obtain. With the exception of the United States Federal Communications Commission, which is charged with the protection of the public interest in the area of telecommunications, there is very little opportunity to present a user's point of view in international and foreign telecommunications services.

Since the only international body having an interest in this area is the Consultive Committee on International Telegraph and Telephone of the International Telecommunications Union, it is of critical importance that users take an active interest in the activities of the American delegation to the CCITT.

In view of the pattern of rapid technological advancement and economic growth in the data processing and telecommunications industries, we believe that a study of the tariff system for full period private line service may be well advised. Because the tariff system profoundly affects the utilization and development of communications based data processing systems as well as other communications based systems, we believe that such a study, if properly handled and provided it receives input from the user community as well as the carriers, may result in workable solutions to the issues at hand. However, such a study must be conducted with a very open mind and without preconceived notions on the part of the international and foreign carriers that replacement of full period transparent private line services is the only solution.

There can be no doubt that the world has entered the information age where continued growth of all elements of society are mutually dependent on the rapid flow of information with the minimum of hindrances. The EDP industry has spearheaded the advancement of information transfer through its technological and manufacturing advances. Prominent among those applying these advances to the direct benefit of the public are the financial, retail and health care activities and certainly the telecommunications administrations.

A key factor in the technological advance of ever-increasing telecommunications oriented data processing has been the widespread availability of full-period point-to-point and multipoint private leased circuits. The most important characteristics of privately leased circuits have been their transparency and a tariff system independent of the volume of information transferrred. Transparency as used in this context denotes a point-to-point or multipoint analog circuit which delivers the electrical signals applied by the user with the practical minimum of delay and distortion consistent with the applicable tariffed characteristics.

The availability of transparent private circuits permits technological innovation in signaling and in information processing network development to the benefit of all concerned. Presently, these innovations can proceed observing only the electrical interface without the constraints of all establishments and telecommunications network administrative control protocols and without the potentially excessive delays even in virtual circuits.

There is no doubt that the introduction by the administrations of new services will stimulate the growth of new information systems which would not have emerged otherwise. There is no essential conflict between the new services and privately leased circuits and it would be contrary to every interest for any tariff system to be based on an unfounded fear of competition.

Loss of transparent flat-rate private circuits would indisputably retard advances in distributed processing and shared data base developments. Furthermore, many existing teleprocessing systems would be degraded in effectiveness and in many cases their services would be withdrawn. Additionally, and as a direct consequence, administrations would suffer erosion of their revenues rather than safeguarding their revenue.

Satellite business systems—Innovative services for business communications

by RONALD W. McCABE

McLean, Virginia

INTRODUCTION

It is a pleasure to participate in the National Computer Conference, and to represent SBS in this session on International Computer Communications. The topic is a most timely one for SBS, even though we are a domestic carrier, because during our extensive market investigations the desire of potential customers to improve their ability to connect their domestic and foreign data transmission capabilities has been expressed quite strongly. SBS believes its proposed offering will provide customers a significantly improved digital network capability within the United States, and SBS is supportive of industry efforts such as this which recognize these expressed concerns of users and which seek to promote an improved environment for uniform international networks. But before I discuss the specific topic of today's meeting, I would like to give you some background on SBS and describe its plans and recent activities.

SBS proposes to offer innovative, high data rate, private switched communications networks for industrial and governmental users. These networks will be designed primarily for organizations requiring large communications networks that have heavy and dynamic traffic loads, and will provide integrated digital transmission of voice, data, and image traffic among geographically dispersed locations—much as a private branch exchange (PBX) provides switched communications within a single facility. Importantly, it is this same class of user which is more likely to be multinational in scope and to have far-reaching requirements for various types of international communications. Thus, SBS' market emphasis is closely allied with the matters of interest here today.

As you are probably aware, the SBS system will operate at higher frequencies (12/14 GHz) than present terrestrial and satellite carriers to minimize frequency interference with other systems. This will permit more geographical flexibility in the location of earth stations than is possible at the lower frequencies. These earth stations, which will incorporate specially-developed modulation and access equipment, will be located on the customer's premises, thereby minimizing the cost of access from customer nonearth-station locations to the nearest earth station customer location.

Satellite Business Systems is a partnership of COMSAT General Business Communications, Inc., Information Satellite Corporation, and Aetna Satellite Communications, Inc. These partners are, respectively, wholly-owned subsidiaries of COMSAT General Corporation, International Business Machines Corporation, and Aetna Life & Casualty Company.

SBS filed applications with the Federal Communications Commission in December 1975 and obtained approval for operation in February 1977. Major system developments and procurements are now under way, and we look forward to implementation. SBS expects to begin providing services with its operational system in early 1981. Prior to that time, SBS will be engaged in an intensive pre-operational program using leased satellite and terrestrial transmission capacity to connect a number of IBM locations; this activity is designed to evaluate the service approach and communications techniques planned in the operational system. The first phase of this effort, now successfully completed, involved experimental traffic tests between SBS earth stations at Poughkeepsie, New York and Los Gatos, California. Phase II has been under way since early this year and consists of a common carrier service, offered under terms of a tariff on file with the FCC, among these two locations and a third SBS earth station installed in Raleigh, North Carolina. An important objective of the Phase II program is to provide a stable environment into which components of the SBS operational system can be introduced and field trials conducted.

Another activity designed to demonstrate and better understand the usefulness of enhanced communications in the business environment was the PROJECT PRELUDE experiment which was recently completed. SBS was authorized by the FCC and NASA to use the Communications Technology Satellite, owned jointly by NASA and the Canadian Department of Communications, and transportable earth stations to conduct an innovative business communications experiment with newly-developed terminal equipment and business machines. The experiments were conducted successively at three pairs of business locations at the host companies—Rockwell International, Texaco, and Montgomery Ward. These companies were selected because they represented a cross section of the user community, and

helped to assure that representative data were collected. Experimental transmission of high speed data, high speed facsimile, and voice and televisual communications took place and the results were reported in the spring to both NASA and the FCC. In general, these experiments solidified our belief that these emerging applications will indeed satisfy unmet communications demands and become widespread in future networks.

SBS UNIQUE CHARACTERISTICS

Now let me describe briefly the uniqueness of the services that SBS plans by contrasting them with present communications. Satellite services are generally provided through very large earth stations located at some distance from urban centers because of their size, and to avoid interfering with terrestrial microwave facilities. Some small earth stations have been introduced but only in a limited way, again to avoid interfering with existing systems. The services currently offered by both terrestrial and satellite systems are primarily of an analog, full-time, point-to-point nature, and the switched services currently available are for voice and low-speed data.

In contrast to this environment, SBS will offer innovative, high data rate, private switched communications networks. These networks will provide integrated digital transmission of voice, data and image traffic among geographically dispersed locations, with full switching capability from one location to another.

Network is a key word in understanding SBS's uniqueness. It implies that there is connectivity among all of the locations at any time. This particular feature is perhaps the primary factor in SBS's system design. SBS will provide a customer complete connectivity among all his earth stations with sufficient transmission capacity to meet normal operating requirements; additional capacity will be available, on demand, to meet incremental requirements. This service approach, offered through small earth stations located on the customer's premises, results in a single multi-application network capable of handling virtually all of a customer's internal communications.

Locating earth stations on the customer's premises also provides a high level of security. This, combined with the use of time division, multiple access (TDMA), will make it impractical to intercept or decipher communications. The modulation and access equipment, burst modem, and radio frequency equipment of the earth station operate in a controlled access environment. Further, privacy equipment (such as cryptographic encoders) can be adapted for use as required.

SYSTEM COMPONENTS AND MANAGEMENT

To provide these dynamic, switched high data rate digital transmission services to the locations of an enterprise, SBS will install at each customer's traffic concentration points earth stations, owned and operated by SBS, through which he will obtain access to his network. The stations will use antennas five or seven meters (16 or 23 feet) in diameter and will include innovative modulation and access equipment to accomplish switching and multiplexing and to control the assignment of satellite capacity among the earth stations serving each customer. A variety of access ports is provided in each earth station for analog signals and for a broad spectrum of digital rates, based on the amount and types of traffic requirements of that particular station.

The system that SBS intends to implement initially will include three satellites—two in orbit (one spare), and one ground spare. As part of the SBS service, the customer will be able to obtain satellite transmission capacity for his private network on a full-period dedicated basis, and on an on-demand basis for overflow situations. The customer's total leased satellite transmission capacity will be dynamically allocated to meet his traffic demands (both as to routing and type—voice, data or image) based on priority assignments he establishes.

Within each customer's network, the SBS service will include a network management facility. This "window" into the customer's communications network will enable him to monitor network status and performance, change traffic handling priorities, order changes in service and collect usage statistics for internal accounting purposes.

A separate management facility will be used internally by SBS to monitor satellite and earth station performance, assist customers in designing networks to satisfy their requirements, distribute the customer networks efficiently among the satellite's transponders, and support system maintenance.

The proposed SBS system will best serve organizations requiring large communications networks with heavy and dynamic traffic loads. To install earth stations at all of a customer's remote sites, including those where the traffic would not justify an earth station, is not the intent. Rather, the objective is to provide an optimum system for each customer in which SBS ties together his traffic concentration points, while smaller offices—each connected by terrestrial services to the nearest earth station—are also brought closer to the center of the organization.

SBS has strived since its inception to look beyond the present needs of potential customers and to address, and hopefully provide for, their future requirements. The PROJECT PRELUDE experiments discussed previously touched on this future perspective by assessing new satellite applications in actual company operating environments. Additionally, SBS recognizes the absolute necessity for advanced terminal equipment to be available in the marketplace when SBS becomes operational. To assist in this, SBS has held a series of vendor conferences to advise about SBS system plans and capabilities, provide interface and service information, and to encourage these companies to intensify their development of advanced communications products. A conference for facsimile equipment manufacturers was held in December 1976 and a second conference for televisual equipment vendors was held in November 1977. A data

transmission equipment vendors' conference is planned for the near future.

ADVANCED APPLICATION POTENTIAL

It is clear that the SBS offering must provide capability for traditional voice and low speed data networks, but it is in the area of the emerging advanced applications that SBS sees the greatest future potential. SBS has conducted a number of in-depth case studies of the future communications requirements of individual potential customers and I would like to summarize for you briefly some of the findings. The advanced applications requirements we have identified and structured our proposed offering to serve would seem to be just as applicable in an international context as they are domestically. It should be emphasized that the leased services which SBS proposes to offer are for 24 hours, seven days per week. It is expected that this capacity, used during the day for conventional voice and low speed data communications, will allow for buffering of domestic batches of high speed data and facsimile for off hours shipment. And based on our investigations, an international requirement exists for this same kind of capability, taking advantage of off hours and time zone differences.

High-speed data communications

One clearly expressed requirement is for high-speed digital transmission, and SBS will offer data communications users a fully-switched network capability among a customer's earth station locations. Data rates include all standard speeds and range up to 6.3 megabits per second. This means that the data base or file that now takes an hour to transmit at typical, high-speed 50 kilobit service will be transmitted in one minute. Or a one-billion-byte file (8 billion bits) which now has to be distributed by truck could be transmitted to multiple locations in half an hour. Distributed processing to meet operational requirements will be facilitated by these high speeds, with the side benefits of load leveling among data processing facilities, redundancy of files for security in case of fire or accidents, and redundancy of processing capacity in case of machine outages.

The high data rate networks will provide direct communication links between computers, with no distance restrictions or penalties. As a result, a large data base can be managed at a central computing facility, retaining the simplifications associated with a single control point, but with the capability to distribute parts, or all, of the data base to remote locations. This capability will add new dimensions to the management of data base systems and yield some improved management tools. These data networks will enhance real-time central management of raw materials, purchases, inventories, production schedules, distribution, cost and pricing analyses, credit checks and postings, customer orders, competitor activities, etc. Many of these considerations are just as critical from an international perspective as from a domestic one.

Facsimile communications

SBS market investigations have shown that the availability of high-speed facsimile transmission capability can be expected to open up entirely new opportunities in document distribution from hard copy or memory as well as correspondence and first-class mail alternatives. To meet this requirement, the SBS offering will include the capability for digital facsimile transmission through a customer's SBS network at speeds two to 20 times faster than through current systems.

Teleconferencing

A very important finding in the case studies and other efforts undertaken by SBS is the desire expressed by all levels of management for a teleconferencing capability. The expense, inconvenience, and time associated with frequent travel offer an excellent reason for holding many types of meetings using satellite conferencing, and these factors become even more significant when international travel is addressed. SBS' offering of variable bandwidth on demand will accelerate teleconferencing applications as a cost-effective alternative to a large portion of business travel, and the same capacity that permits high-speed data rates and large voice traffic volume will be available for teleconferencing among multiple locations at very little incremental cost. Teleconferencing applications will range from slow-scan to full-motion color, with the customer deciding which he wishes to use.

INTERNATIONAL ENVIRONMENT

The same user needs that SBS perceives for domestic networks would seem to apply equally well for international applications. Certainly different service costs would be involved and the intensity of usage may not be as great as that for a domestic network, but the advantages to business operations of improved management and control through improved communications would be just as important. The benefit of being able to load level computer operations and take advantage of differences in prime shift hours is equally in evidence whether the computer centers are on the east and west coasts of the United States or in the United States and a European location.

This audience is particularly familiar with the shift within the United States and other countries toward an information-based society, and the ability to communicate or access that information effectively is becoming increasingly important. Many things are now under way or planned which are likely to spur increased improvements in international data communications. The efforts of COMSAT, the international carriers and foreign administrations in offering digital and

packet-switched services are a good example. Further, the plans of Intelsat and the European Space Agency to implement 12/14 GHz satellite systems in the 1980's, most likely with digital transmission, promise a future common carrier environment more conducive to the types of computer communications of interest to this group.

It may be helpful to discuss for a moment the existing industry structure. AT&T has the monopoly for dial-up voice and data services and represents about 60 percent of this $1 billion market. The International Record Carriers (IRC's)—RCA Global communications, ITT World Communications, Western Union International (not affiliated with Western Union), and TRT Telecommunications, account for the remainder. The IRC's provide dial-up and leased telegram/telex message services and some private line voice and data. Each of these carriers deals individually with the appropriate foreign communications agency for the terminating portion of the circuit, and either underseas cable or satellite (provided by COMSAT as a carrier's carrier wholesaler) facilities are used for transmission. The Federal Communications Commission has designated five "gateway cities"—New York, Washington, New Orleans, Miami, and San Francisco, and all international communications must be routed through these locations.

Presently, a customer with intermittent international communications requirements will automatically go by AT&T when he makes a dial-up voice or data call or will use Western Union for the domestic part of his record message, with the international segment apportioned by a pre-determined settlements formula to one of the IRC's. For leased private line voice and data circuits, the customer will deal directly with one of the IRC's (or in some cases, AT&T). The IRC's may "accept" the customer's communications anywhere in the U.S. although they are prohibited from providing services in the normal sense outside the gateway cities. The IRC will then lease the U.S. portion of the circuit from one of the domestic carriers and route it through the nearest gateway offices to the appropriate cablehead or satellite earth station for transmission overseas. In addition to the domestic and international circuit charges, the customer pays for the "backhaul" of the service from the gateway city to the nearest cable head or earth station, e.g., a circuit from Chicago to London might be routed to Washington and then backhauled to the Etam, West Virginia earth station for subsequent transmission.

SBS has generated a great deal of interest in the user community, and questions are frequently asked about how the company plans to interconnect its services internationally. Because we are licensed by the FCC as a domestic carrier, we are restricted from providing service to foreign locations and must rely on the appropriate carriers serving those points. Additionally, SBS has chosen initially to provide services to the 48 continental United States and will not serve Alaska, Hawaii, or Puerto Rico. Nor may we interconnect directly with COMSAT for service because, under present regulations, COMSAT is a "carrier's carrier" and, as such, may deal only with licensed international carriers.

We will, however, keep the customer's needs uppermost in our planning and work cooperatively with international carriers to achieve simpler and more direct connections for the customer's higher speed international data communications. The type of interconnect between an SBS customer's domestic network services and his international locations—including Canada and Mexico—will naturally depend on the type (voice, data) and nature (speed, volume) of the communications and on an evaluation of costs compared with other alternatives. However, under present regulations, the customer may interconnect with the international carrier at his SBS earth station closest to that carrier's gateway office, or he may use facilities totally outside the SBS system, just as he does today, if that is appropriate.

There are some obvious limitations in this approach. Now let me describe briefly the type of service environment SBS would like to see for interconnecting its customers' networks for international services. It will be over two years before SBS is operational and the international environment may be quite different then. While there is no circuit-switched higher speed digital service available, the need for such a service would seem to be clear. Many of the future applications identified by SBS require periodic, bulk data movement, and this holds true for interconnecting with international locations.

The FCC is presently investigating the public benefits in expanding the number of gateway cities in which international carriers may operate and, should a decision to expand result, it may prove to be best technically and economically for SBS to locate earth stations, conceivably its own or those leased to customers, in close proximity to the international earth stations and interconnect directly with the international carriers. This would avoid the expense and lower speed implications associated with backhaul and would permit a much simpler and higher quality international transmission.

The double-hop situation which will be encountered using a combination of domestic and international satellites may pose an initial problem for some users, but our conversations with potential customers indicate that this is far from insurmountable. Indeed, several have either adapted, or are planning, advanced data link protocols which minimize the effect of transmission delay and take advantage of the effective transmission capacity of satellites.

Additionally, SBS would welcome the implementation by foreign carriers of a customer premises earth station service concept in their own countries, along with a wider availability of high quality local distribution facilities. From our perspective, these are needed before uniform high-speed digital international networks are achieved.

SBS would hope that foreign regulatory bodies would prove to be just as responsive to clearly demonstrated customer demands as has the FCC and foster an environment that enables a customer to assemble a uniform communications network capability where there is little operational difference between his domestic and foreign locations.

SBS's efforts to date have focused on the domestic private-line communications requirements of a very specific

customer set—large, geographically-dispersed companies—and we believe that the unique service approach described earlier provides these organizations an innovative network capability for meeting forthcoming communications needs. It is SBS's hope that implementation of this service within the United States will stimulate the international community with whom our customers must interconnect to move to provide compatible facilities and services. And SBS will continue to study the future requirements of the marketplace and make its findings known publicly. It is only through this open exchange of information that the potential international user will benefit.

Emerging markets for satellite data communications in the public service*

by JAMES G. POTTER
Public Service Satellite Consortium
San Diego, California

INTRODUCTION

The Public Service Satellite Consortium (PSSC) recently completed a study for NASA's Goddard Space Flight Center which addresses the basic requirements of four potential telecommunications markets in the public service: the U.S. health care system, elementary and secondary education, American libraries, and that sector of the public service which is concerned with the provision of continuing education to health professionals.[1] The composite requirements of these and several other promising market groups are reviewed in this paper.

The potential demand in 1982 for satellite communication capacity from public service users is projected under the optimistic assumption that an appropriate satellite communication network will be available, a network in which numerous, inexpensive earth stations are located at the point of use. It is also assumed that there will be no "gap" in the development of public service satellite communications, which may occur if NASA's endangered species of experimental satellites, such as ATS-6 and CTS, cease to function adequately before a growing and influential community of public service users graduate to operational service on common carrier facilities.

PSSC's surveys among its members have reconfirmed what other studies have shown: that video applications are likely to predominate.[2] Seven of the ten transponders projected by PSSC to support 1982 requirements are related to video applications. Four of these seven transponders already are committed to support public broadcasting. Six represent new markets.

What is surprising about PSSC's projections is evidence of a growing market for satellite data communications service. While projected 1982 channel capacity is modest (on the order of 90 MHz of bandwidth or three conventional satellite transponders), the potential transmission revenue is substantial. This potential revenue, which is estimated to be on the order of $100 million annually, dwarfs that which is likely to accrue from provision of private-line video service.

* This work was sponsored in part by the Goddard Space Flight Center, Contract NAS 5-23865, under the direction of Dr. Edward A. Wolff.

THE UTILITY OF COMMUNICATION SATELLITE NETWORKS

Throughout the public service there are three recurring needs: improved access, maintenance of quality, and containment of costs. The appropriate application of communications satellite networks could ameliorate each of these concerns. Indeed, low cost communications is a prerequisite for organizational arrangements which depend upon the substitution of communications for transportation to achieve higher productivity.

Synchronous communications satellites have generic properties which make them attractive vehicles for performing certain functions of interest to public service organizations:

1. Broadcasting, in which expensive audio-visual programs are aggregated at a few points of origination and distributed to many receivers, as in a TV or radio network.
2. Archiving, in which expensive computer capacity, data bases, audio-visual, and/or computer programs are concentrated at a few central locations where they may be accessed (and updated if appropriate) from a large number of remote points. An example is the computer utility of the Ohio College Library Center in Columbus, which is used by over 1100 libraries in 44 states to construct catalog cards and to purchase serials.
3. Flexible routing. It is possible to allocate the available capacity among the possible routes in the network in an extremely flexible manner. Although the demand for private-line communications satellite circuits from public service organizations may be in excess of $100 million in 1982, the geographic distribution of this traffic, its time distribution, the connectivity patterns, and the magnitude of the peak loads are unknown. The communications satellite will provide a cost-effective, "toe in the water" capable of aggregating related private-line requirements throughout a geographic region.

THE PUBLIC SERVICE SATELLITE CONSORTIUM (PSSC)

PSSC is a growing organization of over ninety non-profit public service agencies from the fields of education, health

care, library service, public broadcasting, and related interests. PSSC was created in 1975 to inform the public service user community about the capabilities of satellite technology and to facilitate aggregation of public service telecommunications requirements and resources.

Most individual public service organizations cannot now afford access to the sophisticated information systems presently (or soon to become) available. Before cost-effective information networks which are responsive to individual user requirements can become operational, it will be necessary to aggregate sufficient numbers of users to allow effective negotiations for core service requirements.

PSSC's role is that of a consultant and broker. It is important that the established carriers have access to comprehensive, objective information regarding the communications requirements of PSSC's members and that PSSC's members are aware of important capabilities which the established carriers can—and cannot—provide. Thus far PSSC has worked exclusively with NASA experimental satellites, but within the next year it will begin buying appropriate communications capacity in bulk from established carriers and re-selling this capacity in smaller increments to its members on a non-profit basis.

PSSC has been working with the State of California and an ad hoc committee of federal agencies, which includes the White House Office of Science and Technology Policy, the Agency for International Development, the Appalachian Regional Commission, the Department of Interior, the Department of Health, Education and Welfare, NASA, and the Veterans Administration, to develop an effective program for accelerating the transfer of communications satellite technology to the public service in the 1980s. Two alternatives are under discussion: (1) use of federal funds to place an appropriate communications payload on the Syncom IV satellite of the Hughes Aircraft Company, which will be launched by the Space Shuttle in 1980; and (2) a competitive service procurement involving established carriers and perhaps aerospace companies, whereby the federal government will provide incentives for the private sector to meet projected public service network requirements using relatively inexpensive satellite earth stations. There is agreement that the growing momentum within the public service community to use cost-saving communications technology must be nurtured without interruption and that public service users must pay some, and eventually all, of the fair price of providing needed service through established common carrier mechanisms.

BASIS FOR DEMAND PROJECTIONS

The projections to follow, while speculative, are based on two assumptions: that significant increases in telecommunications utilization will not occur over a five-year period unless:

1. The organization obviously will benefit from changing its way of doing business, and
2. The required organizational tremors will be mild.

The public service sector has been partitioned into three categories:

1. Category A—modest institutional adjustments are necessary and significant productivity gains are likely, resulting in "modest" risk to the supplier of telecommunications services. (More specifically, the risk is probably still too high for a common carrier in the absence of federal participation to reduce his downside risk; but the likelihood of successful market aggregation is relatively high.)
2. Category B—the institutional requirements picture shows promise, but more information is needed to assess probable benefits and risk.
3. Category C—major institutional adjustments are necessary, the risks to the communications supplier are high, but the possible benefits are also high. Examples include an electronic mail system tailored to the requirements of the U.S. Postal Service, or a telecommunications/computer system addressed to core curriculum subjects in elementary and secondary education, freeing the classroom teacher to concentrate on individual problems rather than mass problems. Small scale experiments which were addressed to "Category C" problems would be appropriate for inclusion in a NASA experimental program, although it may be years before a viable commercial market develops.

The time frame for the projections is 1982, using the best 1976 data available to PSSC. In general, it is assumed that approximately one-third of the total projected telecommunications traffic would be carried by a communications satellite if an appropriate network were available.

The projected levels of telecommunications utilization are based on estimates of what it costs the organization to do a job now—inefficiently. PSSC assumes, for example, that hospitals should not have to spend 10 percent of their annual operating budget on record-keeping functions and is attempting to promote increased use of information networks on this basis. PSSC is assuming implicitly, however, that once a hospital commits to increased use of computers and telecommunications, it will begin using the extra capabilities thereby made available to perform new, unforeseen tasks.

U.S. HEALTH-CARE SYSTEM

PSSC concluded in its study for NASA that the three opportunities which are most likely to lead to extensive utilization of satellite communications in the U.S. health-care system involve the aggregation and sharing of:

1. Computer power, data bases, and software for use in hospital information systems for accounting, billing, inventory control, and patient records;
2. Clinical-support systems for radiology, cardiology, and pathology; and
3. Audio-visual materials and programs for computer-managed instruction to support the continuing educa-

tion requirements of various professional groups who work in a hospital environment.

The U.S. health-care system has been plagued by rampant inflation. Whereas the Consumer Price Index increased by 98 percent in the period from 1950 to 1973, hospital costs increased by 600 percent.[3] In this same period, the federal contribution to health-care costs increased from 25 to 40 percent.[4] In an effort to contain these costs, the Carter Administration attempted to place a ceiling on the rate of increase in hospital expenditures of 9 percent a year in 1977. Although this proposal was not approved by Congress, the health-care industry was placed on notice that effective, voluntary cost-containment procedures must be developed or mandatory federal regulations are likely.

The average American hospital is estimated to spend $20 per patient per day on record keeping,[5] an expense which amounted to $5.6 billion in 1976, or 10 percent of total expenditures.[6] A number of companies, including Technicon, Shared Medical Services, Computer Sciences Corporation, and McDonnell-Douglas Automation, have developed effective automated record keeping procedures which have resulted in productivity gains in participating hospitals.[7] Unfortunately, present indications are that only hospitals having in excess of 200 beds can justify the expense of a dedicated management-information system or can afford access to a shared system. Yet, 70 percent of the 7,174 hospitals in the U.S., many of which are located in rural areas, have less than 200 beds.[8] The availability of an appropriate satellite data communications network would permit a larger fraction of U.S. hospitals to access the automated administrative-support systems which are now being used successfully by larger, urban hospitals.

The advantages of an automated hospital information system include: (1) reduced clerical personnel costs; (2) reduced incidence of lost charges and rejected claims; and (3) improved cash flow. Since such a large portion of health-care expenditures are reimbursed by a third party (e.g., Medicare, Blue Cross, or Blue Shield), use of central data bases and electronic information transfer can lead to a dramatic improvement in cash flow. The average payment cycle is reported to have been reduced from sixty days to twelve days in several California hospitals which recently implemented automated record keeping systems.[9] Other advantages of hospital information systems which include the patient history are: (1) improved professional communications, which enhances continuity of care (the possibility of lost or incomplete records is reduced) and reduces the incidence of episodic care; (2) groups of patients at risk can be identified, and preventive medicine can be practiced systematically; (3) the quality of care can be audited more easily; and (4) the continuing education needs of the providers can be determined more systematically.

The disadvantages of automated record keeping systems are: (1) there are potential privacy problems (although no system is immune from unauthorized access); (2) the relative strengths and weaknesses of providers can be evaluated more systematically, which may or may not create barriers to acceptance; and (3) such systems require structured input, which necessitates annoying changes in the working routine of health practitioners.

In projecting the magnitude of the satellite data communications market in 1982, PSSC makes the following assumptions:

1. The rate of growth of hospital expenditures will stabilize at a compounded annual rate of 9 percent, as requested by the Carter Administration. (The rate of growth in 1975 and 1976 was about 14 percent, and total hospital expenditures amounted to $55.4 billion in 1976.[10])
2. Economies of scale resulting from use of a satellite data communications network will make hospital information systems cost effective for hospitals having at least fifty beds. (Hospitals having more than fifty beds accounted for 97 percent of total expenditures in 1976.[11]).
3. Hospitals will continue to spend approximately 10 percent of their total budget on record keeping functions.
4. The percentage of the record keeping budget spent on automation (given that automated procedures are used at all) will remain at its present value of 12 percent.[12]
5. The percentage of the automated record keeping budget spent on telecommunications will be 15 percent.[13]
6. The percentage of telecommunications service provided by satellite will be 33 percent.

The projected 1982 satellite revenue is then: $(\$55.4B)(1.09)^5(0.97)(0.12)(0.15)(0.33)=\$49$ million.

Preliminary information available to PSSC suggests that an American hospital performs an average of sixty-two record keeping transactions per patient per day.[14] Approximately 270 million patient-days of service were administered by American hospitals having fifty beds or more in 1976. Assuming that the volume of traffic grows at a compounded rate of 9 percent, that 50 percent of the total volume is processed locally, that 33 percent of the remaining volume is carried by satellite, and that the average administrative form contains 8,000 bits but that only 50 percent of this information content needs to be transferred back to the data base in an average transaction, the estimated volume of hospital administrative traffic in 1982 is: $(270\times10^6)(1.09)^5(62)(0.5)(0.33)(8{,}000)(0.5)=1.7\times10^{13}$ bits per year.

PSSC has not included possible traffic associated with clinical support services in its estimates. Three areas which show near-term promise are radiology, cardiology, and pathology. PSSC is evaluating these areas but does not now have sufficient information to estimate probable demand.

One must exercise caution when projecting demand for telecommunications in clinical medicine. It would be logical to consolidate health-care delivery throughout a geographic region, substituting communications for travel and treating patients at the lowest possible level of a hierarchical health-care system in the interest of convenience, fairness, and cost. Dr. Maxine Rockoff of the National Center for Health Services Research notes a basic fallacy in this line of think-

ing, however:[15]

"To the extent that the cost of care increases with each level in the hierarchy, avoiding referrals reduces costs, and benefits those who pay for care, including patients and insurers. But considered from the perspective of that 'next level up' whose expertise is to be brought to the patient via telecommunications technology instead of having the patient referred to it, this may be no benefit at all. Indeed, the pecuniary interests of the 'next level up' may be best served by maximizing referrals, not minimizing them."

A possible implication for those who wish to market telecommunications services to clinicians is that one should concentrate on the sharing of computer and audio-visual resources, not scarce human resources.

CONTINUING EDUCATION

In a survey which was administered in the summer of 1976, 81 percent of PSSC's membership expressed interest in a network for continuing education. More recently, PSSC conducted a survey of the membership to determine composite requirements for a federally subsidized Public Service Communications Technology Satellite (presumably Syncom IV with an appropriate communications payload). In the period between October 17, 1977 and January 10, 1978, forty-two public service organizations responded in writing or were interviewed by senior staff. Quantitative information regarding the probable demand for private-line video, voice, and data circuits was received from seventeen organizations.

The response was strongly oriented toward one-way video. If service which is comparable to that planned for Syncom IV (which is expected to provide an EIRP in excess of 43 dBW throughout the continental U.S.) is available at approximately $400 per transponder-hour, an estimated 8,170 channel-hours would be utilized annually by these seventeen organizations. On the basis of this response, PSSC projects a demand for 12,000 channel-hours of one-way video in 1982, which represents an annual revenue of approximately $4,800,000. Although the time distribution and peak load of this requirement is unknown, PSSC estimates that three protected transponders will provide adequate service.

PSSC plans to respond to this requirement in 1979 by using facilities of the Western Union and RCA satellite networks. Westar will interconnect one hundred and fifty Public Broadcasting Service earth stations and one hundred and ninety-two National Public Radio stations.[16] PSSC is now engaged in a study for the Corporation for Public Broadcasting to develop equitable arrangements for sharing the public broadcasting network. PSSC plans to supplement coverage available from Westar using RCA's Satcom network, which now interconnects approximately one hundred and eighty cable TV systems.

When economical service becomes available, PSSC plans to develop a continuing education network which provides one-way television and two-way data to each classroom. Much of the material to be distributed will be pre-recorded, but an important element of the programs will be interaction involving use of mark-sense cards and optical card readers. Prior to the class, the students will receive study guides which contain a number of questions. The answers to these questions and others raised during the class will be answered in a multiple-choice format and relayed to the studio during the class. The lecturer and his assistant will receive a histogram of responses in real-time, which will help to determine what supplementary material to emphasize. Each student's responses will be evaluated in non-real time by computer, and each student will be mailed an evaluation after the course is completed. Although this evaluation will be computer-generated, resources in the student's community will be identified to follow up progress made during the class.

The projected volume of data communications traffic is modest. Assuming that 12,000 channel-hours of programming are delivered annually, that there are an average of 1,000 students per class, that the average student responds 16 times an hour, and that 30 bits of data are transferred per response, only 6×10^9 bits per year of data need be transferred while maintaining individual records. The required system throughput is so low that the economics are significantly enhanced by relying exclusively on mark-sense cards and not allowing voice feedback, which tends to be ineffective in large-audience situations anyway.

A one-way video and two-way data network could combine the best features of pre-recorded lectures, live interaction, and computer-managed instruction. Even with production costs as high as $20,000 per hour and transponder costs of $400 per hour, it would be possible to administer such a network at a profit while charging course fees of approximately six dollars per student-hour if an average of 1,000 students per class could be attracted.[17]

EQUIPMENT MAINTENANCE

Federal and state government agencies have extensive investments in equipment which is dispersed throughout the country. PSSC does not have adequate information regarding the dimensions of this requirement, but preliminary insight may be obtained from the experiences of the Federal Aviation Administration in its VORTAC (VHF Omni Range Tactical Communications) system.[18] In 1975 the FAA had a total maintenance budget of $320 million, of which 80 percent was personnel related. Through use of telemetry and centralization in its VORTAC program, the FAA could eliminate the need for many on-site technicians and spare parts, which would result in a considerable savings. Studies by the Mitre Corporation indicate that the maintenance budget for the VORTAC program, which amounted to $38 million in 1975, could be reduced to approximately $10 million annually through appropriate use of telecommunications.[19]

Use of telemetry, microprocessors, and telecommunications probably could effect tremendous savings in equipment

maintenance and load management of various resources (power, water, light, heat, air conditioning, oil and gas pipeline flow, control of traffic lights and vehicular flow, etc.). To gain a tentative estimate of the volume of the associated telecommunications service, PSSC makes the following assumptions:

1. The total investment in capital equipment by public service agencies is $100 billion, an amount which is growing at 5 percent annually;
2. Five percent of this equipment is subject to savings through appropriate use of telemetry and centralized maintenance procedures;
3. The annual cost of maintenance averages out to be 10 percent of the capital cost of the equipment;
4. In those cases where savings can be effected through use of telemetry, 15 percent of the maintenance budget is associated with telecommunications service; and
5. One-third of the resulting traffic is carried by satellite.

The resulting projected potential satellite traffic is: $(\$100B)(1.05)^5(0.05)(0.1)(0.15)(0.33)=\$32$ million.

The annual bit rate is projected under the assumption that the average cost of this dispersed equipment is $25,000, that thirty-two bits of data are sufficient to address and encode the message, that each piece of equipment is interrogated every ten minutes on the average, and that all of this information is relayed by satellite: $(\$100B/\$25K)(1.05)^5(0.05)(32)(6)(24)(364)=4.3\times10^{11}$ Bits/Year.

AMERICAN LIBRARIES

Requirements to support so-called "technical services" in American libraries (cataloging, serials control, acquisitions, circulation, and inter-library loans) will be projected from the present budget of the Ohio College Library Center (OCLC), which now spends approximately $2,280,000 annually on leased terrestrial lines to reach 1,100 libraries in 44 states. PSSC makes the following assumptions:

1. Use of automated services in libraries which already accept the concept will grow from a present level of 3 percent of the total operating budget to 8 percent of the operating budget.[20]
2. The number of libraries which use automation will grow at a compounded annual rate of 15 percent; and
3. One-third of the total telecommunications traffic potentially could be routed by satellite.

The potential revenue in 1982 for technical services is estimated to be $(\$2,280,000)(1.15)^5(8.0/3.0)(0.33)=\$4$ million.

5,707,828 books were cataloged in the OCLC system in 1976, using an average of 4,800 bits per request.[21] PSSC projects the potential volume of satellite traffic in 1982 to be $(5,707,828)(1.15)^5(8.0/3.0)(0.33)(4,800)=4.8\times10^{10}$ Bits/Year.

To gain a qualitative appreciation of the potential demand for information retrieval services in 1982, PSSC makes the following assumptions:

1. One percent of the U.S. population will interrogate a data base on the average of once a week;
2. The average cost of each search will be $2;
3. Fifteen percent of this revenue will be related to telecommunications; and
4. Thirty-three percent of the traffic will be routed by satellite.

The estimated revenue is then $(220\times10^6)(\$2)(52)(0.01)(0.15)(0.33)=\$11$M.

Assuming that an average of ten bibliographic records are retrieved with each search, each of which is encoded with 4,800 bits, the potential volume of satellite traffic is $(220\times10^6)(52)(0.01)(0.33)(10)(4,800)=1.0\times10^{12}$ Bits/Year.

The total revenue deriving from library-related services is estimated to be $15 million.

ENVIRONMENTAL MONITORING

The National Oceanic and Atmospheric Administration (principally the National Weather Service), the Environmental Protection Agency, the U.S. Geological Survey, the Corps of Engineers, the Department of Agriculture, and the Department of Interior all have extensive requirements for monitoring atmospheric, edaphic, and/or oceanic data. Ecosystems International Inc., under contract to the Goddard Space Flight Center, determined that in 1975 these agencies maintained 90,714 stations in the U.S. having an average of four sensors apiece.[22] The annual cost of the present operation is estimated to be $98.3 million and the volume of information is 1.36×10^{11} Bits/Year. Only 6 percent of these platforms are remotely interrogated at the present time. PSSC estimates that if an appropriate satellite data communication network were available, environmental monitoring would contribute another $5 million of business annually. In arriving at this estimate, it is assumed that 10 percent of the present $100 million budget would be spent on telecommunications services, of which half would be directed to satellite carriers.

OTHER POTENTIAL MARKETS

PSSC does not have sufficient information to evaluate a number of other promising candidates for service. Other possibilities are:

- Department of Defense training
- Training of other federal and state employees
- Law enforcement (fingerprint data, automobile registration and license information, LETS, and NCIC functions)
- Access to data regarding eligibility for welfare benefits
- Search and rescue/disaster relief
- Internal Revenue Service, Social Security data transfer
- Job bank involving the Department of Labor

TABLE I.—Projected Market for Public Service Satellite Communications (1982)

Service Sector	Est. Revenue	Est. Volume
American Hospitals	$ 49M	1.7×10^{13} Bits/Year
Equipment Maintenance	$ 32M	4.3×10^{11} Bits/Year
American Libraries	$ 15M	1.0×10^{12} Bits/Year
Continuing Education	$ 5M	Three video channels 5.8×10^{9} Bits/Year data
Public Broadcasting	$ 4M	Four video channels Four 15 kHz audio channels
Environmental Monitoring	$ 5M	6.8×10^{10} Bits/Year
Total:	$110M	Four Western Union transponders Six additional transponders

SUMMARY OF TRAFFIC PROJECTIONS

PSSC's projections of "Category A" service sectors are summarized in Table I. Seven video transponders, which represent space-segment revenues of $9 million annually, and three additional transponders for data, which represent total transmission revenues of $101 million, are projected. Four of the projected seven video transponders will be used by public broadcasting, which has entered into a seven-year contract with Western Union. In addition, approximately one-third of a Western Union transponder will be used by National Public Radio to distribute four 15 kHz audio channels to its licensees.

In a large network of small stations, the space-segment revenue associated with the estimated data traffic will amount to approximately 20-30 percent of the total, or $20-$30 million. It is noteworthy that such a small amount of bandwidth could generate so large a revenue—given adequate market aggregation.

COMMENTS ON THE NATURE OF THE TRAFFIC

PSSC's near-term market projections are dominated by the requirements of the health-care industry, both in terms of volume and revenue. Public education is conspicuous by its absence. Dr. Louis A. Bransford, Director of Service Development of PSSC, concluded in the recent market study for NASA:[23]

"The structure of the present system of public education in America, both economically and programmatically, appears to be inconsistent with the requirements of a broadly-based telecommunications network. Implementation of a comprehensive information network may face organized resistance and probably will take years to accomplish."

The projected volume of satellite data communications traffic is on the order of 2×10^{13} bits per year. To place this figure in perspective, a single Satellite Business Systems transponder operating continuously at 50 megabits per second has a peak capacity of 1.6×10^{15} bits per year, about an order of magnitude higher than that required to support projected public service requirements, assuming that the peak load will be about ten times the average load. The earth stations which SBS allegedly plans to install have a capital cost of approximately $474,000.[24] The possibility of exchanging reduced system throughput for reduced earth-station cost immediately suggests itself.

Table II was suggested by Norman Abramson of the Aloha Systems Project, who is an expert on "affordable" satellite data communications.[25] Dr. Abramson advocates use of a packet-switched satellite data communications network, operating at a speed somewhere between one and two orders of magnitude below the SBS network. For concreteness, Table II assumes a system throughput of five megabits, although this figure is arbitrary and not the result of a cost-performance evaluation.

In a network which is composed of many point-to-point links which interconnect a large number of nodes, such as the Bell System's Direct Distance Dialing Network for message telephone service, it is not economical to connect every node to every other node. Rather, the messages are routed through a hierarchy of nodes, using expensive switching machines to provide the necessary connectivity. When the application calls for direct connection of nodes, as in broadcasting or archiving, the additional links and switching machines of a hierarchical network add unnecessary cost, complexity, and noise to the system.

Dr. Abramson observes:[26]

"The natural structure of satellite communications links does not require the establishment of point-to-point communications channels in the traditional sense. A more natural form for satellite communications resources is a broadcast structure, allowing each network node to communicate directly with every other network node. The communications architecture which best matches the broadcast structure of the satellite communications channel is therefore one which starts from the premise that communications can proceed from many transmitters to many receivers in a communications environment analogous to that of a multi-person conference. And in the case of data communications it is possible to implement such a broadcast architecture using small earth stations."

TABLE II.—An Affordable Satellite Data Communications Network

Application	Capacity	Capacity Using Low-Cost Earth Stations
Continuous Data	50 Mbps	5 Mbps
Two-Way Video	One Conversation	Not Applicable*
Two-Way Audio	800 Conversations	80 Conversations
3,000 Word Reports	400 Reports/Sec.	40 Reports/Sec.
200 Word Messages	6,250 Messages/Sec.	625 Messages/Sec.
Interactive Computer Terminals	500,000 Active Users	50,000 Active Users

* Two-way video would not be physically impossible in this hypothetical network, but the earth stations probably would cost at least $85,000 apiece. PSSC assumes arbitrarily that earth stations must cost less than $25,000 in an "affordable" satellite communications network.

To make a satellite data communications network for modest-throughput requirements more affordable, Dr. Abramson suggests that: (1) multiple access of the transponder be accomplished using Aloha-type packet-switching techniques; (2) the satellite transponder be designed to transmit at a peak power which is approximately ten times higher than the average power; and (3) that such transponders use relatively narrow bandwidths (about two MHz). With these modifications, the required sensitivity of two-way data earth stations could be reduced substantially and/or the system throughput could be maintained at levels which approach those attainable with more expensive TDMA multiple-access procedures. But if conventional satellite transponders are used in the early 1980s to meet public service data communications requirements, it is still likely that the earth stations can be built in lots of 50 for less than $25,000 apiece. Hughes Aircraft already has developed a similar earth station for operation at four and six GHz which it plans to market for about $25,000.[27]

CONCLUSION

The communications capacity required to serve some important public service requirements is modest, and the potential revenue is significant. What is needed is a cooperative effort by common carriers and major public service institutions to aggregate the market. The federal government may or may not elect to accelerate the communications-technology transfer process by providing initial subsidies. In any case, PSSC will continue to focus on the requirements of its members and to impress on the carriers that there is money to be made by responding to these requirements.

ACKNOWLEDGMENTS

PSSC's information regarding the requirements of the health-care industry was assembled primarily by Dr. Thomas E. Terrill of the Akron City Hospital in Akron, Ohio. The material concerning continuing education was synthesized by Ms. Kathleen King of PSSC's staff and by Ralph P. Christenson, M.D. I am indebted to Dr. Norman Abramson of the University of Hawaii and to Gregory Nichols of PSSC's staff for numerous insights concerning network architecture and systems engineering. To John Witherspoon, President of PSSC, I owe most of the insights I have obtained regarding the institutional factors which will be the predominant influence underlying the ultimate acceptability of the emerging communications techniques which now show such promise in the public service.

Packet switching services for the autodin community

by DONALD J. O'ROURKE
United States Government
Washington, DC

INTRODUCTION

The AUTODIN II Program brings the advantages of packet switching technology to the Defense community. The concepts and advantages demonstrated successfully in the AUTODIN I store and forward message switching technology are not being discarded, but rather supplemented by a parallel operating AUTODIN II in order that the best transmission techniques for the efficient transfer of bulk transaction and interactive type data can be made available to the community of data system users.

This paper reviews the management decision to add packet switching capabilities to the AUTODIN I store and forward message environment; examines the technology to

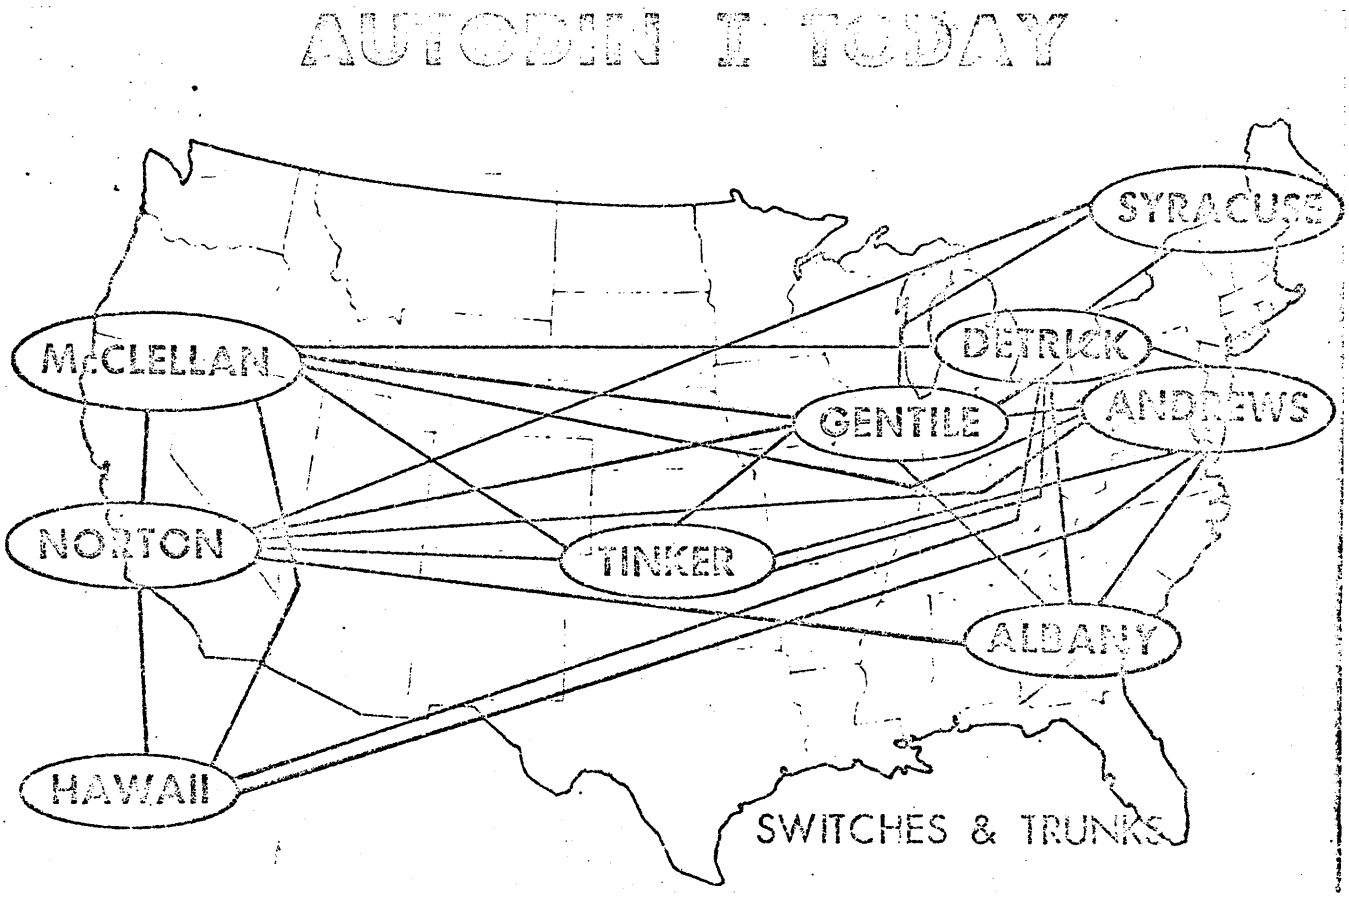

Chart I

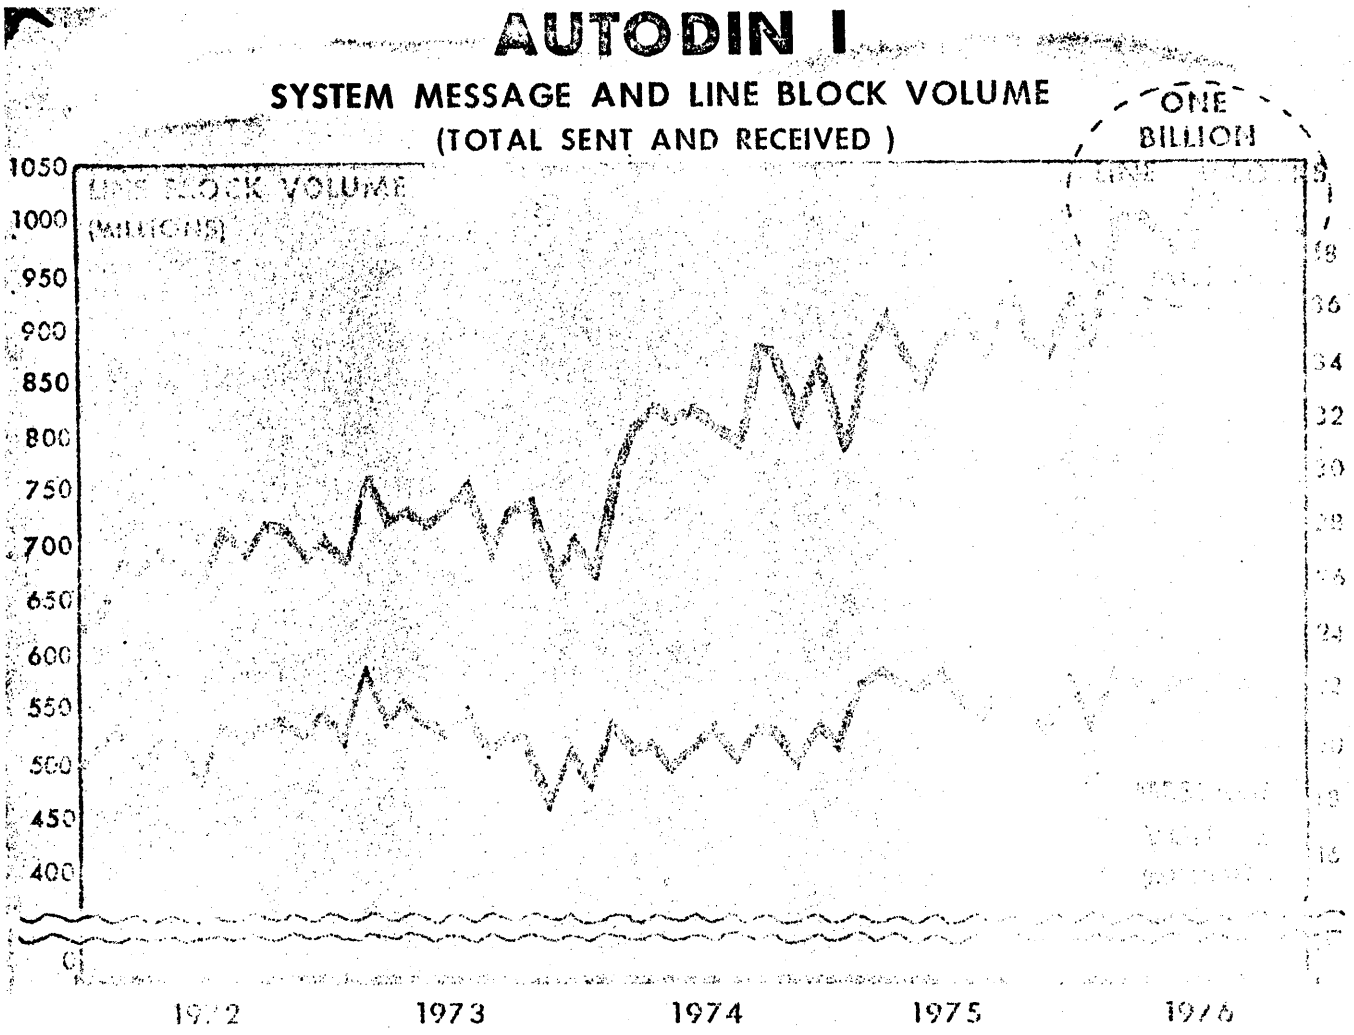

Chart II

be employed, discusses the implications for future growth and utility in this environment, and provides a report on the progress toward realizing that goal.

PLANNING FOR AUTODIN II

Since the advent of data processing, the Federal Government has experienced a steady growth in the numbers of computer based information systems employing remote terminals. The development and implementation of the AUTODIN I in the early 1960s was the first step in providing computer oriented communications network capabilities to this community of users. The AUTODIN I provides message switching store and forward communications on a worldwide basis.

Chart I shows the presently operating switches of the AUTODIN I System within the Continental limits. Eight additional switches located on foreign soil provide the overseas extensions of the AUTODIN I System.

The traffic on the AUTODIN I System has steadily grown through the years, requiring periodic increases in the system's capacity and the expansion in the type of services rendered. While the number of messages shown in Chart II has only grown at an average yearly rate of 5 percent, the type and length of messages have changed drastically over the past five years. The system traffic, measured in lineblocks (each lineblock equals 640 bits), has grown from 625 million lineblocks in 1972 to over one billion lineblocks per month in 1977 (640 billion bits per month). This increase in traffic, plus the characteristics of the traffic itself clearly indicated the increased use of AUTODIN I for computer oriented data transfer.

Studies by the Department of Defense and others have

AUTODIN II

TRAFFIC ANALYSIS

	USAGE AT INSTALLATION		POSSIBLE PROJECTED USAGE IN THE '80'S
	% BUSY HOUR PACKETS	% BUSY HOUR BITS	
O INTERACTIVE	6	1.2	45.0

O NARRATIVE	5	4.5	10.0
O AUTODIN I TRUNKING	9	8.7	5.0
O OTHER NETWORKS	--	--	

Chart III

shown a continuing trend toward the growth of transaction oriented interactive systems, in addition to the established requirement for remote job entry and bulk data and narrative transmission. A study initiated in 1972 indicated that by 1976 there would be approximately 250 computers involved in on-line communications functions with approximately 8,000 terminals associated with these systems. Projections into the mid-1980s indicated that within the DOD, there will be approximately 2,500 computers with some 20,000 terminals involved. These studies led to an examination of the methodologies to be employed to meet these requirements. Among the earliest conclusions was the decision that to the fullest extent possible common-user rather than dedicated networks must be employed to ensure the most efficient and economical service possible.

- HIGH TRUNK UTILIZATION
- NO BUSY CONDITIONS (System accepts traffic-stores until transmitted.)
- MESSAGE RESPONSIBILITY
- SPEED, CODE AND FORMAT CONVERSION
- MESSAGE RETRIEVAL CAPABILITY
- MULTIPLE ADDRESSING
- INEFFICIENT FOR MIXTURE OF INTERACTIVE AND TRANSACTION ORIENTED OR PRECEDENCE GOVERNMENT TRAFFIC.

Chart IV—Characteristics of Message Switching vs. Circuit Switching

- EXCELLENT FOR INTERACTIVE AND TRANSACTION ORIENTED OR PRECEDENCE GOVERNMENT TRAFFIC
- TRANSPARENT TO ALL USERS DESPITE USER PROTOCOL
- HIGHER SPEED—LOWER ERROR RATE
- HIGH RELIABILITY—ADAPTIVE ROUTING
- RAPID TRANSIT THROUGH SYSTEM
- NO MESSAGE RESPONSIBILITY
- NO MESSAGE RETRIEVAL OR RECOVERY
- HIGHER OVERHEAD REQUIREMENTS
- TRAFFIC HELD AT SUBSCRIBER VIAL FLOW CONTROL
- SMALL INTRANSIT STORAGE

Chart IV A—Characteristics of Packet Switching vs. Message Switching

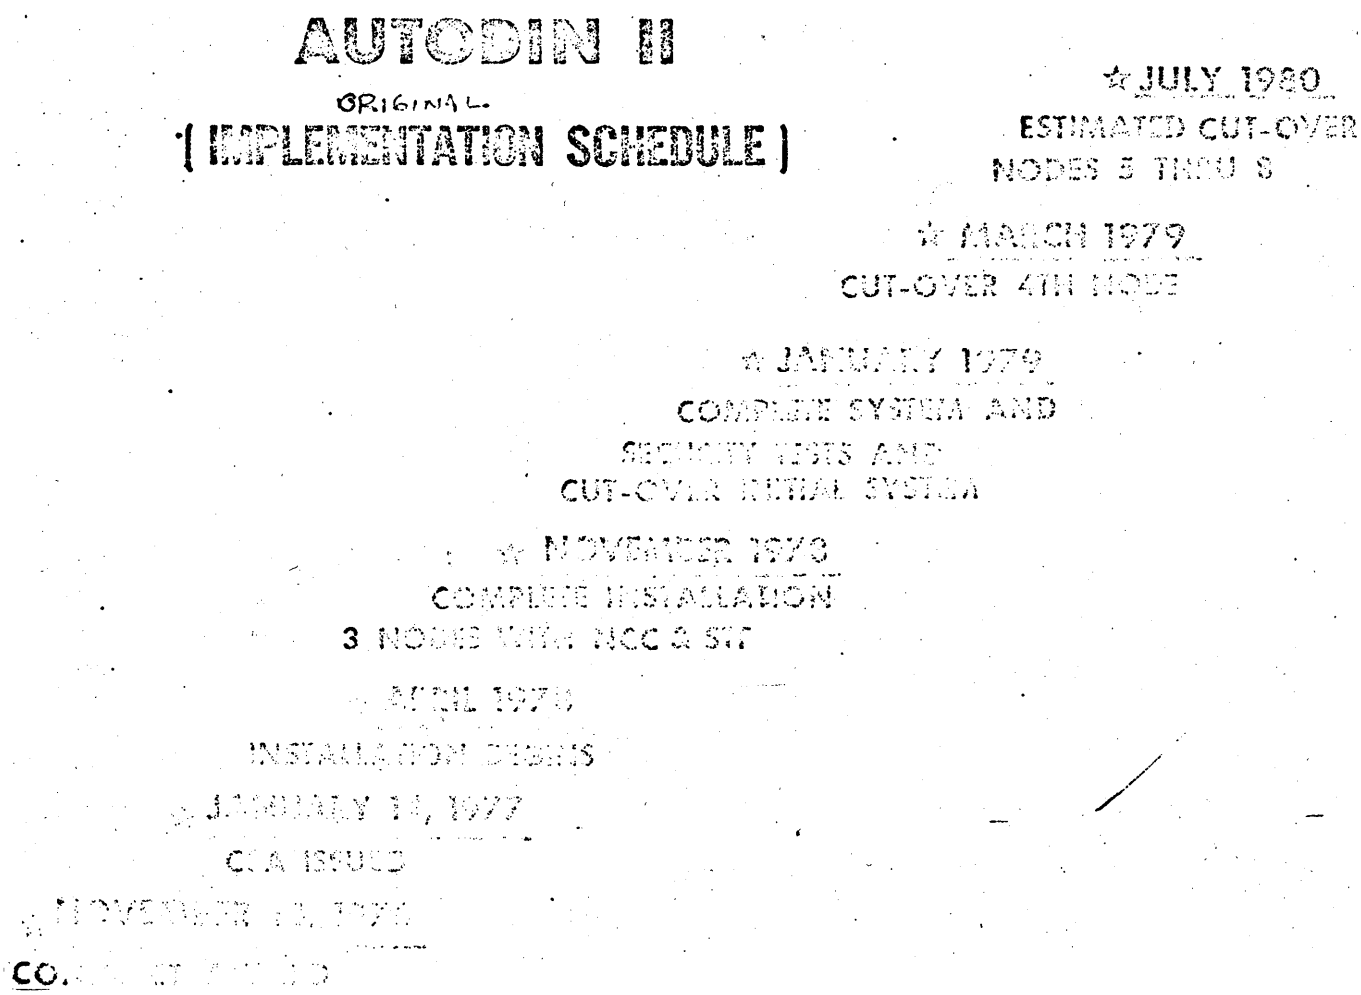

Chart V

The economies of AUTODIN I, as a common-user message system, have been well documented. With the possible demise of TELPAK rates and their replacement by higher cost facilities, the decision by the Defense Department to continue their dedication to the common-user network concept through the implementation of AUTODIN II, is even more commendable in today's world than it was even just five years ago when the basic design concepts of DIN II were originally conceived. A study of the various switching alternatives highlighted the characteristics of Circuit, Message and Pocket Switching.

An examination of these summaries suggests that there is an advantage to maintaining a store and forward capability in the Federal Communications environment for message type traffic while adding packet switching capabilities to satisfy the requirements of the interactive and transaction oriented user.

The trend toward interactive type traffic, as opposed to bulk transfer, has been clearly demonstrated (Chart III). While the initial traffic introduced into the AUTODIN II System shows that 85 percent of it is devoted to the transfer of bulk information, the amount of interactive and transaction oriented requirements will greatly expand so that by the early 1980s, a cross section of the AUTODIN II traffic will show that 45 percent will be in this category of service. Since packet switching, as indicated on Chart IVA, provides the most efficient transmission scheme for this mixture of traffic, the decision by the Department of Defense to implement a packet switching network, is commendable. Accordingly, a decision was reached to acquire packet switching network capabilities and to have that network (AUTODIN II) work in conjunction with AUTODIN I. High speed interconnect channels will connect the two systems together. The message type traffic handled by AUTODIN I will be transferred over these dedicated links to AUTODIN II and transmitted over a common high speed transmission net-

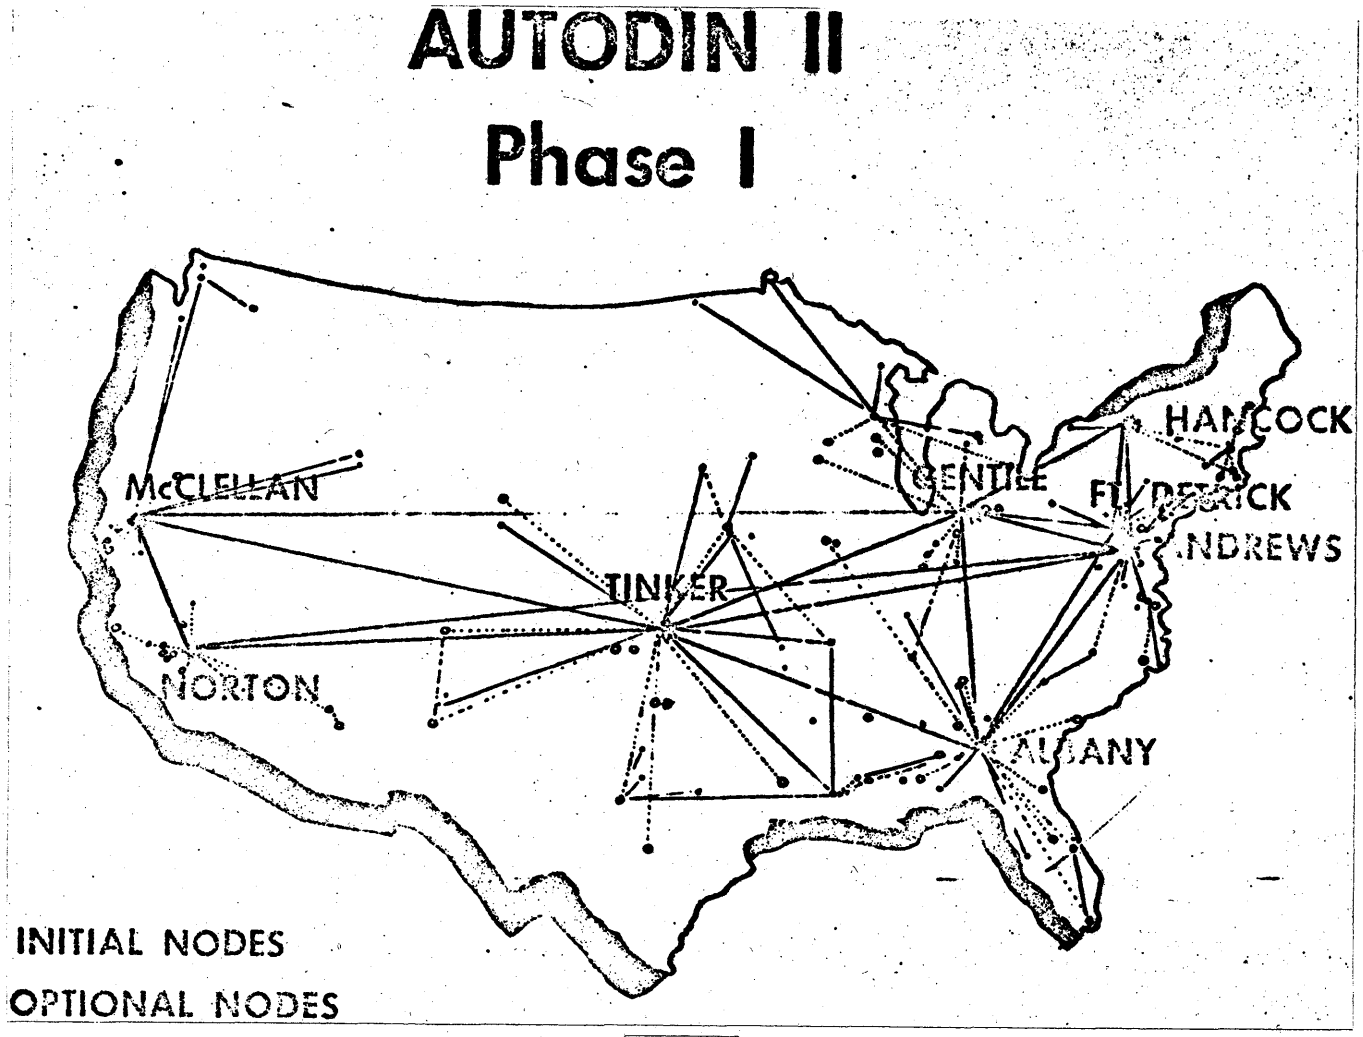

Chart VI

work, thereby providing to the users the choice of two types of data switching facilities through a common transmission network.

The request for proposal for this service was released to industry on November 26, 1975. An award of a contract for development and implementation of the system was made to The Western Union Telegraph Company on November 10, 1976 with the Commercial Service Order issued January 1977. Computer Sciences Corporation and Ford Aerospace and Communications Corporation are the primary sub-contractors to Western Union. (Chart V)

The contract awarded for AUTODIN II, Phase I, covers the CONUS operation only. Phase II will expand AUTODIN II into overseas locations. Until Phase II is implemented, the overseas AUTODIN I System will handle data traffic and will be interconnected into the AUTODIN II System overseas at suitable gateway locations. (Chart VI)

TECHNOLOGY EMPLOYED

At this point it is advisable to ask "What is Packet Switching?" The answer could fill volumes but, here we will restrict ourselves to the CCITT definition (Chart VII).

"A group of binary digits, including data and call control signals (address) which is switched as a composite whole. The data, call control signals and possibly error control information, are arranged in a specified format." Essentially, each addressed packet occupies a transmission channel for the duration of the transmission of the packet only. The channel is then available for use by packets being transferred between other users. Thus, channels between packet switches are shared between many users on a demand basis, and it becomes possible for a user having a single link to engage in the exchange of data packets with a number of other users at the same time. This technique results in the

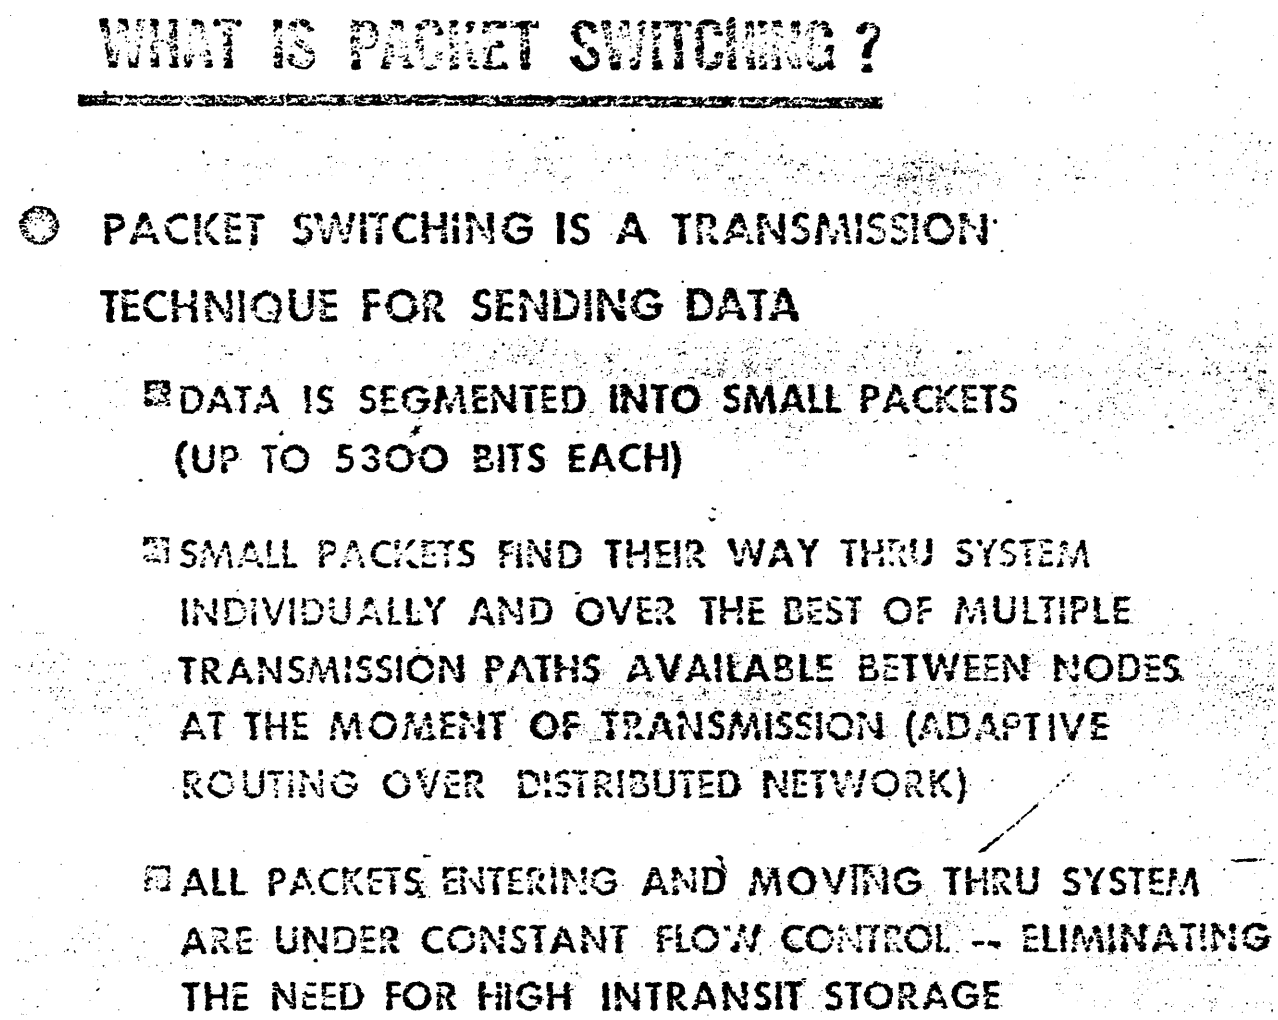

Chart VII

achievement of adaptive routing over a distributed network. With all packets entering the system and moving under constant flow control, therefore, the need for intransit storage is eliminated.

To the maximum extent possible (Chart XIII), the AUTODIN II specification and performance recognizes the technological advancements which evolved over many years from the development and operation of the Defense Department's ARPA network. While the AUTODIN II System is based on this technology, the operational characteristics and the operating performance varies greatly as shown on the following chart. Unavailable within the ARPA technology were the requirements for multilevel classified and precedence type traffic, high throughput with tremendous surge requirements in case of national emergencies and an unprecedented 12 percent growth factor each year through the life of the system.

REQUIREMENTS SPECIFICATION

Based upon a series of studies, the DOD developed the following list of primary requirements:

1. Phase I network configuration of four nodes, network control center and test facility, with capacity for 200 subscribers with 13 subsystems.
2. Modular growth capability to eight or more nodes with some 1500 subscribers operating in 47 subsystems.
3. Node capacities:
   - 150-200 full duplex line terminations.
   - Each line can be 110 bits per second to 56 kilobits per second (KBPS) for subscribers and 9.6 KBPS to 230 KBPS for trunks.
   - Throughput form 300 KBPS to 2.5 MBPS.

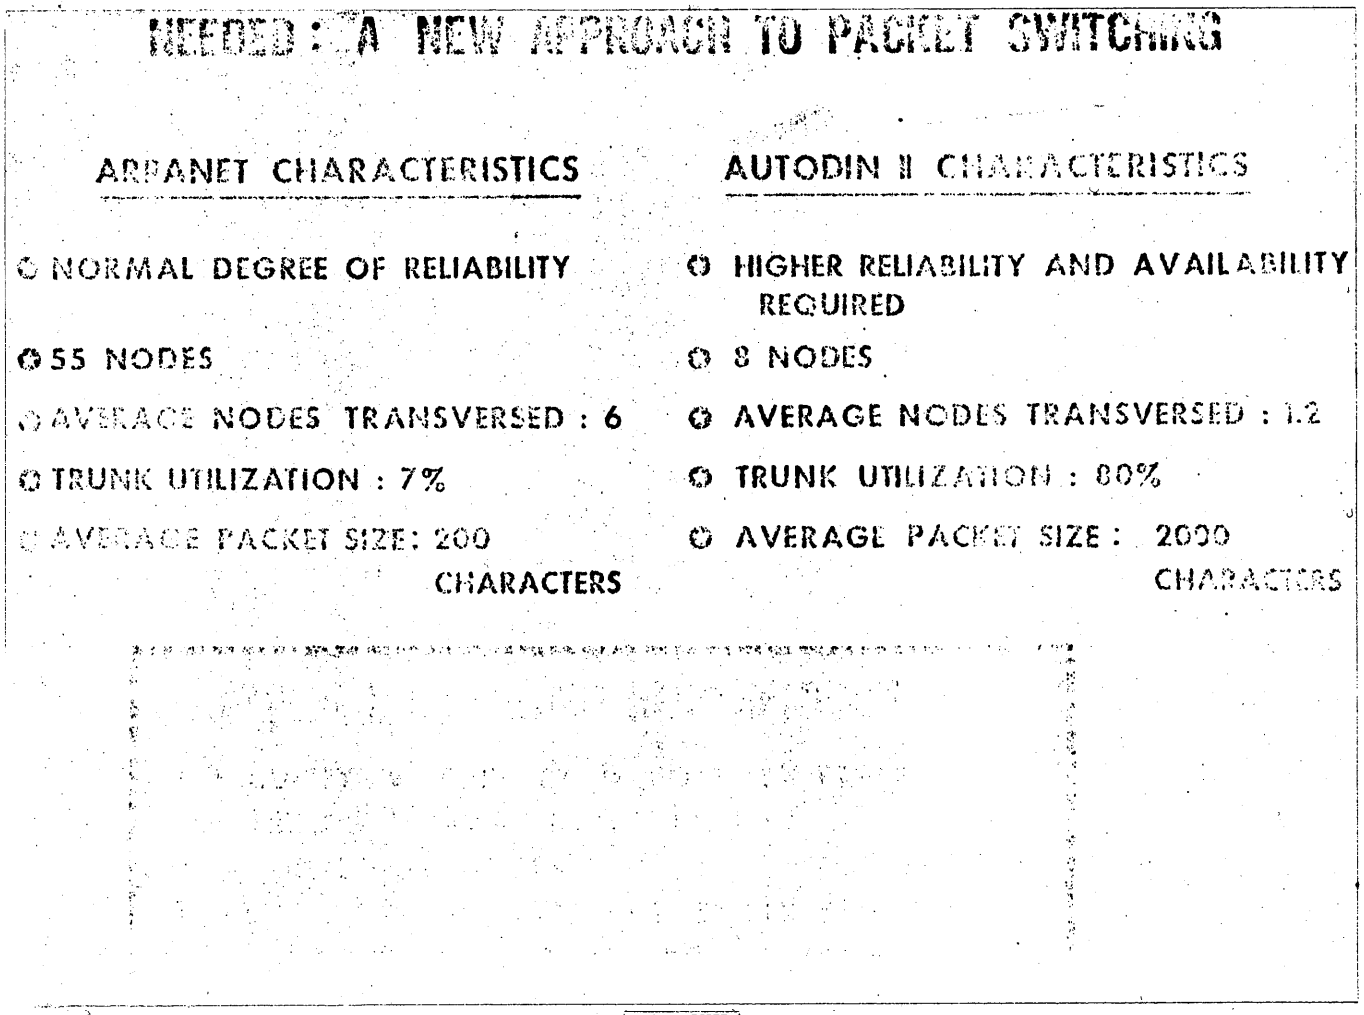

Chart VIII

4. Maximum packet size—5300 bits.
5. 16-level precedence system.
6. Non-blocking for high precedence interactive traffic.
7. Availability of 99 percent for single-homed and 99.5 percent for dual-homed subscribers.
8. Minimum impact on existing subscriber equipment software system.
9. End-to-end undetected error rate of less than 1×10^{-12}
10. Segment misdelivery rate of less than 1×10^{-11}
11. 300 ms. max backbone delay for interactive and query response, based on 600 bit packets.
12. Transparent to text.
13. Capable of being certified to handle all levels of classified traffic.

NETWORK DESIGN

The Network Design was predicated on the following Government provided projected subscriber data on the present AUTODIN I System and the future system:

TRAFFIC STATISTICS (BUSY HOUR)

Average Traffic Volume, including AUTODIN I	7.2×10**9 Bits
AUTODIN I Traffic Volume Trunk	4.9×10**8 Bits
Peak Traffic Volume Originated in any one second	8.1×10**6 Bits
Computer Traffic Volume	5.9×10**9 Bits
Terminal Traffic Volume	8.5×10**8 Bits

Based upon these and other data, a network design of eight packet switching nodes (PSNs) located at the eight AUTODIN I sites in the Continental U.S. was developed. Backbone trunks between these nodes will operate at 56 KBPS with sufficient connectivity to provide at least three routes out of each node.

Chart IX shows the trunk speeds between DIN II sites and between AUTODIN II and AUTODIN I sites.

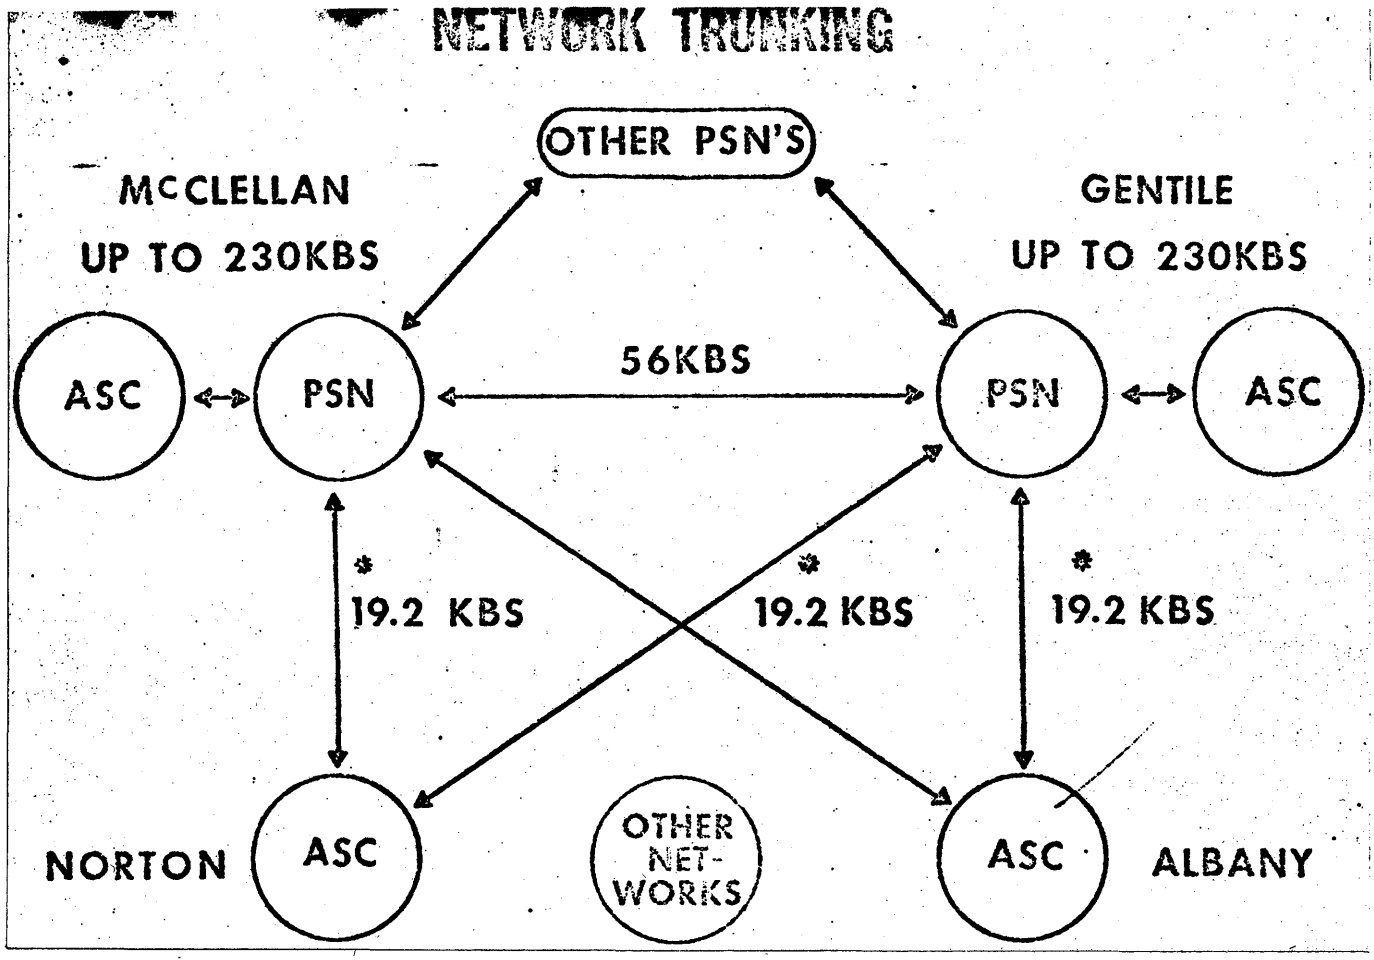

Chart IX

The initial network is scheduled for cutover in January 1979 with three nodes at Fort Detrick, Frederick, Maryland; Tinker Air Force Base, Oklahoma City, Oklahoma; and McClellan Air Force Base, Sacramento, California. After system testing, a fourth node will be added at Gentle Air Force Base, Dayton, Ohio in April 1979. The system capacity can be increased by modularly expanding the four initial nodes and by adding additional nodes.

It is anticipated that by 1981 traffic will have increased to require four additional nodes to be located at the Hancock Air Force Base, Syracuse, New York; Marine Corp Base, Albany, Georgia; Andrews Air Force Base, Maryland; Norton Air Force Base, California. At this point in the implementation plan, all CONUS AUTODIN I sites, except Hawaii, will have a colocated DIN II switching center.

SECURITY REQUIREMENTS

The overall AUTODIN II security requirement is to provide a system which does not allow unauthorized acquisition or alteration of classified information.

This is accomplished by a combination of techniques and procedures which include personnel security, physical security, administrative security, communications security, emanations security and software security.

The first five of these are well developed and well-known to military communicators. Software Security, however, is not so well developed and considerable research is still going on in this area. In AUTODIN II, software security will be achieved by use of security kernel technology derived from the MITRE model of DOD security regulations. This approach integrates all of the security controls for the system into a small portion of the operating system code which can be verified to operate correctly and to be unalterable by any other part of the system.

The basic elements are summarized as follows:

1. *PACKET SWITCHING NODE (PSN)*

   (a) Switch Control Module (SCM)
   (b) Line Control Module (LCM)

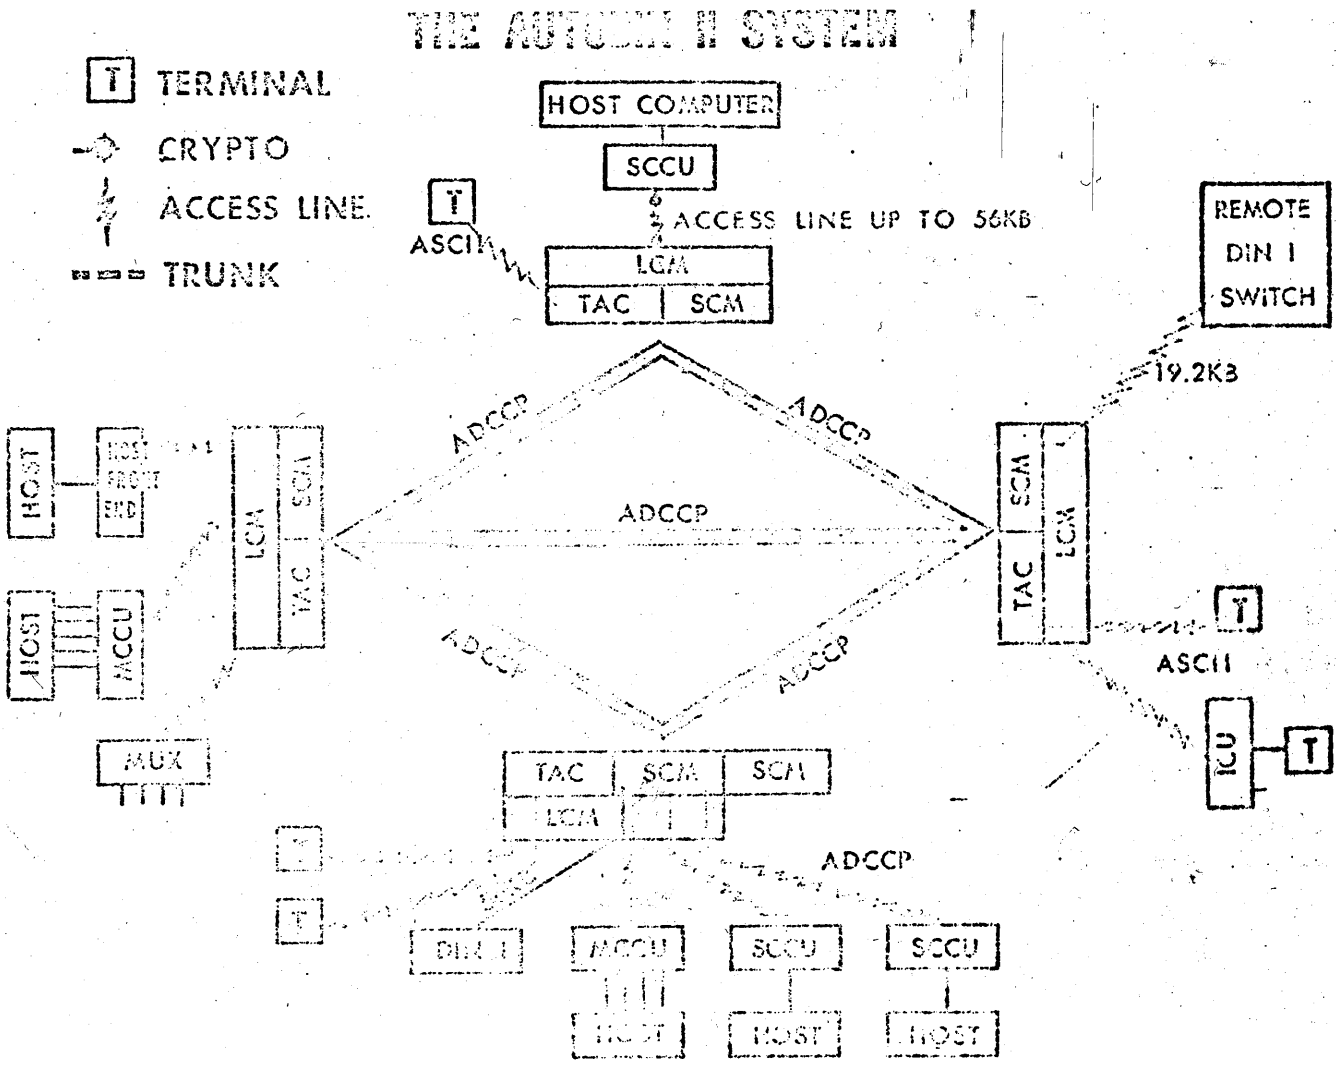

Chart X

2. *TRANSPARENT TERMINAL INTERFACE*
   (a) Terminal Access Controller (TAC)
   (b) Interface Control Unit (ICU)
3. *TRANSPARENT HOST INTERFACE*
   (a) Single Channel Control Unit (SCCU)
   (b) Multiple Channel Control Unit (MCCU)
4. *TRANSMISSION NETWORK*
5. *NETWORK ENCRYPTION EQUIPMENT*

7. *CENTRAL NETWORK CONTROL CENTER AT DCA HEADQUARTERS*

Chart X highlights, in an overall system configuration, most of the above-mentioned network elements. The distributed network, using 56 KBS trunks initially interconnects all four of the initial system nodes directly providing the adapted routing principle to this packet switching network. A colocated DIN I facility illustrated in the southern switching node is directly interconnected by a high speed local trunk, while a remote AUTODIN I switch is terminated into the eastern node by a 19.2 KBS interstate transmission circuit. The chart also illustrates the use of the various host interface devices that may eliminate the need for reprogramming directly in the various host computers interconnect into the AUTODIN II System. Single-channel (1) and Multichannel (32) Control Units are illustrated at each of the four packet switching nodes. The SCCU and MCCUs are located on customer premises directly associated with the host computers.

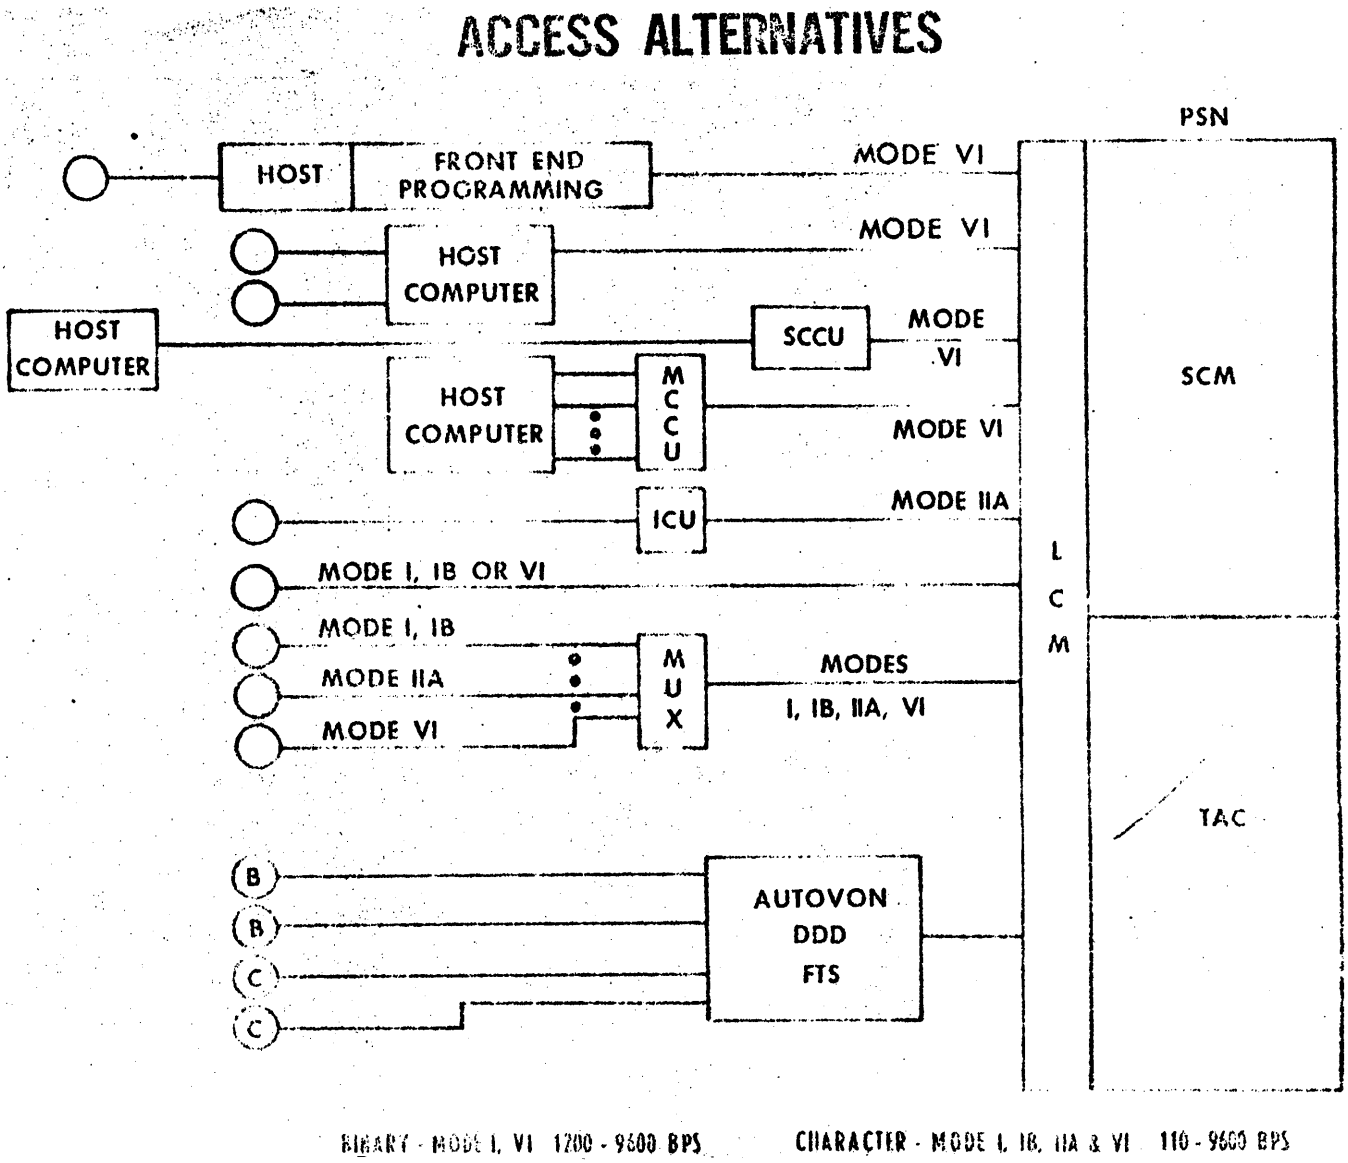

Chart XI

The system also indicates that terminal devices connected to the system go directly to the Terminal Access Controller (TAC). The TAC, however, is located within each node for one TAC unit can, in fact, handle 250 individual remote terminal devices. An Interconnect Control Unit (ICU) can be provided, if necessary, when terminals do not themselves have direct interconnectability.

Chart XI highlights in more detail the various means to access the system. Host computers can provide the interconnect protocol himself by reprogramming the host computer or adding a front-end device, or more simply they can employ either of the Western Union furnished Channel Control Units (single or multichannel) and avoid any local software modification. Shown also are the various terminal modes terminating directly into the TAC, either directly or through the ICU device. Also illustrated is the ability of the system to terminate circuits utilizing the DDDs, the Government AUTOVON, or the Federal Telephone System.

Chart XII illustrates the makeup of the packet, which is distributed throughout the network. The packet is 5300 bits in length with approximately 600 bits devoted to overhead and 4700 bits reserved for the transmission of data. The host information coming through the Channel Control Units and terminal information coming through the Terminal Access

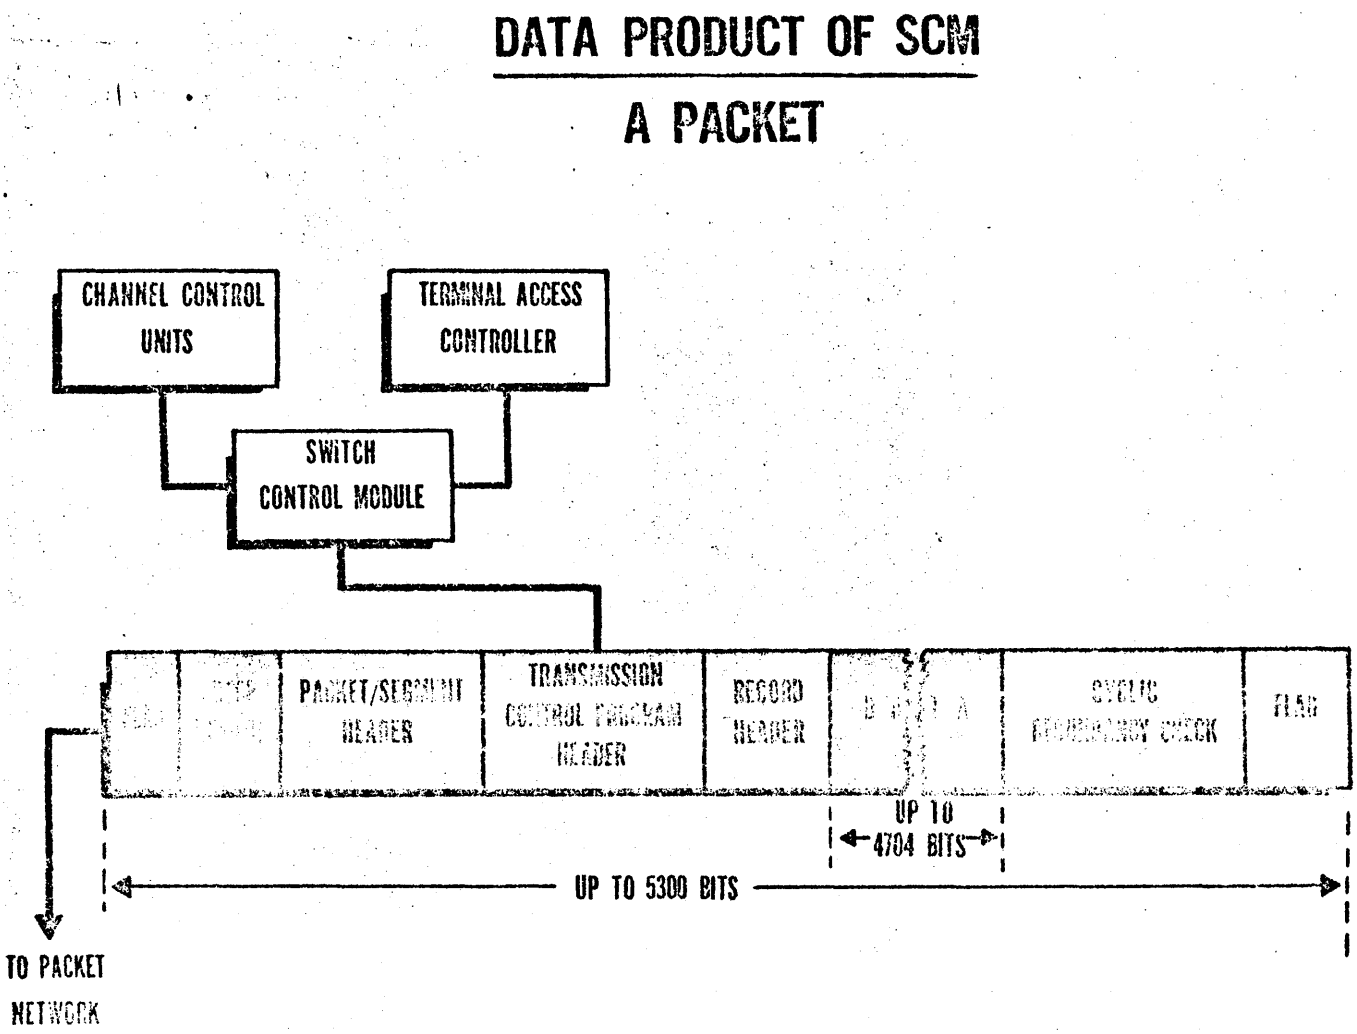

Chart XII

Controllers are first converted to segments in these two units and then converted to packets in the Switch Control Module just before entering the transmission system.

NETWORK CONTROL CENTER (NCC)

A Network Control Center monitors the operational status of the circuits, switching computers and user computer. It will assist in the diagnosing and correction of malfunctions. The NCC will achieve this by using the same DEC PPD 11/70 Processor as is used in the PSN. This PDP 11/70 will be complemented with magnetic tape and disc storage, high speed printers and four CRT positions for operator interface. It will be connected to at least one PSN and possibly two for redundancy connection will take place via communication links.

PATCH AND TEST FACILITY SUBSYSTEM

The second segment of the PSN is the Patch and Test Facility. At the AUTODIN I colocated sites, the AUTODIN II PTF will be integrated with the existing AUTODIN I PTF. In these combined facilities monitoring function will be performed by the SCM. All monitor points that have a direct bearing on circuit reliability and quality will be automatically scanned, and the scan results sent to the SCM. All control commands required to restore or maintain opera-

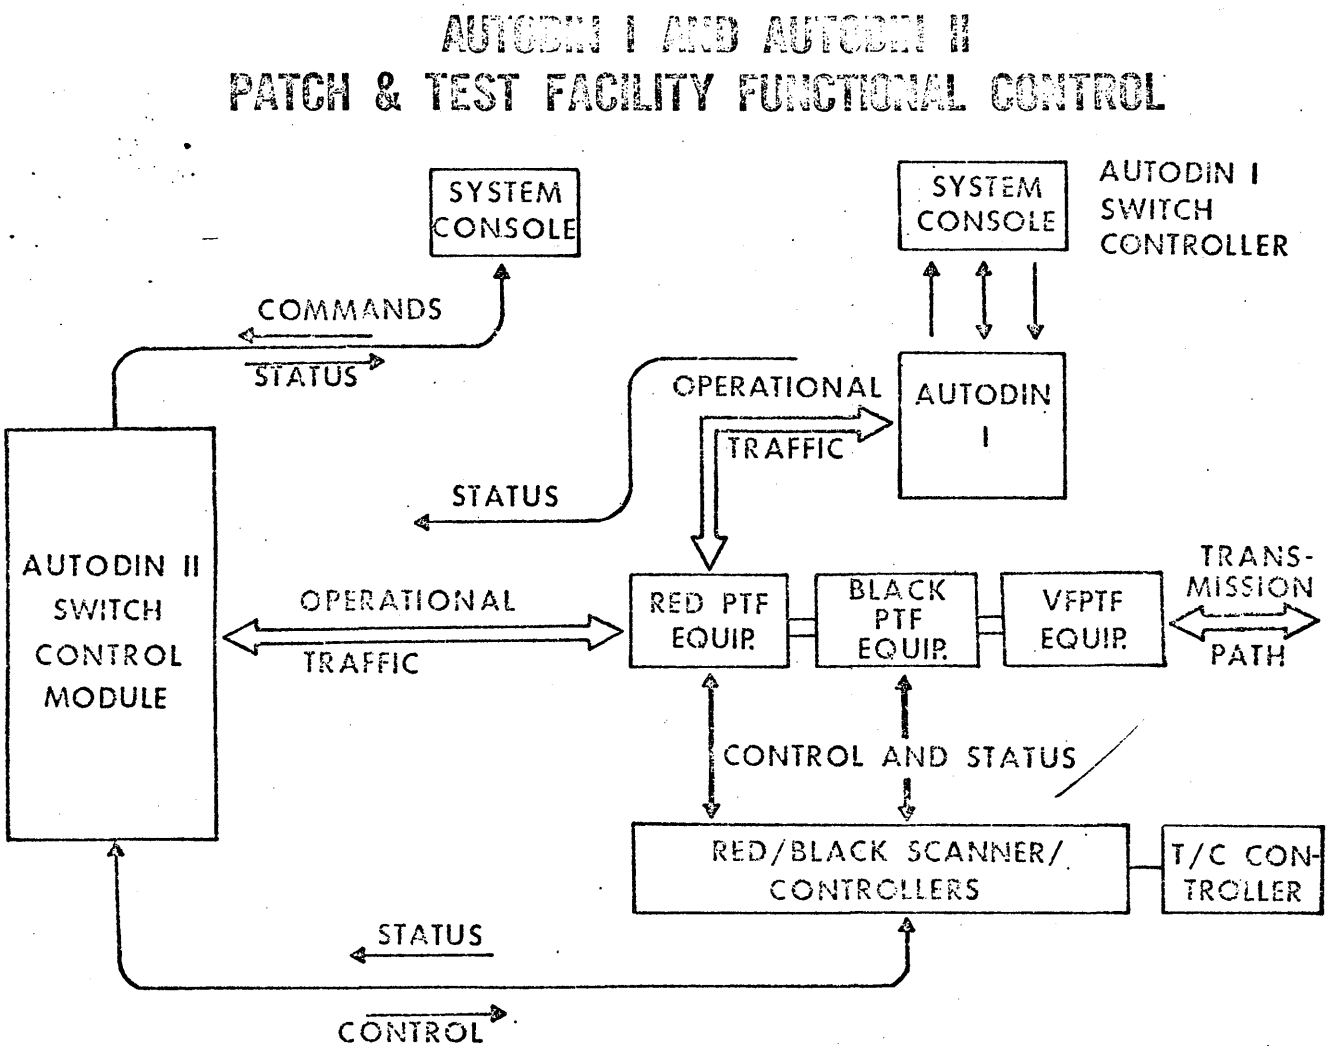

Chart XIII

tional circuit integrity will be formatted and transmitted by the SCM (either automatically or upon request from the tech controller) and will be executed by the PTF equipment. (Chart XIII)

CONCLUSIONS

Packet switching technology as added to the AUTODIN provides an example of the adaptation of new technology to an established environment. The user of this and the earlier implemented message switch technologies now has an opportunity to employ that unique capability that best satisfied his data communications need.

With the interconnect capability to be established between the AUTODIN I and AUTODIN II, the user can select that optimal network which meets his immediate need.

INTRODUCTION

A national computer network linking educational and research institutions is frequently proposed as a means of making available specialized computing resources, minimizing duplicate software development, and making more efficient use of the nation's total computing resources. However, a number of economic, political, and organizational, rather than technical, issues must be resolved before such a network is constructed. A Network Simulation Project, supported by the National Science Foundation, has been investigating these issues. Now in its third year, the project has gathered and analyzed a variety of data contributed by representative institutions concerning their computing resources, user profiles, and computing policies and practices.

Results of the modeling and data analysis support the arguments for operational economy, software development and maintenance economies, specialized service availability, and other proposed benefits of resource sharing at a national level. On the other hand, a number of barriers have been identified that must be addressed. These include institutional constraints on balance of payments (both positive and negative), institutional inabilities to expand service offerings to the network, difficulty of account control, and several network organizational and management problems.

The results of simulation and gaming exercises involving institutional administrators and other personnel were obtained too late for inclusion in the proceedings. These will be discussed at the presentation.

THE PROBLEM

Decision makers at educational and research institutions are grappling with increasingly difficult questions concerning the best means to satisfy the computing requirements of students, faculty, and staff members. The computing needs of these groups are increasing in variety and complexity, as well as in magnitude; and the means of satisfying these needs are becoming broader. Consequently, it is clear that attempting to meet all computing requirements "in-house" is no longer feasible. Technological advances in computing hardware will not, in themselves, solve the problem, for software and data base development, maintenance, and user support represent an increasingly larger part of the total cost of computing. As the variety of computing requirements increases, the non-hardware portion of computing costs can only escalate.

One mechanism for alleviating some of the problems posed is the computer network. Not only can networks provide ready access to a wide variety of available and supported software, but they can make these resources available very cost effective.[1] In 1972-73 EDUCOM,* with the financial support of the National Science Foundation, organized a series of General Working Seminars[2] on the subject of computer networking in higher education and research. Participants included university administrators, computer center directors, users from key disciplines, and computer scientists. Both general and specialized working sessions were organized to investigate many aspects of networking.

In session after session, regardless of their professional roles, participants came to similar general conclusions—namely, that it is now technically feasible to create a network linking computer facilities at colleges, universities, and research institutions around the country. Although many technological problems remain, the primary difficulties confronting such a network were felt to be non-technical in nature, involving economic, political, and organizational

* This work is sponsored by the National Science Foundation under Grant Number MCS75-03634, "A Simulation and Gaming Project for Inter-Institutional Computer Networking" (Network Simulation Project).

* EDUCOM is a consortium of more than 250 colleges, universities, and non-profit organizations that serve higher education. It was founded to help its members make the most effective use of computer and communications technology.

considerations. Obtaining a clear understanding of these factors before undertaking any large-scale networking development was seen as critical. It was this judgment that led to the initiation of the current research project.

THE RESEARCH PROJECT

While existing networks provide an indication of the costs and technical characteristics that might be associated with a national network, they cannot indicate how member institutions would be affected by economic, organizational, political, and intellectual considerations; how users would be affected by the availability of multiple resources at a variety of prices; how "balance of payments" problems (both deficits and surpluses) would impact institutions; and how a network might be impacted by institutional actions.

No existing network has the necessary characteristics to permit the study of these issues. Although the ARPA network, for example, offers interconnection between computing facilities at many universities and research institutions throughout the country, the single-source nature of the funding for most of the computing activities removes the source of many of the problems that need to be investigated.

The use of an actual network to examine many of these issues poses a number of other problems. Experimentation on a national basis would be extremely costly, would take several years to conduct, would be severely restrictive in the approaches and alternatives that could be investigated, would be disruptive to the normal operations of both the network and its institutions, and would require an inordinate commitment of energy and personal time from key individuals across the country.

In recognition of these difficulties, a simulation apporach was selected to investigate some of the behavioral and policy issues of such a computing network. Focus is on the potential impact of the network upon member institutions, as well as the impacts of institutional decisions and policies upon the network. The simulation approach provides flexibility as to the types of networking situations that can be examined, and allows for the testing, at a relatively low cost, of a variety of alternatives. For example, the model can be used as an analysis tool to investigate the impacts of a wide variety of behavioral assumptions. It can also support a game, played by institutional representatives, to investigate questions pertaining to likely behavior encountered in a networking environment.

Initially, a six month planning study was conducted by eight individuals knowledgeable in the areas of model building, gaming, economics, resource administration, and educational and research computing.[3] The present Network Simulation Project is a three-year project implementing that plan.

The first phase of the project was devoted to basic data collection and analysis. Each of eighteen participating institutions contributed data on their computing resources (hardware and software), pricing schedules, priorities, turnaround levels, demand, and user behavior profiles. The network simulation model was developed and used with the accumulated data base to conduct a series of preliminary investigations. Details of the phase one model development and findings have been reported in References 4 through 10.

The second phase of the project was devoted to including computing policy information in the institutional data base, and to refining the simulation model. Visiting teams interviewed administrators, users, and computer center personnel at each participating institution. The computing policies and practices in effect at each institution were deduced from this information and subsequently confirmed with the participants. This updated data base is currently being used in a series of further experiments using the network simulation model. The data has also been used to support many of the analyses discussed below.

The third phase of the project, currently in progress, has converted the simulation model into a gaming version with a conversational interface. Using this version, both a remote and a centralized set of gaming experiments are being conducted. Personnel from each of the eighteen institutions are actively participating, each representing the "best" interests of their home organization. In the remote experiments, each institution is operating with a "straw network," a static network using programmed decision rules for all institutions (except for the player's own institution). This provides for controlled experiments in which responses to particular types of circumstances and environmental conditions can be tested. The centralized experiments will then be conducted during an intensive live three-day session, which will permit the investigation of dynamic inter-institutional interactions.*

BENEFITS OF A NATIONAL NETWORK

Analyses of the resources and policy data collected from the participating institutions, as well as investigations using the network simulation model, have revealed a variety of positive factors associated with a national network. Several of these are summarized here.

Operational economies

The availability of network computing resources can lead to the combining of facilities, a reduction in size or range of offerings at some computer centers, and better utilization of the remaining facilities. Any of these alternatives can result in operational economies. For example, Harvard has been able to significantly reduce the size of its central computer facility, relying heavily on remote services obtained via telecommunications access. Similarly, Harvard's primary supplier, MIT, was able to justify an expanded and better staffed operation because of the guaranteed outside usage (income) from Harvard. This results in a more powerful and cost effective service to the MIT community. Obviously, a national network will not enable everyone to participate in this

* These experiments will have been completed by the NCC, and the results will be discussed during the authors' presentation at the Conference.

manner. However, the opportunity is there for institutions in appropriate circumstances.

Software and data base economies of scale

For a variety of services, software and data base maintenance costs—including associated user services such as documentation and support—do not vary significantly with usage. Since a centralized center permits spreading these costs over a larger number of users, it can provide substantial economies. As hardware costs continue to decline, and software-related costs continue to increase, these economies will become increasingly important.

Availability of specialized services

One of the great advantages of a network is that it allows specialization while still exploiting economies of scale. A computer center that offers a specialized service can attract enough network users to justify the high fixed costs of maintaining the service. Thus, the availability of such services is likely to increase rapidly. Networks can, in this way, complement localized centers. A computer center can choose to provide relatively standard services for its own users, plus a few specialized services for the national market, and then look to the network to obtain specialized services that it does not provide.

Data collected by the project indicate that there is a vast array of specialized services already available that are appropriate for a network environment. However, it is likely that these services only represent a small fraction of the total that would be developed once the potential usage base was realized.

Economies of comparative hardware advantage

Not every computer system can process every type of job with the same relative efficiency. Hardware and operating system differences, as well as local modifications to computer systems, have resulted in a wide variety of configurations, each having different processing characteristics and capabilities. As a consequence, systems have different relative advantages. If one were to take the processing that is being performed at a set of institutions, and redistribute it among these same institutions on the basis of the comparative advantage of their computer systems, net computer resource usage would decrease relative to capacity.

The EDUCOM Planning Council* [11] has developed a series of benchmark programs that illustrate the point dramatically.[12] Although subject to all the usual problems of "representativeness," the benchmarks have been run at each of the participating institutions. They provide a system-by-system comparison of the difficulty of converting a program from one site to another, the computer resources required to execute the programs, and the cost to execute the programs.

In the tests, there were several examples of price differences on the order of 10:1 and even 20:1 for the processing of a given job. Although the lowest priced facility is not always the most effective when all factors (e.g., turnaround and user support) are considered, these price differences are attractive enough to encourage individual users to take advantage of the comparative advantages of different systems, thus resulting in major economies. Admittedly, prices are not always directly tied to costs,[13] and many of the price differentials would diminish in a free market environment. However, the institutions involved believed that their pricing was an accurate reflection of true costs at their facility and that substantive changes would be unlikely.

The identities of the "lowest cost" and "highest cost" institutions were not constant across the benchmark jobs. That is, one institution was more efficient for some job classes but not for others. Thus, the trading opportunities are not one-sided and there should be a reasonable distribution of usage. This situation is analogous to the economies of comparative advantage in international trade.[14]

National software marketplace

At the present time there is no simple marketing or distribution mechanism for available software. To market a product, the developer must prepare user documentation and installation instructions, must prepare versions for different computer systems, must be prepared to consult on implementation problems, and must develop and distribute maintenance updates for all systems. For the person or organization that is not in the business of software development, this is a significant barrier. Thus, most local developments are not exported, forcing duplicate development if the capability is to be obtained at all.

The existence of a national network would change much of this, since prospective users would be able to use the software on the developer's own system. All users would run with the same program on the same system, permitting a single set of documentation materials and a single maintenance operation. Thus, the burdens upon the developer (who is often more interested in his discipline or research subject than he is in software development and marketing) are greatly reduced.

A national market would also make it possible to apply usage royalties. Not only could this be used to provide an economic incentive to develop and support good software, but it could also provide a mechanism to support the additional costs of polished documentation and user support. Thus, the network framework could support greater sharing of software development and a faster spread of beneficial software.

* The Planning Council is a cooperative effort of twenty-two universities that have decided jointly to "determine how the computing needs of their institutions can best be met, assess the means of achieving efficient and effective resource sharing, and develop a national 'facilitating network' linking computers at colleges and universities throughout the United States."

Management improvements

Although computing has grown into a substantial business at many institutions, the effectiveness of the management and operation of the local computer center has not always developed analogously. In all too many instances, our data and on-site interviews revealed that large computational facilities are being run as if they were small service facilities (which indeed they were not very many years ago). Yet large computing operations are a business and must be recognized and operated as such.

The existence of a national network would bring a measure of comparison and competition to all participating institutions. Not only would there be price comparisons by prospective users, but there would also be service, support, and reliability comparisons as well. Poorly managed facilities would find themselves in a poor competitive position. If local administrations permit free choice, such facilities would be forced to either upgrade operations or lose business to the better-run facilities. From the viewpoint of many individual facilities, this would be a traumatic experience. In any event, though, the user will perceive more effective service.

Positive attitude

A positive attitude is critical to the success of any endeavor. Surveys of regional networks in higher education[15,16] showed that many networks succeeded (or failed) in large part becuase of the beliefs of key participants that the network would succeed (or fail). In the case of a possible national network, our interviews with administrators, computer center directors, and others revealed a consensus of positive attitudes. Administrators envisioned cost savings, increased research potential, and better overall service to their community. Computer center personnel anticipated a wider audience for their offerings, greater service to internal users, and elimination of some costly local services. Users felt that "competition" would eventually bring more cost effective service to them, and that the expanded availability of suppliers and offerings would be beneficial. Although such attitudes do not, of course, guarantee the success of a networking activity, they are a vital ingredient.

Preliminary model results

A number of explorations have already been conducted using the basic simulation model.[4,9] For these tests, perceived decision and behavior patterns of all sites were preprogrammed (as compared to the gaming studies in which real people will be making decisions at each site). Although results are not yet conclusive or comprehensive, indications are positive in all areas tested. The network appeared stable in the face of large shocks; there is the opportunity for large cost savings to users; communications costs are relatively low for many of the likely early usage categories; the more "attractive" supplier sites seem to have sufficient available capacity; and the different hardware configurations appear to present useful differences in performance features. More sophisticated and revealing research experiments, as described in a later section, are now being conducted.

BARRIERS TO NETWORKING

Our analyses to date have also revealed a number of barriers to networking. Although adverse, these barriers are not insurmountable. However, they must be addressed by any network undertaking.

Institutions are unprepared to modify computer facilities

Many institutions are viewing the network as a mechanism for selling "a little" excess capacity and for obtaining "a little" extra revenue. They are not prepared to serve the growing computing requirements of a national user community. That is, most institutions, even if they had a highly sought after set of services, would be very unlikely to install additional large-scale computing equipment solely to serve the needs of network users. In many cases, the charter of the institution or the laws or policies under which it operates preclude such an expansion.

On the other hand, most institutions believe (in most cases, quite strongly) that they must have a major central facility on site if they are to maintain their research and educational position. Further, few institutions have a great deal of short-term flexibility to reduce their scale of computer operations, even if they deemed it advisable. There are purchased equipment, long-term leases, personnel commitments, state restrictions, and other considerations that make rapid change difficult.

Thus, we have a situation in which facilities are unlikely to be expanded or contracted significantly. This implies that the imports and the exports of computer services at a site must either be fairly closely matched, or must be small in magnitude relative to the total computing budget. We have made several simulation runs using a policy of "no imbalance of payments" on the part of each institution. The results do not bode well for network vitality, for the work flows that can develop under these assumptions are rather limited.

Lack of incentives for sharing

One of the serious problems that is likely to constrain the growth of network computing is the lack of strong incentives to encourage sharing. Incentives are missing for both the buyer and the seller of services, and at the level of both the individual and the institution.

On the buying side, individual users are likely to be frustrated by shortcomings in documentation, consulting, and other support services; by the unreliability of existing software and data bases; and by difficulties in locating and accessing appropriate remote resources. At the institutional

level, money spent on remote services by internal constituents is usually perceived as "real" money resulting in a financial drain to the institution; whereas the cost of local services is largely fixed and does not impose significant incremental costs in the short run if usage is increased (nor incremental savings if it is reduced). Consequently, there is often a reluctance to permit access to outside services.

Unfortunately, the situation is just as difficult on the supplying side. Faculty members and other individuals who create programs and data bases typically receive neither financial benefit, nor professional rewards such as those associated with the publication of a paper in a prestige journal. Consequently, there is little incentive to undertake the incremental work required to document, remove errors, and otherwise convert a successful "local" resource into one that is acceptable for a network environment.

Similarly, institutions lack strong incentives as suppliers. Economies of scale in computer hardware have traditionally been one of the primary justifications for concentrating a variety of computing functions into a single large central processor. However, except for a few quite specialized cases, hardware economies are no longer an important motivation. Minicomputers now compete economically with the large machines for raw cycles, and any significant economies of scale for very large jobs can usually be obtained regionally, if not locally. Further, the cost of the central processor as a fraction of total computing costs is shrinking rapidly. However, economies of scale still hold for large, specialized processors in such fields as physics and meteorology. Thus, for example, the ILLIAC IV computer at NASA Ames is likely to become a major network resource. Most institutions, therefore, have little to gain from the use of network demand to justify a larger central processor.

Unfair competition

Not all institutions that might belong to the network are bound to operate under the same pricing regulations. For example, most educational and non-profit research institutions performing government-funded research are bound to operate all services on a fully cost-recovered basis. On the other hand, government laboratories often acquire computing equipment with capital funds which do not appear in their cost base. Thus, they can and do offer services to other users at marginal or operational cost. Further, commercial organizations could offer services via the same or a compatible network. Loss leaders and other types of promotional prices could be established. Thus, institutions committed to a large central facility could find their user base severely eroded by price competition, their ability to compete on price severely restricted, and their ability to reduce expenses limited.

Guarantees

Institutions that might potentially offer computer services over a national network have shown little willingness to provide service guarantees to outside users, except in some very special cases. Their basic operating policy is "our users first" (and properly so according to their charters). Thus, if demand were to exceed available capacity, the local user would be served and the network user would often be denied service. This means that other institutions and users cannot depend upon the continued availability of service. Although it is unlikely that abrupt large-scale cut-offs would ever occur, the possibility of disruption is a significant concern.

Looking at the problem the other way, most users are not in a position to make long-term usage commitments. However, without such commitments, most supplier installations are unwilling to assume the risk inherent in expanding capacity or services.

Usage barriers

While price (economics) is a powerful motivator with respect to users shopping for and switching to outside services, user behavior profiles developed at each institution confirm that current computing technology limitations are significant. First, there are differences in command languages, file procedures, accounting methods, and the like from site to site. Even such things as "standard" FORTRAN compilers have differences and unique "quirks." Learning to work with many different sites is such a personal burden for most users that only a small number of them are even potential network customers.

Second, software conversion is time-consuming and "unrewarding." Once a site is selected as the supplier, the software will likely be developed and then executed at that site for the duration of its useful life. Evidence indicates that even sharp differences in price or service levels are unlikely to cause any appreciable shifting of existing programs between sites.

A third barrier is information. The user needs to find out "what is offered where," how the system operates, what the pricing structure is, and so forth. Further, he needs a mechanism for determining how effective each site is for his own computing needs. Unless this fairly costly process can be written off over a significant amount of future computing, it is not cost-effective to consider many other supplier sites. To the extent that there is no central organization to collect, keep current, and distribute such information, many users will be unable to find alternate computing sites that would be beneficial.

Network overhead

Participation in a network is not without cost. In addition to the base cost of communications between sites, interfaces to the network communications facilities have to be implemented for each host computer; billing and accounting routines have to be modified so that this information can be provided to each user, institution, or network clearing house as appropriate; administrative structures must be implemented; and standards and interface procedures must be

provided and enforced. For an institution that only wants to distribute or gain access to a small volume of services, these requirements could be formidable.

Security

Current systems provide inadequate protection against malicious or unintentional access to system resources. Until this situation is corrected, most institutions will choose not to maintain sensitive data on remote storage devices accessible via a network. Applications involving personnel or student records, detailed financial data, or other confidential information will thus be unlikely candidates for early network service.

Another aspect of security is protection against unauthorized use of network resources. When an institution provides its own computing services, its total financial risk is limited to the expenses of running the computer center. In the case of a network, however, an institution's potential consumption of resources could be virtually unlimited.

Government, regulatory, and tax issues

There are a number of unresolved legal and regulatory issues that must be faced. For example, can a nonprofit educational institution freely sell computing services and still retain its nonprofit status? How will the federal government requirement that it receive the most favorable price offered to any buyer impact the ability of institutions to use flexible prices in rationing their resources more efficiently? Will the constraint imposed by many state legislatures that both the sale and purchase of computing resources at state universities be limited to in-state facilities exclude these institutions from national network participation?

Many institutions, because of educational discounts associated with equipment acquisitions, institutional charters, or tax regulations, are unable to process particular types of work. Commerical work, for example, is prohibited or severely limited at many sites. Although an institution can exercise control to some degree over its own local users (i.e., forbid commercial accounts), it is very difficult to exercise such control over unknown network users. Thus, a commercial user that can't use the low-cost service at institution "X", might be able to obtain system entry at less restrictive institution "Y" and hence be able to access institution "X" as a "Y-user." This is a serious concern to some institutions.

Unfulfilled expectations

While many administrators, computer center directors, and others have very favorable attitudes toward networking (as mentioned earlier), there will be many disappointments due to inappropriate expectations. For example, our data show that most institutions believe that they offer attractive, economical services and that, in a free market environment, they would be net sellers to the network. It is not the position of this research to critique the individual viewpoints; however, it is obvious that not all institutions can be net sellers. On numerous occasions in the regional networking programs undertaken in the late 1960's,[15] such disappointments resulted in changes in attitudes and the erection of artificial barriers to trade that adversely affected the networking endeavor.

LIKELY CHARACTERISTICS OF A NATIONAL NETWORK

Although our research has not been completed, a number of indications have been found as to what the likely characteristics of a national network might be. Some of the areas being investigated more thoroughly are listed below.

Network development

1. Usage Growth—Network usage is likely to increase at a steady rate without any sudden surges in growth. A relatively long transition to a network environment is expected for buyers to gain experience with network services, for institutions to adjust their internal capacities in conformity with changes in demand patterns, and for suppliers to develop more powerful aids for assisting remote users.
2. Evolution—The network is likely to evolve gradually, rather than be implemented in one major step. To adapt to changing needs and technology, the design at each stage of implementation should be kept as open-ended as possible and should avoid large fixed costs (e.g., costs should be incurred in proportion to the level of network activity).
3. Volume of Usage—Among participants there will be a wide variance in network activity, with individual sites ranging from no use to total dependence. The most optimistic present estimates suggest that network dollar volume will represent less than five percent of the total computing done by member institutions. Note, however, that even at very low per unit levels, aggregate flows from all members could ultimately be very large.

Network characteristics

1. Hierarchy of Networks—It is likely that there will be a hierarchy of networks available to users, each serving a different need. These would include local mini-computer networks, campus centers, regional and state networks, national networks, and commercial facilities.
2. Autonomy of Members—Colleges and universities in this country are largely autonomous and show no intention of weakening this autonomy in their quest for computing efficiency or power. This strongly suggests that a successful national network for higher education must be largely decentralized. Each institution should be allowed to choose which services it will buy, which services it will sell, and to whom it will sell them. An institution should also be free to

set both the prices and the quality of services it provides to others.

3. Central Facilitating Function—Although decision making is likely to be largely decentralized, certain facilitating functions need to be provided centrally. Included in such functions are billing mechanisms, information on services and prices, standards, security procedures, and provision of network-wide user services.

4. Financially Self-Supporting—A national network of autonomous members must be self-supporting and will likely rely on a free market mechanism to provide incentives for both suppliers and buyers. Although financial aid from government agencies and private foundations might be available to accelerate the development process, the operational network must be economically viable on its own without subsidy.

5. Evolution of Successful Suppliers—The data collected to date indicate that many of the most popular sites will "spin-off" their computing facilities (or at least that portion serving external customers) to a separate, not-for-profit or even for-profit subsidiary. Under such a scenario, many universities and research institutes would reduce their own local computing capabilities and either use or provide service from a "computer service business." Consequently, what started as a network linking the computer facilities of a number of research and educational institutions, might well turn into a network linking a number of university-owned service bureaus. Several examples of such "spin-off" activities already exist. The best known are the Dartmouth Time Sharing System (DTSS), the Ohio College Library Center (OCLC), and the Stanford Library System (Ballots).

Network usage modes

1. Functionally Distributed—Economics favors local or regional computing for most services, with the national network providing specialized services that cannot be economically supplied or maintained locally. Most suppliers will therefore concentrate on providing a relatively few specialized services that exploit their comparative advantage.

2. Specialized Services—The specific specialized services that are likely to exist in a network environment are difficult to predict in advance, although communications constraints are currently forcing an emphasis on services with low to medium volumes of data transfer. Candidate specialized services will be those that require some combination of complex software, large data bases, sophisticated support, or specialized facilities. Examples include library services, bibliographic services, person-to-person communications ("electronic mail"), chemistry and census data bases, econometric forecasting systems, and high energy physics computations.

User support

One of the barriers to network usage mentioned earlier concerned the difficulty of appropriately supporting remote users. In addition to all of the forms of user services currently provided, the network will likely also offer some combination of the following:

- Both local and central consultants who are knowledgeable about services available over the network, or at least can facilitate the acquisition of information.
- "Circuit riders" who periodically visit remote sites.
- Remote consulting services provided on-line over a "hot-line" or by means of an "electronic mailbox."
- High quality documentation designed to serve the independent remote user.
- Computer-assisted training aids.
- On-line information data bases to assist users in locating remote services appropriate to their needs.

CONFIRMATION EXPERIMENTS

The findings discussed above are based upon the resource and policy data that have been collected in the first two phases of the Network Simulation Project and upon the initial simulation experiments. In order to confirm the validity of these findings, a further series of experiments is currently under way.

The first set of experiments is being conducted by project staff using the basic network simulation model together with site-specific data bases and behavioral information. General topics such as the following are being investigated:[10]

- Expected network performance
- Site specialization
- Network stability
- Network resource-sharing potential
- Communications costs
- Service pricing policies
- Provision of special services
- Network equilibrium conditions
- Quality of network information provided
- Network growth effects

These investigations will continue in parallel with the participant experiments (see below).

The second series of tests (referred to as the "straw games") involves active participants from each institution playing against a programmed network ("programmed" is used in the sense that behavior patterns, decision rules, offerings, and so forth are pre-entered for all sites except one). This permits a series of experiments to be performed testing institutional reaction to controlled environmental circumstances. Typical experiments in this series involve:

- Reactions of supplier sites to increasing levels of demand from the network
- Latent demand for various proposed science information services
- Effects on supplier sites of large erratic demands from the network
- Shocks, such as major suppliers leaving the network unexpectedly

- Commercial vendors joining the network
- Reactions of supplier sites when they lose usage
- Effects of small schools attempting to satisfy much of their computing needs via the network.
- Implications of sites reducing their in-house facilities as network dependence increases.

The third series of experiments (the "live game") will be conducted at a central site with live players from each institution on the network playing simultaneously. This will permit a series of experiments to test inter- and intra-institutional interactions on a dynamic basis.

Typical experiments in this series involve:

- Institutional budget crises
- Unexpected federal edicts that affect the way many institutions have been using the network
- Changes in tax regulations for non-profit institutions
- Availability of a variety of competitive science information services
- Network "shocks"
- Technological breakthroughs in communications cost, capacity, interfaces, etc.
- Breaches of security
- Impact of changing network administrative structures

SUMMARY AND CONCLUSIONS

The studies to date support the expectation that establishment of a national resource-sharing computing network for higher education and science research is a formidable task. The barriers described in this paper will not be easily overcome. However, all evidence points to a potential high payoff from, if not a vital requirement for, such a network. In particular, the specialized hardware and software resources that would be accessible could not be made broadly available via any other mechanism.

Early indicators are extremely favorable. Both potential suppliers and potential users see it in their self-interest to participate in networking activities. Attitudes toward networking are positive and constructive, and administrators at the highest level are becoming actively involved. The likely deciding factor is whether or not short term pay-offs can be made attractive enough to sustain interest during the difficult development period.

Much research still remains to be done, and the efforts described in this paper are continuing. The various gaming studies are enabling decision makers at participating institutions to gain experience with operational considerations in a network environment. As their experience matures, they are becoming more confident in their ability to properly represent their institutional needs in such an environment. The above experiences are also permitting more general, long-term research into the design and impact issues relative to the evolution and operation of a national network.

A comparison of network architectures— The ARPANET and SNA

by GILBERT FALK
Bolt Beranek and Newman Inc.
Cambridge, Massachusetts

INTRODUCTION

The ARPANET is a packet-switched data network which facilitates resource sharing and supports distributed data processing. The ARPANET technology and its descendants have had a significant impact on the direction of data communications over the past eight years. More recently, IBM announced Systems Network Architecture (SNA) which is targeted at satisfying a similar set of requirements. SNA will undoubtedly also have a major impact on the future of data communications. This paper presents a comparison of these two network concepts by discussing architectural and protocol similarities and differences employed to support process-to-process level communication. The goal is both to provide useful information and to stimulate interest in the analysis of alternate architectural approaches.

The presentation that follows identifies key properties and functions of data networks in general and discusses briefly how they are performed within each of the two network architectures. An elementary knowledge of both the ARPANET and SNA is assumed. Information describing the design and implementation of the ARPANET can be found in References 1-3. A presentation of the concepts embodied within SNA can be found in References 4-8.

Architectural similarities in these two designs result from fundamental similarities of objective. Both network architectures have as primary goals the abilities to support distributed processing and to facilitate resource sharing. In the case of the ARPANET the motivation for providing these capabilities was the need to share large hardware and software resources and to establish a facility to support computer system research. The development of SNA by IBM, on the other hand, was largely driven by the economic need to take advantage of equipment based on LSI technology. This technology provides the capability to locate many previously centralized functions in terminals, device controllers, communication front-ends, etc. Both designs have attempted to provide a single general-purpose interprocess communication facility upon which application level communication rests. A central theme in the development of both architectures is the separation of the data processing and data communication functions.

Perhaps more important than the similarities of objective are a number of fundamental differences between the ARPANET and SNA environments. These environmental differences provide a partial explanation of the individual architectural differences that are present in the two designs. The ARPANET was developed for operation within a research environment. Within such an environment it is possible to experiment a bit in the design and operation of an evolving network. In a commercial environment, on the other hand, conservatism dictates more cautious development. While SNA has been developed as a new network architecture, it nevertheless has the requirement of accommodating a large existing base of installed software systems (e.g., IMS, CICS). ARPANET development, on the other hand, was not constrained in this way. ARPANET host software was developed for the most part independent of any existing application software within the hosts. SNA was designed to provide a networking capability for equipment from a single vendor. The ARPANET, on the other hand, was developed from the start to provide a networking capability for subscriber equipment from many different vendors. Finally, SNA and the ARPANET differ in the nature of the two network concepts. SNA is an implementation independent architecture. This architecture is realized differently within different IBM computer and communication products. The ARPANET, on the other hand, is an evolving implementation of the general concept of packet-switching.

COMPARISON OF NETWORK CONCEPTS AND MECHANISMS

The following subsections provide a side-by-side comparison of a number of aspects of the ARPANET and SNA network architectures.

Physical network concept

Figure 1 illustrates typical physical network configurations within SNA and the ARPANET. Figure 1a illustrates four distinct types of physical units (PUs) that can exist within an SNA network: PU.T5, PU.T4, PU.T2, and PU.T1. Units of type PU.T5 are host computers (370s). Communication controllers (e.g., 3704s or 3705s) are described as

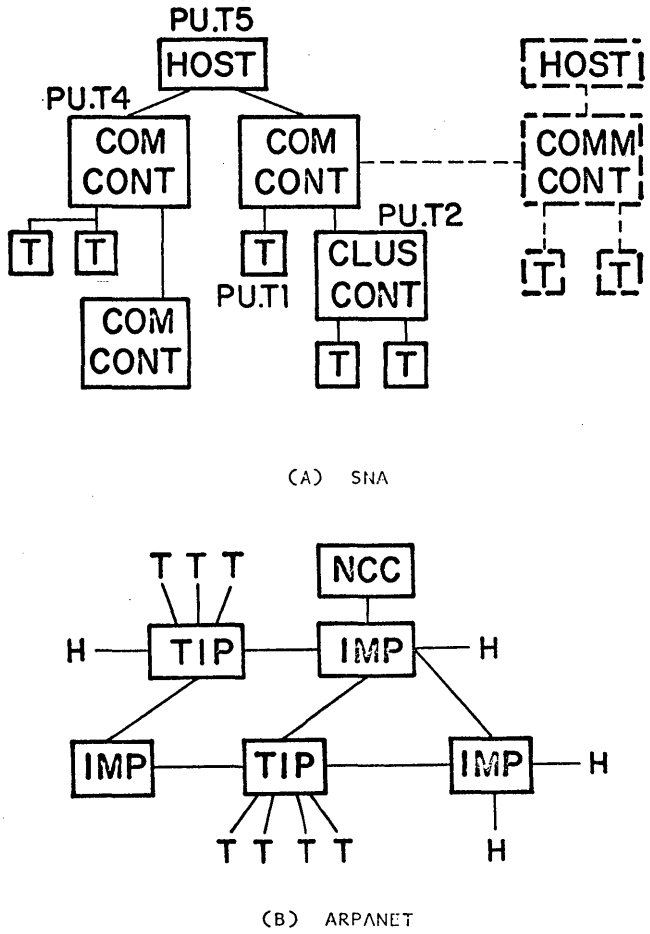

Figure 1—Physical network

units of type PU.T4. Cluster controllers (e.g., 3601s) are described as units of type PU.T2. Finally, terminals (e.g., 3270s) are units of type PU.T1. A basic concept of SNA is that there is only a single SNA node description and PU types are obtained as subsets of that single description. In this sense, PU.T1, PU.T2, and PU.T4 are subsets of PU.T5. The original announcement of SNA permitted configurations consisting of only a single host as shown by the solid lines. A more recent announcement from IBM has described expanded SNA implementations consisting of multi-host configurations (indicated by the dotted lines).

Figure 1b illustrates a typical physical network arrangement that may exist in the ARPANET. The two types of network nodes are referred to as IMPs and TIPs. The IMPs provide a store-and-forward switching function in addition to providing an interface for connecting host computers (H). The TIP is an IMP with an additional front-end concentrator function providing network access for unintelligent terminals (T). Arbitrary topological interconnections of IMPs and TIPs are permitted within the ARPANET design. A Network Control Center (NCC) provides a central facility for network monitoring, diagnosis and maintenance.

Logical network concept

Figure 2 contrasts the two network architectures with respect to their basic communication facilities. Within SNA the fundamental communication system is referred to as the transmission subsystem. The transmission subsystem provides process-to-process level communication between entities referred to as Network Addressable Units (NAUs). Three types of NAUs exist. The Logical Unit (LU) provides an interface port for SNA end-users. End users may be either human operators at a terminal or application programs. Physical Units (PUs) comprise a second set of network addressable units. A distinct PU is associated with each shared communications resource (host, cluster controller, etc.) in the network. The PU is the entitiy to which communication is directed when one wants to communicate with the associated physical device. Finally, each SNA network has one (more in a multi-host network) System Services Control Point (SSCP). The SSCP provides central monitoring, coordination, and control of its domain in the SNA network.

In the case of the ARPANET the IMP subnetwork consisting of interconnected IMPs (and TIPs) provides the basic communication facility. At this level the network hosts are the addressable units. It is important to point out that it is

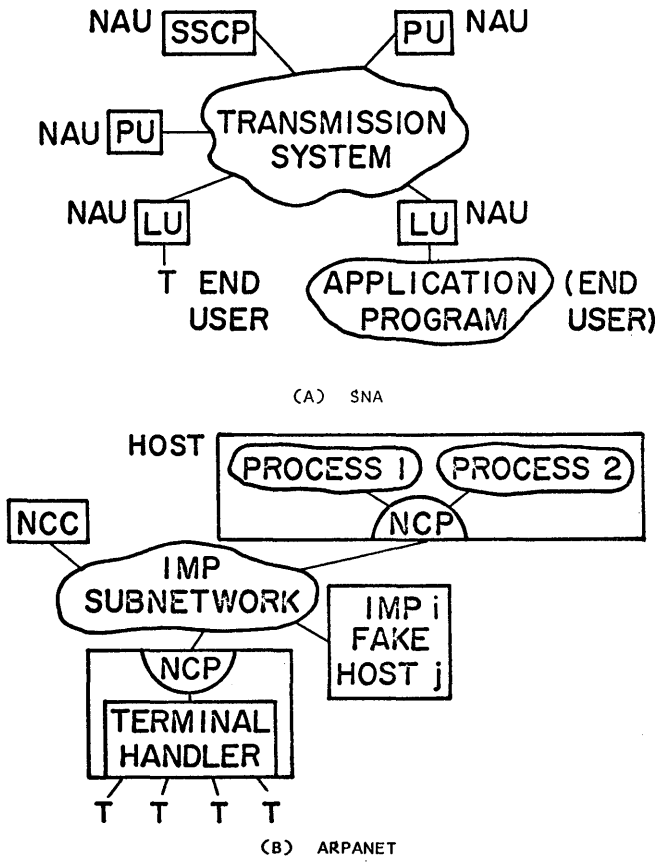

Figure 2—Logical network

the combination of the IMP subnetwork and the Network Control Program (NCP) software within the hosts which provides the process-to-process communication analogous to the SNA transmission subsystem.

Although there are not any logical entities within the ARPANET which correspond directly to the three types of NAU under SNA, certain analogies can be drawn between the two designs. Regular host computers (including the concentrator pseudo-host associated with each TIP) are the most common type of host subscribers interfaced to the IMP subnetwork. The internal processes supported by these regular hosts correspond to the logical units within SNA. Certain fake hosts such as PARAMETER CHANGE and DEBUG, on the other hand, exist within each of the IMPs and provide a means of effecting changes in network operation. They are, therefore, analogous to the physical units within the SNA design. Finally, the NCC facility can be viewed as analogous to the SSCP in the sense that it is the single network-wide coordination entity within the ARPA Network. A distinction between the SSCP and the NCC is the importance of the former for each conversation carried out over the network. In particular, it is directly involved in the initiation of LU-LU sessions as described in a later section.

Figure 3 illustrates the types of communication between addressable units under the two network concepts. A line in this figure indicates communication between the entities corresponding to its end points. We have assumed in the case of SNA that only a single SSCP exists. If multiple SSCPs exist, then these entities will clearly require communication between one another in order to synchronize their activities. In addition, in the case of the ARPANET, we have neglected end-user to fake host communication which, while possible, is only incidental to the primary communication capabilities supported by the ARPANET.

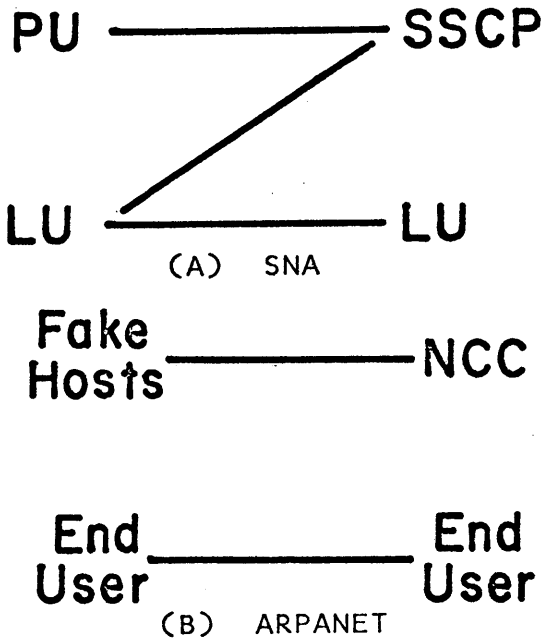

Figure 3—Types of communication supported

Key architectural characteristics

Figure 4 summarizes a number of selected architectural characteristics in the case of the two network designs. The first entry in the table indicates that both SNA and ARPANET are based on block or packet-switching technology. In the case of the ARPANET, a packet has a fixed maximum number of bits. In the case of SNA, the maximum packet size is not only implementation-dependent but can also vary from node to node within the network. Under both designs packets are passed through the network according to a routing algorithm. SNA has adopted a routing approach based on static tables within the nodes. The tables are centrally maintained by the SSCP. The ARPANET, on the other hand, has implemented a distributed adaptive routing algorithm in an attempt to dynamically adapt the flow of network traffic to changes in network topology and circuit loading. The routing algorithm is carried out periodically at each of the network nodes based on information that each network node receives from its neighbors describing the best path to each destination.

	SNA	ARPANET
Switching Technology	Store and Forward Packet Switching	Store and Forward Packet Switching
Routing	Centralized Static	Distributed Adaptive
Segmenting / Reassembly	Can be Performed at Each Node	Packetized at Source Node, Reassembled at Destination Node
Blocking / Deblocking	Yes	No
Sequencing	BIUs and BIU Segments Kept in Order Over Entire Path	Packets Reordered at Destination Node

Figure 4—Key architectural characteristics

The processes of segmenting and reassembly provide the means for translating between data units (SNA PIUs and ARPANET messages) presented to the network and packets switched through the network. Under SNA, segmenting and reassembly can be performed at each node along the source-to-destination path. Within the ARPANET, packetizing is done only at the source IMP and reassembly is performed at the destination IMP after all of the packets of the message have arrived. Blocking and deblocking are associated with the combining of logically unrelated packets into a single block (superpacket) for efficiency of transmission over in-

dividual network links. This concept exists only within SNA where it is used for efficiency of transmission over 370 channels. As indicated by the last entry in Figure 4, messages (BIUs) and message fragments are kept in order over their source-to-destination path within SNA, whereas ARPANET packets are routed independently and only reordered at the destination node. The ARPANET approach has potential benefits with respect to end-to-end delay and throughput but requires careful design of the control and buffering procedures in order to avoid the possibility of network lockups.[9]

The concepts of packetizing and blocking within the two network architectures are illustrated in more detail in Figure 5. This figure illustrates the data envelopes associated with transmitting an application buffer of data from one process to another via the network. In the case of SNA the application buffer is first split into a number of Basic Information Units (BIUs), each consisting of a Request Header (RH) and a Request Unit (RU). A set of related request units is referred to as a BIU chain. (Note: A BIU chain can also be assembled from multiple application buffers.) The BIU chain is treated as a unit with respect to acknowledgment and recovery procedures. The Request Headers contain only control information to support process-to-process level communication. Application data is contained within the Request Unit portion of the BIU. Before a Request Unit can be transmitted, a Transmission Header (TH) is attached as shown. The Transmission Header contains end-to-end control information such as destination address, sequence number, etc. The combination of Transmission Header, Request Header, and Request Unit is referred to as a Path Information Unit or PIU. If required, a BIU can be segmented into BIU segments (each of which then becomes a PIU), as shown, prior to transmission over any network link. The PIU with Data Link Control (DLC) appended at the beginning and end is ready for transmission over the network link and is referred to as a Basic Link Unit (BLU). As illustrated in the last two lines of Figure 5a, independent PIUs can be combined or blocked at a node as described previously for purposes of transmission efficiency.

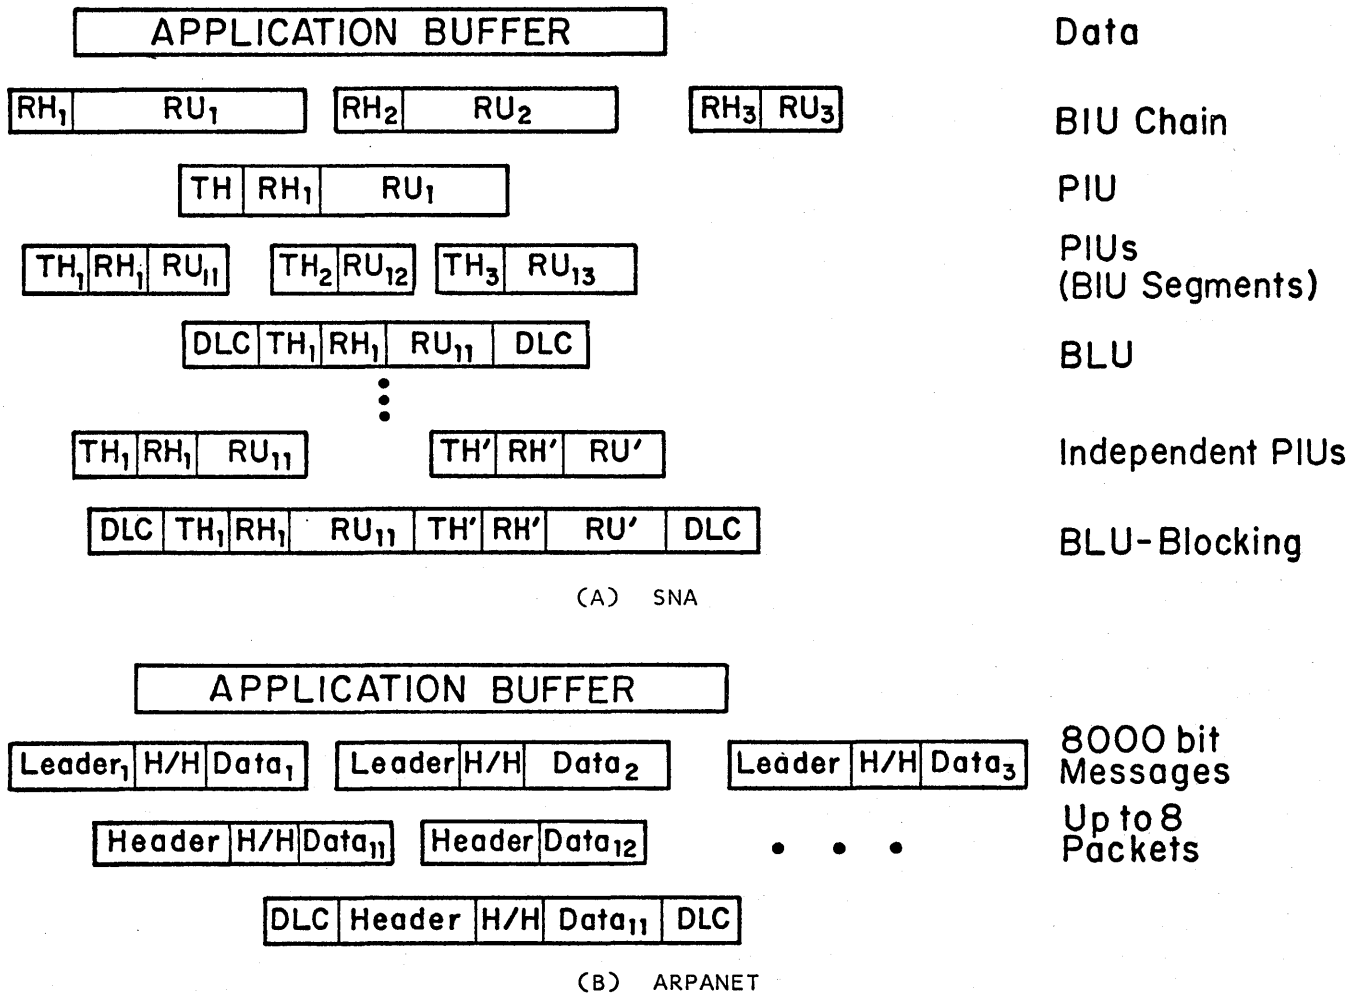

Figure 5—Data envelopes

The situation is somewhat simpler in the case of the ARPANET. Here an application buffer is split by the host into an arbitrary number of network messages, each message less than 8000 bits in length. Host-to-host protocol control information (H/H) is added and interpreted by the network control programs in each host in order to support process-to-process level communication. Each message is then divided into no more than eight packets of approximately 1000 bits in length. These packets are routed independently through the IMP subnetwork. Host-to-IMP control information is provided by a leader attached to each message transmitted by a host. This leader is used to create the control information contained in the header of each of the data packets.

Link control procedures

Two types of link control are supported under SNA, the 370 channel protocol and Synchronous Data Link Control (SDLC).[10] Analogous link control procedures supported in the ARPANET are the standard host-to-IMP interface,[11] the very distant host interface,[11] and the IMP-to-IMP protocol.[2] The most appropriate of these protocols for purposes of comparison are SDLC and the ARPANET IMP-to-IMP protocol.

Although SDLC and the ARPANET IMP-to-IMP protocol both support communication over transmission circuits, these two protocols differ along several dimensions. SDLC implements data transparency by bit insertion in the data stream. Five sequential one bits in a row are always followed by a zero in the data stream to distinguish such patterns from framing patterns (which involve a sequence of six sequential ones). Transparency in the ARPANET protocol is based on doubling of DLE characters. This procedure is similar to the one implemented under IBM's older link protocol, BSC, which was the basis of the IMP-to-IMP protocol frame structure.

Another difference between SDLC and the protocol used on the links between IMPs is the diversity of the data links supported. Under SDLC a variety of data link configurations are supported, including point-to-point, multi-point, loop, etc. The ARPANET IMP-to-IMP protocol, on the other hand, is only designed for dedicated full-duplex point-to-point links. A third distinction between the two protocols is in the fundamental relation between the two ends of the link. Under SDLC each link has a primary and a secondary end. The primary end is typically associated with the station having superior processing capabilities. Under the ARPANET protocol both stations are assumed to have identical capabilities and the two ends of the link are symmetric. A minor difference between the two protocols is the length of the CRC checksum added for error detection. This checksum is 16 bits in the case of SDLC and 24 bits in the case of the ARPANET.

Perhaps the most interesting contrast between the two link control procedures is illustrated in Figure 6. As indicated, under SDLC the link control procedure implements what is fundamentally a single logical channel capable of supporting eight outstanding (unacknowledged) frames. These frames are numbered sequentially in order to enable the transmitting end to associate acknowledgments with data units. The analogous arrangement between IMPs is a sequence of eight logical channels each of which can support only one outstanding frame. In a sense these alternate approaches are identical: if all frames are acknowledged properly, both approaches support the same throughput over the link. If a frame is not acknowledged, however, the SDLC procedure requires retransmission of everything following the unacknowledged frame, whereas the IMP-to-IMP protocol conserves channel bandwidth by requiring retransmission of only the unacknowledged data. A more fundamental difference is a result of the dependency between frames which for SDLC is inherent in the sequential numbering procedure. In particular, failing to acknowledge any single frame completely blocks the flow of data over the link within eight frames of the frame which was unacknowledged. In the case of the ARPANET protocol, on the other hand, failing to acknowledge an individual frame transmitted over any logical channel does not impact the transmission of new frames over the remaining seven logical channels.

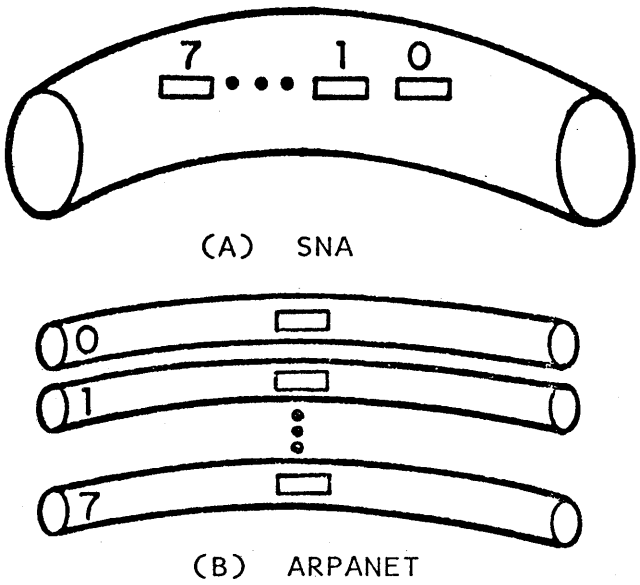

Figure 6—Link control

The ARPANET IMPs take advantage of this independence by permitting packet discard at the link control level. If a packet cannot be handled due to local congestion, the receiving IMP fails to acknowledge the packet as many times as necessary, being assured that its neighbor will continuously retransmit the data. Under SDLC this type of flow control cannot be carried out at the link level and an additional higher level mechanism must be incorporated for this purpose.

Error control

There are at least two types of errors which are associated with the transmission of data through packet switched networks. Each type of error is typically handled by a distinct mechanism. Corrupted data due to burst noise on the communications channels or errors within the communications hardware is detected by appending checksums to transmitted data. Lost, duplicated, and out of order data is typically detected by the addition of sequence number information to each frame transmitted. These mechanisms can be applied both over individual links and over end-to-end paths. Figure 7 illustrates the mechanisms for end-to-end error control which exist in the ARPANET and SNA designs. As shown in Figure 7a, there is a single end-to-end sequence number attached to each request unit transmitted by a process in an SNA network. This 16-bit sequence number is generated by the transmission control (TC) function of the source node. It is passed back to the source process in order that acknowledgment and error recovery information associated with that request unit can be identified. Errors due to corruption of the data are handled by checksums on the links (associated with SDLC).

In the ARPANET environment, sequencing is done on a host-to-host basis. Internal sequence numbers within the IMP subnetwork guarantee that messages are delivered to the destination host in the same order that they were submitted by the source host. A 12-bit sequence number ("message I.D.") field which is passed between the host and its IMP can be used for identification of responses (e.g., RFNMs) for multiple outstanding messages. It is also passed through to the destination host so that the destination can detect out of order errors due to subnetwork failures. As in the case of SNA, corruption of data on the lines is handled by link checksums. An additional end-to-end checksum is implemented in software in order to detect corruption of data originating within the nodes. This software checksum is computed on each packet by the IMP as it comes in from the source host and is checked at each node along the end-to-end path.

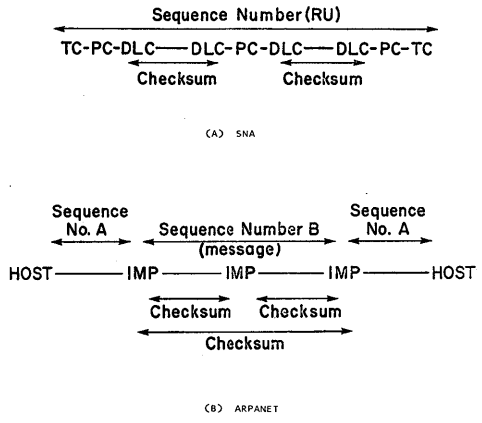

Figure 7—Error control

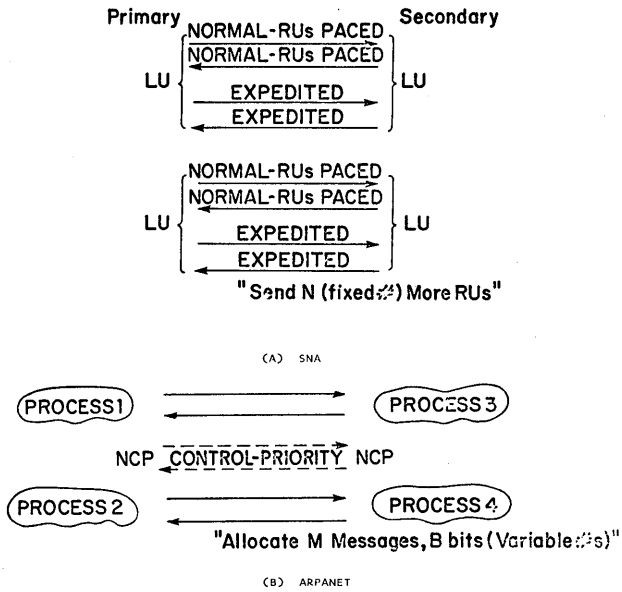

Figure 8—Flow control

Flow control

Figure 8 illustrates the type of process-to-process flow control implemented in the two network architectures. Under SNA, two logical units are always connected by two logical full-duplex flows, a normal flow and an expedited (priority) flow. The expedited flow is typically used for the transmission of process-to-process control messages. On the normal flow a form of flow control termed pacing is applied. Pacing messages sent from the receiver to the transmitter take the form of "Send N More RUs". Such pacing requests can be sent after fewer than N RUs have been received in order to keep the end-to-end logical channel full in support of high throughput applications.

In the ARPANET process-to-process communication typically is carried out over a single pair of simplex channels. Control messages between all processes on two communicating hosts share a common control connection over which messages are handled with priority. Flow control is applied in both directions and allocations take the form of "Allocate M More Messages and B More Bits." [12] Both M and B can vary from one allocate message to the next.

Both of these flow control schemes can be described as incremental. This means that they both take the form of the receiver telling the transmitter that a certain number "more" data units are allowed. It has been argued[13] that such incremental flow control schemes have the potential for loss of synchrony if allocated messages are lost within the communications system and no notification of this loss is provided. Windowing schemes tied more tightly to end-to-end sequence numbers have been proposed recently.[14,15] Such windowing schemes have the property that they are self-synchronizing.

Addressing

A major difference between process-to-process addressing in the SNA and ARPANET architectures is the use of network names for NAUs under SNA. Names or logical addresses have the advantage of facilitating transparent movement of services between physical facilities by separating the concept of network name from the location of the named facility. Mapping between names and addresses under SNA is handled by the System Services Control Point during session initiation as described in the next section. Under the ARPANET design end-user identification is tied to physical location.

The formats of the network addresses themselves provide another interesting contrast. SNA network addresses consist of 16 bits. The 16 bits are split between a sub-area address (used for store-and-forward routing) and an element within the sub-area (used for local routing). ARPANET network addresses consist of a 16-bit IMP number (used for store-and-forward routing), an 8-bit host number (used for local routing), and a 32-bit socket number (used for process identification). In order to avoid having to transmit a pair of 32-bit socket identifications with each message transmitted between processes, an 8-bit shorthand called the "link I.D." is used in the ARPANET. This puts a (realistic) limit on the number of simultaneous conversations between any pair of hosts.

Session initiation

Figure 9 illustrates the procedures involved in setting up a logical session (connection) between two end users under the SNA and ARPANET architectures. The key point to note in this figure is that session initiation under SNA involves the SSCP as well as the two communicating processes, whereas session initiation within the ARPANET involves only the two communicating processes themselves (and their NCPs). Figure 9a illustrates the sequence of exchanges assuming a primary LU wishes to establish a connection to a secondary LU. The primary LU first sends an INITIATE command to the SSCP. The INITIATE indicates the type of session requested, the name of the LU with which the primary wishes to speak, and password information for authenticating the request from the primary. If the establishment of the requested connection is permitted by the SSCP, it will respond to the primary by the transmission of a CONTROL INITIATE command. The CONTROL INITIATE command contains a "bind image." The bind image includes all of the parameters which are subsequently sent in a BIND command from the primary to the secondary LU. The parameters in the BIND command specify the type of session being established in detail. Assuming that the secondary accepts the BIND request, the primary notifies the SSCP via a SESSION STARTED message. Session authorization checks carried out by the SSCP are associated with the allocation of reusable resources as well as the name-to-address map.

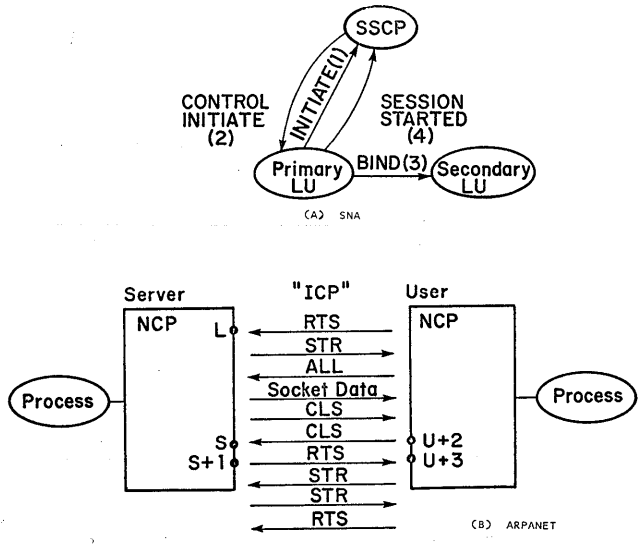

Figure 9—Session initiation

Communication between a user and a server process in the case of the ARPANET is established in one of two ways. For a service process which handles only one user process at a time, a simple pair of connection requests is exchanged. For multi-user server processes supporting multiple simultaneous conversations, a standard procedure referred to as the Initial Connection Protocol (ICP)[16] is implemented for session initiation. The set of control messages which comprise the ICP is illustrated in Figure 9b. The complexity of the required exchange is a result of the fact that connections are fundamentally simplex under the current ARPANET protocol standards (two are typically used for process-to-process communication), and the fact that two connections cannot have either of their ends in common. The ICP works by having the server process continually listening for connections from users on a "well-known socket" (L in the figure). A user wishing to obtain the service connects to this well-known socket and is subsequently switched by the server from the well-known socket to another pair of sockets which the server chooses. The server then continues to listen on socket L for connections from other remote users. In contrast to the tailoring of process-to-process communication which under SNA is carried out as the result of the BIND exchange, tailoring of the session between user and server processes is a higher level protocol function. The ARPANET supports only a single type of process-to-process communication.

Word length mismatch

The issue of word length mismatch was of great concern to the designers of the ARPANET. This is due to the fact that the IMPs are 16-bit machines, and the hosts supported are heterogeneous. Attached host systems include IBM 370s (32-bit word length), PDP-10s (36-bit word length), PDP-1s

(18-bit word length), minicomputers (16-bit word length), and CDC6600s (60-bit word length). Word length mismatch is not so important an issue under SNA because equipment from only a single vendor is involved. In addition, most IBM mainframes and peripherals have byte handling facilities.

In order to neutralize the problems of word length mismatch, the ARPANET designers provided two capabilities. The first enables the transmission of messages containing arbitrary numbers of bits (less than the maximum message size) through the network. The second facilitates the combining of multiple successive messages into a single application buffer without excessive bit shifting. The first goal was achieved by having the host/IMP interfaces add and interpret hardware padding sequences. The IMP interface at the source adds padding bits at the end of each message it receives from its host. The padding consists of a 1 followed by as many zeros as are required to fill out an IMP word. The host interface at the destination adds as many additional zero padding bits to the message as are required to fill out the word length of the receiving host. To avoid excessive bit shifting, the host-to-host protocol is defined to have a "message header." The length of this header in conjunction with the leader associated with each message insures that the text portion of the message starts in a "good place" for most machine word lengths (i.e., on a word boundary). In addition, the host-to-host protocol specifies a "connection byte size" which can be used to guarantee that the message text also ends in a "good place."

SUMMARY AND CONCLUSION

The previous sections have detailed and contrasted the mechanisms supporting a variety of network functions in the ARPANET and in SNA. An important similarity of approach is the hierarchical layering of functionality and protocols which is characterisitic of both designs. Communication in both cases is characteristic of both designs. Comnication in both cases is carried out between pairs of peer functional layers in the two communicating entities. This approach has advantages with respect to ease of comprehension, maintenance, debugging, and expansion. Both designs are fundamentally packet switching technology and both designs involve some amount of physical separation as well as logical separation of data communication and data processing.

More interesting than the conceptual similarities are the key architectural differences. These differences are more evident in SNA implementations than in the definition of the architecture itself. Centralization of network functionality is one such critical difference. Perhaps due to its ancestry, centralization is more clearly in evidence in the SNA design. A key example of this is the SSCP involvement in session initiation in single SSCP implementations. Symmetry of peer elements with respect to control is a second important distinction. Two communicating entities in an SNA environment often communicate as a primary to a secondary. One logical (physical) end of the communication path (link) is endowed with more control capability than the other. In the ARPANET, on the other hand, communication is typically symmetric (primary to primary). A third important distinction between the two designs is the nature of the routing strategy. The distributed adaptive approach developed for the ARPANET is one of the key features of that design. While such routing strategies are not necessarily excluded from implementation under SNA, there does not appear to be a strong leaning in this direction on the part of the SNA designers. Finally, we point to general complexity as an area where the two architectures differ. The architecture of SNA is capable of supporting both half and full duplex links, switched and non-switched links, multipoint links, and loop configurations. SNA session protocols are tailored at the transmission subsystem level for efficiency in contrast to the single process level communication protocol within the ARPANET. In addition, a variety of network elements with different physical capabilities are accounted for under SNA, whereas only a single type of network element exists in the ARPANET design.

The previous sections have attempted to present a side-by-side comparison of the ARPANET and SNA architectures. The goal of this comparison was not only to provide useful information but also to raise questions and spark some interest in comparing the relative merits of different architectural approaches. Moreover, by carefully examining two points in the space of possible architectural implementations, it is possible to gain a better understanding of additional architectural alternatives.

and

DONALD R. OESTREICHER
USC Information Science Institute
Marina Del Rey, California

INTRODUCTION

A primary requirement for a message system in an operational military environment is that it be secure enough to process messages at multiple levels of classification. But for the system to be accepted, the operator interface must be "usable." Usability relates to three things: features provided, ease of entering commands, and overall performance. Certainly an interface that does not perform well in these respects, or is difficult to learn or use, will not be used.

The Department of Defense Advanced Research Projects Agency (DARPA) and the Navy are sponsors of an experiment to evaluate the operational use of a computer-aided message handling system at PACOM Headquarters in Hawaii. The experiment will evaluate the operational and organizational impact of the automated service on a community that now uses a largely manual system. The purpose of this paper is to document the security design of SIGMA,** the system that will be used in the experiment.

In the following section, a description of the SIGMA message processing system is given. The third section provides background and discusses the kernel approach to multilevel security. In the fourth section we describe several security problems encountered in the design. The fifth section presents the design of the SIGMA message service. The additional features that the kernel must provide to support SIGMA efficiently are documented in the sixth section. Finally, a summary is provided to highlight the paper's main points.

* This research was supported by the Defense Advanced Research Projects Agency under ARPA Order Nos. 3338, 2223 Contract Nos. F19628-78-C-0001, DAHC15-72-C-0308, MITRE Project No. 8010, ISI Project Nos. 3D30 and 3P10. The views and conclusions contained in this paper are those of the authors and should not be interpreted as necessarily representing the official policies, either expressed or implied of the Defense Advanced Research Projects Agency or the United States Government.

** The SIGMA message service is one of three services developed during this experiment. The other two are the HERMES system built by Bolt, Beranek, and Newman, Inc.[1] and DMS built by Massachusetts Institute of Technology [2].

THE SIGMA MESSAGE PROCESSING SYSTEM

Information Science Institute of the University of Southern California developed SIGMA specifically to meet the message handling needs of a military command. SIGMA is a secure interactive message handling system providing computer-aided message handling services for the receipt, filing, retrieval, creation, and coordination of military (AUTODIN) messages. We consider it secure in that it presents an interface to the user constrained to abide by the DoD security policy. It is an interactive system since all user-system communications occur via an on-line terminal with a CRT display. Finally, it is a message handling system because it supports the typical message processing functions needed by any formal organizational operation.

SIGMA supports the full cycle for processing incoming and outgoing messages in a military operation. It provides flexible filing capabilities for on-line storage of all messages. Easy access to messages and files is provided by selective search and retrieval functions. Incoming AUTODIN messages move through the system by informal forwarding or by formal action assignment. Outgoing messages are processed by a set of functions supporting message creation, editing, coordination, release, and post-transmission comeback copies.

SIGMA operates on a DEC PDP-10 computer with the TENEX operating system. AUTODIN messages enter through the local AUTODIN message exchange. SIGMA distributes these messages to all pertinent addressees on the system where each user can access them through his SIGMA display terminal.

THE KERNEL APPROACH TO MULTILEVEL SECURITY

The need to process multiple levels of classified data led the Air Force Electronic Systems Division to sponsor several research and development efforts to build an operating

system that could satisfy by technical verification that DoD security requirements had been met.[3] Many of the results of the ESD work have been borrowed in the design of SIGMA, specifically adherence to a mathematical model based on the concept of a reference monitor—an abstract mechanism that controls the flow of information within a computer system by mediating every attempt by a subject (active system element) to access an object (information container).*[4] The hardware/software mechanism that implements the reference monitor is called a security kernel. The kernel uses the rules of the mathematical model[5,6] as a specific policy for mediating access requests. This incorporation of policy into the kernel allows for a proof that verifies that the kernel correctly applies the policy to the information it protects.[7,8]

The mathematical model establishes an "inductive nature" of security by demonstrating that security is preserved from one state to another. Security is defined with two rules: the simple security condition and the *-property.[9] The former states that a subject (active entity) cannot observe the contents of an object (information container) unless its security level is greater than or equal to the security level of the object.** The latter further restricts possible access by stipulating that a subject may only modify an object if that object's security level is greater than or equal to the security level of the subject.

The purpose of the simple security condition is to prohibit users from obtaining data that they are not entitled to see. The *-property is designed to prohibit a program operating on behalf of a user from reducing the classification of any information.

When a user is given a clearance, he is charged with responsibility for maintaining the classification of classified information. A computer utility cannot necessarily be given this same trust. This is due to: the amount of information that may be compromised; the speed with which the compromise may occur; and the difficulty in detecting or apprehending the violating program. By enforcing the *-property on computer programs, a program will not be able to either accidently or maliciously compromise information. Designers of computer utilities constrained by the *-property must ensure that *-property enforcement does not unnecessarily restrict the capabilities of the user.

The enforcement of the *-property allows us to reduce the volume of code that needs to be trusted to a central section of the operating system. This central section of the operating system is the software component of the security kernel. To provide security, a kernel must (1) mediate every access by a subject to an object, (2) be protected from unauthorized modification, and (3) correctly perform its functions. A kernel satisfies the first requirement by creating an environment within which all non-kernel software is constrained to operate and by maintaining control over it.

The requirement to protect against unauthorized modification is satisfied by isolating the security kernel software in one or more protection domains, for example, by a ring mechanism.[10] Finally, the requirement that the kernel correctly perform its functions is satisfied by using a formal methodology. A suitable methodology was introduced by Bell and Burke.[7] It includes: (1) a proof that the kernel behavior enforces the desired policy;[11] and (2) a proof that the kernel is correctly implemented with respect to the description of its behavior used in the first step.[12]

We designed SIGMA with security kernel technology in mind. However, due to the absence of a kernel on the PDP-10 (the machine we used), the current implementation was done without a kernel. We have rigorously scrutinized the SIGMA design to ensure that the user interface provided would remain unchanged should SIGMA be reimplemented on a security kernel. In addition, the security primitives have been evaluated to ensure that their usefulness warrants their being included in a kernel.

SECURITY PROBLEMS OF MESSAGE PROCESSING SYSTEMS

A kernel supporting the current mathematical model of the DoD security policy is well suited for certain environments, such as a programming environment in which users operate at a single security level for long periods of time.[13] A message processing environment presents several problems not found in previous environments, including (1) the dynamic nature of the user's "working security level"; (2) the desire to present to the user information at more than a single security level; (3) the desire to accurately inform the user of the security level of all information he is reading and writing; and (4) the ability of users to extract text information and place it in a message of a lower classification than the source.

The user's "working security level" in a message system environment is considerably more dynamic than in the programming environment. Each time that a user performs an action on a different message, his working security level may have to change; for example, a user reading a Secret message may generate an Unclassified reply. While we could require the user to process messages at a single security level at a time, the resulting user interface would be clearly unacceptable to the user.[14]

To deal with these problems a new approach is needed that includes: a terminal that will allow users to process information at more than one security level at a time; and trusted processes that are able to violate the security rules in a controlled manner. The next section describes the security architecture of the SIGMA message processing system.

SECURE MESSAGE PROCESSING SYSTEM ARCHITECTURE

The SIGMA security design has two goals: to produce a certifiably secure service, and to present the user with an agreeable user interface. In many situations these goals are at cross-purposes. Our general approach has been to present the user with a true picture of what is happening, maintain

* In a computer system, subjects are users and processes, and objects include programs, data files, and peripheral devices.

** Currently the security levels used in SIGMA are only the four standard DoD classifications, i.e., Unclassified, Confidential, Secret, and Top Secret.

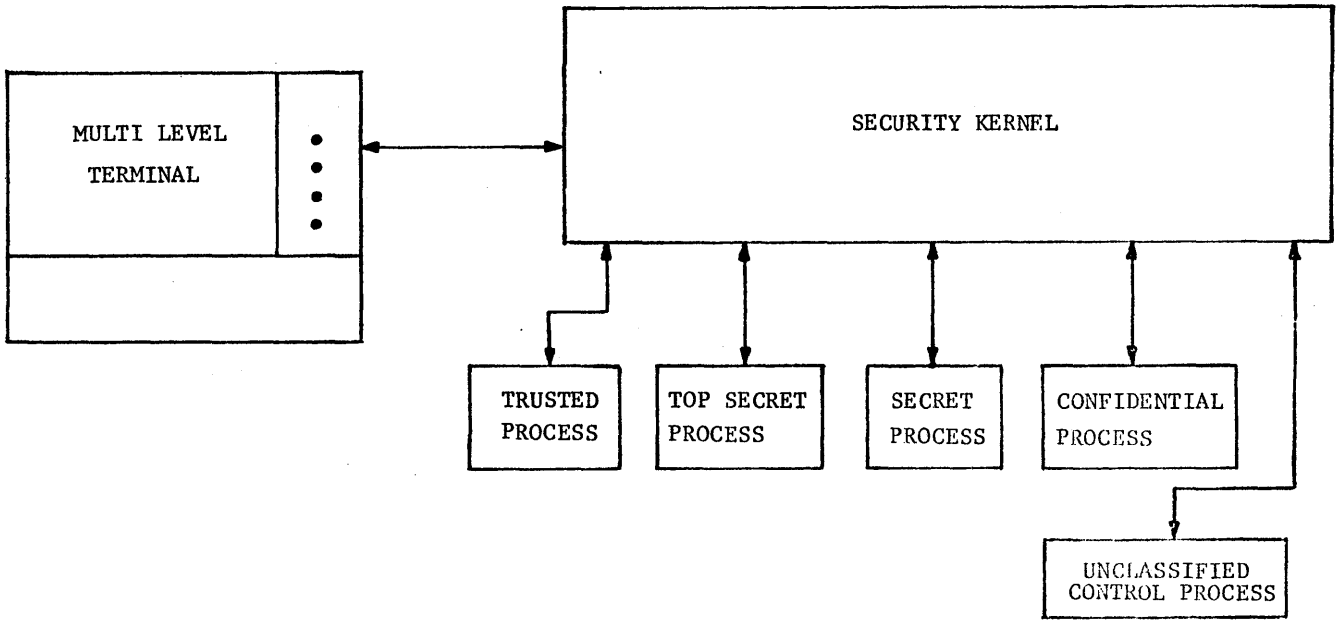

Figure 1—Sigma process structure

the user's data at the proper level (or higher if this is not possible), and make it convenient for the user to do the right thing.[14]

Overview of the design

When using SIGMA, a user is actually interacting with a collection of up to five processes (see Figure 1). These are the trusted process, an unclassified control process, and one process for each classified level that the user/terminal is cleared to operate. Each process (except the trusted process) can write data only at its own level and can read data at its level or lower.

SIGMA attempts to be as helpful to the user as it can, organizing the user's session and cleaning up the user's state (current context) as necessary. The service also attempts to understand the user's current context and conform its behavior to the situation. For this reason the context information must be available to all user processes; thus, it must be unclassified.

The user's state in SIGMA is divided into two parts. The first part contains the current list of objects being accessed and functions being performed by the user. This portion of the state is maintained at the unclassified level by the unclassified control process. The second part contains the current list of message entries (from the open message file) in which the user has expressed an interest. The entry list information is potentially classified at the level of the file and is thus maintained at this classification level by the appropriate classified process.

This dichotomy of state is reflected directly into the security design. Commands are divided into those which access the unclassified state (unclassified commands) and those which access the entry list (classified commands). The latter group includes both commands that use the entry list for input and those that allow the user to enter classified information as part of the command.

Multilevel terminal

We designed the terminal, used by SIGMA, to enable the user to interact with data at more than one security level at a time. The screen of this "multilevel terminal" is divided into "windows" (see Figure 2), each of which is logically an independent terminal. Each window scrolls independently and may have a different security level. Windows are further divided into domains that have various attributes (e.g., enterable, editable, underlined, etc.). The domain's security level is the same as that of the window.

To keep the user apprised of the level of information he is viewing and entering, we added two sets of lights to the terminal. Each set consists of four lights (one for each security level); one and only one light of each set is on at any time. The first set is mounted on the keyboard; it specifies the classification of the window in which the cursor currently resides. If the user wishes to know the level of any particular piece of information on the screen, he may move his cursor to the information. The second set of lights is mounted next to the screen and specifies the maximum level of information displayed on the screen.

Form of command input

We designed command input so that it could be done through a separate window that is normally at the unclassified level in order to keep the majority of the user's state information at unclassified. Certain commands, such as the

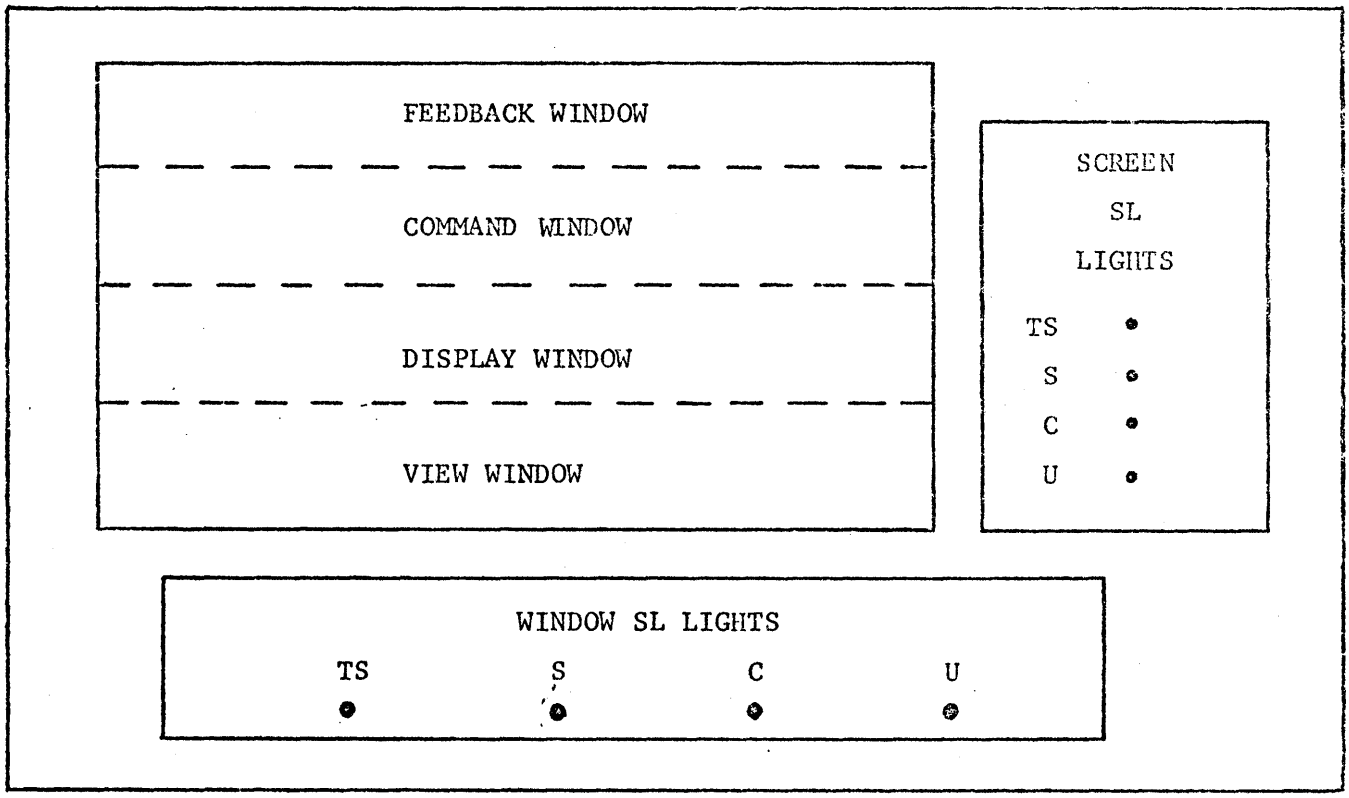

Figure 2—Multi level terminal

"find text string" command, have potentially classified arguments. For these commands the security level of the command window is raised to the level of the object that the command is affecting before the user enters the parameters.

Strict enforcement of the security model eliminates any possibility of a security compromise: a write-down path through the system that could be used to release information of a higher security level to a lower security level.[15] However, even with the enforcement of the model, there are several situations in a message system where the user, by following instructions given by the system, can inadvertently compromise small amounts of information.

Consider the following example: A user asks for a list of all his messages with a subject having word "x" in them. To perform this operation, the user must be at the security level of the file that he is looking at—greater than or equal to the security level of all the messages within that file. The enforcement of the *-property forces the result of this examination to be at the level at which the examination was performed—the security level of the file. Should the user then decide to perform any modification to a message returned by this examination that has a security level lower than the file security level, the *-property would require him to: issue commands at the security level of the message that he desired to modify, and tell the system the unique identification of the message told to him by the classified process. (The unique identification is required here because the system is unable to pass the desired identifier "down" due to the enforcement of the *-property.) However, this transmission through the user of the message-id from the higher process to the lower process is, itself, a violation of the *–property. Although it is conceivable that a maliciously written program could use this *-property violation to compromise information, we assume that the user serves as an effective filter in this write-down path (both in "bandwidth" and in checking for reasonableness), thereby precluding any reasonable software means of making use of this path.

Because of the hardships that strict enforcement of the *-property imposes on the user and because of the existence of *-property violations, a case can be made to ease the user interface in situations where this type of violation exists. The improvement takes the form of allowing SIGMA, in violation of the *-property rule of the security model, but with user concurrence, to write-down the unique identifier of the message that the user wants to modify. We limit the bandwidth of this type of *-property violation, so that it is no larger than the path that otherwise occurs through actions of the user, by allowing only a specific amount of fixed-format information to be transmitted to a lower security level and then only if the user has depressed an appropriate function key that is linked directly to the security kernel. Allowing the system to transmit this information greatly simplifies the user interface.

Trusted process functions

Certain functions need special capabilities to operate (such as the passing of message identifiers) but are relatively message-system dependent and thus are not included in the security kernel. We group these functions together in a "trusted process" that has the ability to transfer information in a controlled fashion in violation of the *-property.

The trusted process in SIGMA performs four functions: change classification; message release; command completion signals; and entry list transmission.

Change classification

SIGMA allows users to change the classification of text that they are allowed to access. When this happens, the trusted process clears the screen and presents the text in a simple fashion (19 lines at a time) for confirmation. When the user has confirmed the entire object, the trusted process logs this action and passes the text to a process at the new security level for refiling.

Message release

In the military formal messages are released with the commander's signature. Therefore, we consider the act of releasing a message a security event. To control message release, we require that the trusted process insure that the user requesting the release is authorized to release and that this user is making the request from an authorized terminal.

An additional security consideration with message release is that some AUTODIN terminals (ours in particular) treat the message header as unclassified. In SIGMA this header is created in the same window as the message text. Therefore, releasing a message implicitly lowers the classification of the header information. During message release the trusted process requires the user to confirm that all of the header information is actually unclassified. The trusted process logs this action before releasing the message.

Command completion signals

We have based the SIGMA design on the concept of an unclassified process that receives the majority of the commands, determines the proper security level needed to execute these commands, and then activates a process at that security level to perform the execution. The disadvantage of this approach is that, should an error occur between the unclassified control process and the classified operational process, the classified process cannot ask for clarification. Thus error recovery is difficult. This problem is referred to as the open loop problem.

Presently we believe that the best solution to the open loop problem is to allow the trusted process to close the loop when an error of this type is encountered, provided the user has depressed a function key since the last such request. Closing the loop improves recovery but has an impact on security, since a *-property violation exists when the loop is closed. As in command input, requiring a user action between successive writedowns restricts the bandwidth of this operation.

Entry lists

When a user process needs to write down a list of message identifiers, "entry lists," it passes this list to the trusted process for user confirmation directly. The trusted process checks the format and bounds of the entry numbers, and asks the user to directly confirm the number of entries being processed at each security level. Thus, the user has the ability to directly monitor (and control) the bandwidth of the writedown channel. This separate step is reasonable even from the user interface side, for if the number is too high or too low, the user can see that he specified his request incorrectly.*

KERNEL REQUIREMENTS

In order to be able to support the SIGMA architecture, the security kernel must provide certain additional features not found in kernels designed to date, including a terminal multiplexor for the multilevel terminal, a variety of object sizes, the ability to support large numbers of processes, an efficient inter-process communication facility, and a policy that can support "trusted" processes.

Multilevel terminal certification

Since the terminal supports the simultaneous display and editing of data at different classifications, we must demonstrate that the terminal (1) maintains the proper levels for all information it contains (possibly 20,000 characters) and (2) marks all information returned to the computer with the proper security level. It is the terminal's responsibility to assure that no information entered in a window by either the user (doing local editing) or the application computer is transferred to any other window. While at first pass the certification of the terminal may seem trivial, one must consider that the terminal code is currently produced for a single INTEL 8080 and occupies 32K bytes of PROM. Eventually multiple 8080's, application of Denning's flow analysis,[16] or the introduction of a kernel in the terminal will be necessary to guarantee separation of the windows.

Terminal multiplexor

A significant problem is the method for attaching the multilevel terminal to a secure system. We have identified two

* If the entry list has only one element, then the appropriate function key is sufficient and the further "confirm 1 entry" step is omitted. This operation allows the user to point to a single entry or mention it by number or context (CURRENT, NEXT) for a display, reply, file, etc., without being required to do more than use the proper function key to enter or confirm the command.

alternatives: each window could have a unique connection to the system or the kernel could multiplex all information to a terminal over the same communication line. We have chosen the multiplexing approach in order to minimize the number of terminal lines.

Communication between the system and the terminal is in the form of NOTICES and DISPATCHES.* The terminal multiplexor must assure that each NOTICE received from the terminal is directed to a user process whose security level is the same as the security level of the window. The multiplexor must also forward Function Key Notices to the trusted process to provide for the capability for a controlled write-down of message identifiers.

The terminal multiplexor must insure the correctness of all DISPATCHES to the terminal. With the exception of "window allocation" DISPATCHES, the terminal multiplexor need only check the window identifier and length to assure that the user process is communicating with a window to which it has access. All requests for terminal window allocations and deallocations must be done by the unclassified user control process. This process provides the terminal multiplexor with the security level for all newly created windows. The unclassified process can, at a later time, request a change in a window classification by notifying the multiplexor. If this new security level is lower than the current window security level, the multiplexor must erase the information currently in the window.

Process structure

The design of the kernel's process structure will have significant implications for the performance of SIGMA. On traditional timesharing systems, such as TENEX, process creation is expensive, and process swapping is lengthy. In order for SIGMA to operate efficiently the kernel must be able to (1) support large numbers of processes; (2) allow for fast process creation and deletion; and (3) swap processes with little overhead. Large numbers of processes are required because SIGMA requires several active processes per user. If SIGMA is extended to handle compartmented intelligence, fast process creation and deletion would be required. Finally, because large numbers of processes are doing small amounts of processing, process swapping occurs often. To expect a kernel to provide this type of support may require significant hardware support.

Interprocess communication

Equally important to the efficient operation of SIGMA are the speed and types of interprocess communication provided for by the kernel. SIGMA will require the kernel to support both preemptive (interrupt-like) and non-preemptive (message-like) types of interprocess communication. In addition, the latter mechanisms must support small messages for passing message-ids and large messages for transmitting entire command strings.

File system

The file system is often one of the most complex portions of the kernel, a quality which can cause unnecessary overhead. For example, SIGMA does not require the kernel to provide a file organization such as a directory hierarchy. A "flat file" system is entirely adequate and can be used more efficiently. The only special requirements for SIGMA are that the kernel should support both small files (512 bytes) and large files (10K bytes).

System integrity controls

To support SIGMA the security kernel must provide a mechanism that implements the notion of least privilege. This mechanism has been given the name "System Integrity."[17] SIGMA uses three separate privileges: a secure write-down privilege used by the trusted process to reclassify text; a release privilege used to restrict the releasing of messages to a select group; and a system security officer privilege used to initiate and set the security level of new users.

The primary rule that the system integrity controls must obey is: to modify an object or execute a kernel call a subject's system integrity level must be greater than or equal to the system integrity level of the object or kernel call.[18] There are no rules on reading or executing programs (programs in execution use the system integrity level of the process that they are executing under). We must therefore demonstrate that each subsystem with a system integrity level greater than system low (non-kernel, no privileges) does not execute any programs other than ones that we know execute properly.

CONCLUSION

The design of SIGMA demonstrates that it is possible to build a secure message processing system based on the kernel approach using the DoD security model. We have shown the refinements to the security policy that are needed to achieve a usable interface and have documented the features that a security kernel must provide to support a secure message processing system efficiently. The techniques used in designing SIGMA should be directly applicable to other transaction-oriented or data base management systems.

Network operating systems—An implementation approach*

by STEPHEN R. KIMBLETON, HELEN M. WOOD and M. L. FITZGERALD

National Bureau of Standards
Washington, D.C.

INTRODUCTION

Networking affords a communications support mechanism among heterogeneous computers. It does not provide any means for alleviating the effects of differences across systems. As a result, network users are forced to resolve such differences; the resulting learning and programming burden inhibits effective utilization of networking capabilities to achieve resource sharing.

Achieving the potential of networking would be increased through masking system differences from the user in many, if not most, applications. Network Operating Systems (NOSs)[1,2] are commonly viewed as the mechanism for accomplishing this objective. The functional objective of an NOS is to support and simplify access to existing services and to expedite the construction and subsequent accessing of new services by simplifying interaction among systems and between systems and users.

The remainder of the Introduction discusses the required enduser support which must be provided by a Network Operating System, identifies the two major resulting implementation issues and describes the constraints which affect the complexity of NOS implementation. Thereafter, the next section describes major NOS design decisions guiding the implementation of an Experimental NOS (XNOS) being implemented at the National Bureau of Standards (NBS) as part of a joint RADC/NBS effort. The third section then discusses the implementation of the user-system interface while the fourth section discusses the system-system interface. The fifth section provides some concluding remarks.

Network operating systems

A Network Operating System providing ease of access and utilization of systems, subnetworks, and services must provide two capabilities for endusers: job ececution and data handling.

A network job consists of a collection of network job steps, each of which may be executed on a different machine. The Network Job Execution function of a Network Operating System should provide the means for initiating job steps, migrating input information as appropriate, suitably disposing of output results and interacting with the user as required.

Network Data Support provides the means for a user to manipulate files using a command language and for a program to access remote records at run time. To provide a homogeneous viewpoint across systems, the NOS must provide a Network Wide Directory listing network accessible data resources, a common command language for manipulating files listed in this directory, and a means for limiting user access to these files to provide appropriate security mechanisms. At the record access level, mechanisms are required for preserving the meaning of data being transmitted between heterogeneous systems.

Implementation of these two enduser functions requires two major support functions: user-system interfaces which provides a common virtual viewpoint for the user across heterogeneous systems and system-system interfaces to support the transmission of data between systems and preserve the meaning of the transmitted data. Such interfaces are discussed in sections three and four, respectively. Their implementation requires resolution of some underlying design issues.

Design issues and alternatives

The difficulty of NOS implementation is critically dependent on the hardware and software environment which must be accommodated. Operationally, such situations can be divided into three categories: (i) those requiring a retrofit of the NOS to a heterogeneous collection of computer systems; (ii) those invovling retrofit to a homogeneous collection of computer systems; and (iii) situations in which there is no constraint to interface to existing software.

A study of these alternatives shows the following: (i) retrofitting to heterogeneous hosts is the most difficult case but maximizes resource sharing and best accommodates

Certain commercial products are identified in this paper in order to adequately specify the procedures being described. In no case does such identification imply recommendation or endorsement by the National Bureau of Standards, nor does it imply that the material identified is necessarily the best available for the purpose.

both planned and existing systems; (ii) retrofitting to a homogeneous collection of host computers is easier than retrofitting to a heterogeneous collection of hosts, but limits the opportunity for resource sharing—a major rationale for network construction; while (iii) unconstrained (e.g., built from "scratch") implementations will be the most satisfactory from a user viewpoint, but lack downwards compatibility and, as a result, will be extremely costly to implement since significant rewriting of existing software is required.[3]

NOS related projects

Before beginning our discussion of XNOS, we first briefly describe three NOS related projects: RSEXEC, NSW and ACCAT.

RSEXEC[4] was the first NOS oriented project. Since it was implemented for a homogeneous collection of computer systems (the TENEX systems within the ARPANET), the user-system interface problem was non-existent. Its primary contribution was exploration of the issues in providing a network wide file space and in resolving references to remote files. Such references were handed through an encapsulation mechanism termed a JSYS trap[5] which, upon trapping such a reference, determined where the file was actually located and arranged its migration to the site of the executing program.

The National Software Works[6] is designed to provide a sophisticated program production service. This is accomplished through networking together some of the more sophisticated program production tools available on different systems and, via NSW support mechanisms, making this collection appear as an entitiy to the individual user. Thus, upon issuance of a request to utilize a particular tool, the user and any appropriate files are automatically migrated to one of the sites at which the tool is available. As a result, the user only sees the provided tool and is unaware of the system on which it is being run. With the spectrum of accessible objects thus constrained, it proves feasible to provide a uniform treatment of error responses.

The Advanced Command and Control Architectural Testbed (ACCAT) is an interesting study in the problems of interfacing a user to a Database Management System (DBMS). A major problem in such an interface is the requirement that the user learn the syntax and semantics of the query language. To circumvent this, ACCAT contains a restricted natural language interface which transforms the user's request into an internal form. This form is then translated into a series of queries against the database.[7,8] Collectively, this provides a fairly "soft" interface of the user to the DBMS.

The preceding projects are primarily concerned with the utilization of networking capabilities to achieve specific functions. An explicit investigation of the interface issues implicit in supporting a general purpose NOS across heterogeneous hosts is being undertaken in the Experimental Network Operating Systems (XNOS) project at NBS. The functional components being investigated by these four projects are illustrated in Figure 1.

Figure 1—Major NOS functional components

NOS IMPLEMENTATION

Implementation of a Network Operating System requires a series of design decisions. This section discusses two of the major configuration related decisions. The following two sections then articulate the issues in supporting the user-system and system-system interfaces and discuss implementation specific factors.

Support components

Construction of a Network Operating System requires both the design of certain procedures and processes, as discussed in the following two sections, and determination of the processors on which they are to be executed. Perhaps the major design decision relates to where computing requirements are to be provided. Two alternatives exist for providing these requirements: the existing hosts within the network (the unaugmented case) or, alternatively, adding specialized processors to satisfy most of these computing requirements (the augmented case) which we will call Network Interface Machines (NIMs).

Utilization of NIMs for satisfying most of the NOS computing requirements has four major advantages. First, it minimizes the impact of the NOS upon the host. This was deemed highly desirable since it is felt that few installation managers would tolerate any significant system overhead for NOS support. Even fewer would be willing to accept modifications of the host operating system.

The second advantage to offloading NOS support is the consequent minimization of the need to recode functionally identical modules to accommodate different systems and architectures. This approach also facilitates centralized design, implementation and support of the NOS. Hence, the third advantage—centralization—reduces costs by minimizing the number of support personnel.

The fourth advantage is facilitation of incremental expansion, modification and enhancement of NOS capabilities. This seems particularly important since evolving experience driven requirements are likely to result in gradual change of the initial NOS.

These four advantages must be considered in the context of two major implementation issues: attaching NIMs to hosts and the cost of providing the NIMs. After discussing the first issue and describing the initial XNOS implementation, we shall return to the second.

Attaching NIMS to hosts

Attaching a NIM to a host can be accomplished in two ways: implementation of the NIM as dedicated host(s) on the network or as a frontend processor to the host. To the authors, the second approach seems appropriate when Network Operating Systems have achieved a greater degree of maturity. A significant amount of work has been concerned with the relationship between the host and the frontend.[9] The primary concern of those studies is with optimization of the provided functions rather than with identification of the functions to be supported. Since present research is more appropriately oriented toward identification, realization of the NIM as a dedicated host(s) on the network allows concentration on NOS support issues and therefore seems preferable.

A major advantage of implementing the NIM as a dedicated computer attached to the subnetwork is the consequent utilization of the host-host protocol to support communication between NIM and hosts. The disadvantage is forgoing the simplification of connecting hosts which are ill suited to interactive use.

The initial implementation—XNOS

An Experimental Network Operating System (XNOS) has been implemented at the National Bureau of Standards to facilitate investigation of the interface issues (discussed in the following two sections) which must be supported to achieve more effective utilization of network accessible resources. Figure 2 illustrates the initial XNOS configuration and shows that NOS support is to be provided through a NIM attached to the communications subnetwork (the ARPANET).

Given that the NIM is to be a dedicated host on the communications subnetwork, only one is required to support a full feasibility demonstration. This follows since ARPANET technology permits a host (the NIM in this case) to establish a network connection with itself. Thus, a single NIM can provide the functions required to interface to a host issuing a request, the functions required to interface to the host responding to the request, and the communications functions required to interface between two NIMs. Thus, the basic implementation approach illustrated in Figure 2 provides a reasonable, general purpose test environment.

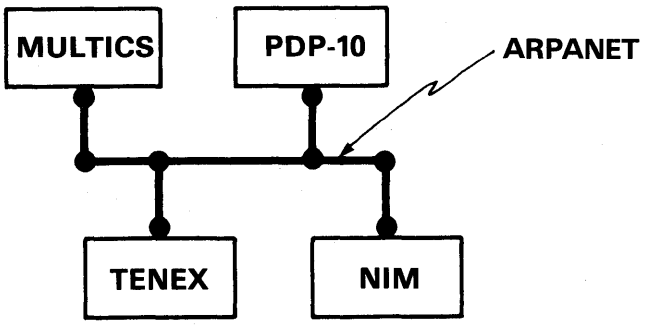

Figure 2—Initial XNOS configuration

The preceding comments have provided a general perspective on the adopted XNOS implementation approach. In this environment, the NIM is a PDP-11/45 running the UNIX operating system and attached to the ARPANET via a slightly modified version of the University of Illinois Network Control Program (NCP).

The XNOS supported hosts are: a Honeywell 6180 running the MULTICS operating system, a PDP-10 running TOPS-10, a PDP-10 running RENEX, and a PDP-11/45 running UNIX. Based upon present experience we foresee little difficulty in supporting any interactive system attached to a communications subnetwork, preferrably using full duplex communications. Support of batch systems has not yet been investigated.

Logging in

Two basic approaches to logging into XNOS can be considered. In the first approach the user is directly logged into a host computer and invokes XNOS support software thereby being indirectly logged into XNOS. In the second the user directly logs into the NIM (and hence directly into XNOS). The first approach potentially allows the network user to see the network as an extension of the host and to use the same command language used by that host computer.

Adoption of the second approach seems more natural from an NOS viewpoint since it permits equal treatment of all hosts. Thus the user physically logs into the NIM, issues commands to the NIM receives responses from the NIM and, in general has the NIM acting as a mediator between the user issuing the requests and the systems satisfying them. This approach also simplifies support of utility functions.

Utility support

Effective support of network users is facilitated through the existence of certain support capabilities, e.g., editors, that function in an identical manner regardless of the host to which one is attached. XNOS supports this requirement by providing such utility functions on the NIM. Invoking these functions requires that any required input data or files also be located on the NIM. This is accomplished through using the mechanisms in sections three and four.

NIM computational requirements and costs

The cost of providing NIMs is dependent upon their computational requirements and the number provided. Such

costs must be carefully considered since the canonical problem in providing any type of frontend support to a host computer is the tendency for such support to require another 'host' of size comparable to that being supported. We feel that this is not a problem of XNOS since the only functions provided by the NIM are those supporting user-system and system-system interfacing together with utilities.

Computational requirements

The computational requirements for supporting user-system interfacing can be divided into: (i) support of the common command language for file manipulation and the network job execution command, and (ii) support of NIM independent interactions. Typically, for an individual user, the average time between issuing commands in the first category would be on the order of minutes. The second category of interaction occurs when no intervention by the NIM is required, e.g., the user is interacting with a program, and the only computational support is that of forwarding commands or responses. We assume that the overhead in handling such commands is minimal.

The discussion in section four shows that the computational requirements for supporting system-system interfacing are those required to provide a network wide Interprocess Communication (IPC) mechanism and those required to support translation and transformation of records generated by remote record accesses.

IPC is used to support both user-system and system-system interfacing. As discussed above, the former is invoked relatively infrequently. We conjecture that the mean time between occurrences of remote record accesses by an individual program will also be on the order of minutes due to the subnetwork delays which occur in accessing remote hosts. Moreover, computational support of the translation and transformation requirement generated by a remote record access is relatively minor as follows from the discussion in section four. (These estimates are only intended to indicate that NIM computational requirements are likely to prove acceptable. Their verification requires measurements which can only be performed after a significant level of user utilization of XNOS capabilities.)

Utility support, particularly editing, can require a significant fraction of system resources. However, such support offloads the host of a function which it could provide (for interactive systems). Since this is done, in part, as a convenience for the host, the requirement for supporting utility functions should not be directly counted against NIM computational requirements.

Cost considerations

The cost of providing NIMs is dependent upon the number supported and the size of each. Assuming that NIMs are implemented as hosts on the communications subnetwork, the minimum number of NIMs is one. A likely upper bound is one for each host. In an operational version of XNOS, the actual number used will probably be heavily influenced by a combination of performance considerations and the opportunity which NIMs afford for offloading certain utility functions (such as editing) from the hosts. A reasonable initial estimate for an operational environment would be one NIM per operating system class.

Utilization of a NIM promises to become increasingly cost effective if declining hardware costs are balanced against increasing software implementation costs. Even now, a relatively powerful NIM can be procured for the equivalent of the burdened cost of supporting one professional programmer. Moreover, since this approach minimizes reimplementation of functionally similar modules and facilitates modification, one must also balance the one time cost against the continuing programmer costs.

Utilization of a NIM also permits offloading certain terminal support functions from the mainframe. As a result, system efficiency is potentially improved and systems which are ill suited to interactive utilization are made more usable in a networking environment. Of course, the relation between the host and the NIM is an important factor in any final decision.

THE USER-SYSTEM INTERFACE

A Network Operating System should present a standardized view of network resources to its users and should provide ease of access to those resources. This section describes an implementation approach for a user-system interface that provides these functions for the XNOS.

Implementation requirements

The network user should be able to view network resources in the same manner that a user would view an individual system. A user knows of files in his workspace, but generally is not concerned with the complexities of the physical device upon which they are located. Likewise, the network user should be able to know there are files in his (network) workspace which exist on the available systems of the network, but should be insulated from the intricacies of the physical systems upon which the files reside. In addition, since the network user would like to view the network as an entity, a common command language is desirable to support communication both with individual hosts and across hosts.

These capabilities are provided within XNOS by a Networkwide Directory System (NWDS) that describes the user, the user's files and the available systems of the network. The NWDS also provides a common command language facility for manipulating known files and programs.

The Networkwide Directory System (NWDS)

The NWDS consists of (i) a data base, the Network Wide Directory (NWD), that describes the files belonging to each

user, the hosts on the network, and the types of interactions allowed among those entities; (ii) the software support required to access the NWD data base; and (iii) the access control mechanisms that insure system integrity and data security.

New users to the network are queried by the NWDS before entries are made into the NWD data base. These entries identify the user and the systems to be accessed. The user's own network directory is then initialized and all connections to hosts are made on behalf of the user by the NWDS. Thus, the user sees the network as a large relatively integrated system composed of the resources available to the user on each of the accessed hosts.

From the user's viewpoint, files have no rigid naming conventions. To accommodate individual system constraints, the NWDS maps these user file names into unique host file names conforming to the requirements of the host on which the file resides. Manipulation of these files is preformed by the NWDS for the user in accordance with user commands.

In addition to providing a common command language for the user, the NWDS contains logical record descriptions and host representation tables to support preservation of meaning in transmitting records between heterogeneous hosts. This supports run time access by a program to records contained in remote files as discussed in the following section.

User commands

The NWDS provides a common command language for file manipulation and a command for executing network jobs. This section describes these commands and presents an example of Network Job Execution.

Common command language for file manipulation

XNOS file manipulation capabilities provide a common command structure for manipulating files residing on an individual system and for transferring files among systems. The chosen set of commands was developed by surveying file manipulation commands available on the systems currently supported by XNOS.

Determination of the precise set of commands to be supported requires some care since support of a 'network' viewpoint of host resources is inconsistent with requiring detailed local host knowledge of how files are actually mapped to devices. As a result, only commands dealing with files as logical entities were selected for implementation as listed in Table I. Note that not all of the systems provided all of these commands. Thus, the NWDS effectively extends system capabilities.

TABLE I—The Common Command Language

File Handling Commands

CREATE	FILE
DELETE	FILE1
ERASE	
LIST	
RENAME	FILE1 FILE2
TYPE	FILE
UNDELETE	FILE
File migration Commands	
RETRIEVE	FILE HOST
TRANSFER	FILE HOST

Network job execution

A network job consists of a collection of network job steps. Each job step specifies a program, the host on which it is to be executed, input data files and output data files. Prior to initiation of the job step all input files are checked to ensure that they are resident at the site where the program is to be executed. If not, appropriate transfer operations are begun and step execution is deferred pending completion of these transfers. The syntax for a job step is:

```
RUN PROG@HOSTA
IN1=INPUT1,IN2=INPUT2,. . .
OUT1=OUTPUT1@HOST1,OUT2=OUTPUT2@HOST2. .
```

where

PROG is the program to be executed
HOSTA is the execution site
INn are the logical names for input data
INPUTn are the names for the input data files
OUTn are the logical names for output data
OUTPUTn are the names for the output data files
HOSTn are the final locations for the output data

A network job and its job steps are defined by an interactive program used in conjunction with the NWDS and the commands described above. The program queries the network user to gather all the information needed to specify a network job. For each job step in the network job, the user enters the program name, execution site, and for each input or output file, the logical name (name expected by the program) and the actual name (name in the user's directory). The program builds a macro that invokes the system interactions necessary to perform the job step. The resulting command, called RUN, is issued like any other command and the network job is executed. Figure 3 indicates a sample session defining a network job.

Access controls

Acceptance of a Network Operating System requires access controls to limit the access of the user to programs and files and to limit the access of a program. User level access controls are provided through a profile capability which contains a complete description of the network user, the

The user wishes to execute the program TEST on the NBS PDP-10 (TEST@NBS10). There are three input files, FILE1, FILE2 and FILE3 which are to be given the logical names IN1, IN2 and IN3 respectively. The program produces three output files: OUT1, OUT2 and OUT3. They are to be renamed and moved to other sites as follows: DATA1 goes to NBSUNIX, DATA2 goes to BBN and DATA3 will remain at the NBS10. There will be only one Network Job step in this job. A carriage return indicates no response.

The following dialogue will take place between the user and the XNOS:

```
Enter Program Specifications : TEST@NBS10
Remote file access? (y or n) n
Logical Name for Input File 1: IN1
Actual Name for Input File 1: FILE1
Logical Name for Input File 2: IN2
Actual Name for Input File 2: FILE2
Logical Name for Input File 3: IN3
Actual Name for Input File 3: FILE3
Logical Name for Input File 4:

HOST 3=
Logical Name for Output File 4:
```

Figure 3—Sample Definition of a Network Job

systems he is permitted to access and the types of interactions allowed.

Program access controls are supported in two ways: (i) run time checking of individual data items to ensure that the program has appropriate authorization, and (ii) execution of the program in its own run time directory to limit references by the program in a manner commensurate with the information provided by the user in issuing the job step execution command.

In addition to these formal access control mechanisms some degree of additional protection is provided by having file names in the directories on individual hosts (Local Host Directories) which differ from the names by which the files are known to the user. Although the individual user will be permitted to determine host file names corresponding to those files in his directory under certain conditions, such information is not available for files belonging to other users.

Support of such access controls requires that the NOS be the "owner" of all files resdient on an individual system. However, to facilitate interactions by a user wishing to directly manipulate files, temporary directories can be set up which contain those files designated by the user and which support direct access by the user rather than access mediated by XNOS.

Implementation support

The common command language described above was implemented using the capabilities provided by the Network Access Machine (NAM)[10,11] developed at NBS. The NAM is implemented on a PDP-11/45 minicomputer running the UNIX operating system and provides directives which permit a user to interact with a remote system on a network. Sequences of these directives stored in files called macro files have been written that will generate the necessary machine-dependent dialog to perform file manipulation functions required for each of the host systems. Thus, execution of each command in the language is actually a call to a macro file that the NAM expands and executes.

The responses that the remote system generates are, in turn, analyzed by the NAM. By permitting the mapping of the varied responses from the remote systems into standardized messages for the network user to see, the NAM facilitated the commonality of the common command language. The user can enter a standard set of commands and see a standard set of responses, and need not become familiar with the responses of each system accessed. (Note that this approach supports standardized error messages across all anticipated error responses; unanticipated responses are transmitted directly to the user.)

SYSTEM-SYSTEM INTERFACING

Successful system-system interfacing within a Network Operating System environment requires two primary functions: (1) a means for transmitting data between systems, and (2) a mechanism for accessing and preserving the meaning of structured data as it is transmitted across heterogeneous systems. The first feature is provided by Interprocess Communication (IPC), and the second by a Remote Record Access (RRA) capability.

In this section we shall discuss the problems of system-system interfacing in more detail and identify required functional capabilities and support mechanisms, while considering some of the alternatives encountered during the implementation of XNOS. A more detailed treatment of the problem may be found in Reference 12.

Interprocess communication

Interprocess Communication (IPC) provides the basic mechanism for initiating and controlling the flow of data between cooperating processes. Since processes are the only active entities within a computer system, IPC is a basic building block for supporting communication between computers.

The National Software Works[6] has implemented a relatively sophisticated IPC mechanism termed MSG[13] which permits the SENDing process to continue execution independently of the activities of the RECEIVEing process, whether or not the message was actually RECEIVEd. Providing such a capability requires fairly complex software support.

The XNOS IPC mechanism might be regarded as a minimum level IPC approach requiring very little host software to support its functioning. This is accomplished using a CALL/RETURN based mechanism that functions analogously to subroutine CALLs in that the WAIT state is entered upon issuance of the CALL. The simplicity of imple-

menting this approach stems from using constructs available in the major existing programming languages and requires minimal host support.

The simplicity of XNOS IPC support derives from the fact that, if we assume interactive jobs, IPC messages can be transmitted over the controlling teletype channel, intercepted at the NIM and diverted from the user's terminal to the appropriate destination where the reverse process occurs. Although the sophistication of this approach is limited and the bandwidth between communicating processes is constrained, the simplicity of its support coupled with the negligible startup costs for any host supporting interactive processing have led to its adoption.

Remote record access

Remote record access permits a process executing in one computer to access data records located in another computer at run time. This requires transmitting data between possibly dissimilar hosts which is complicated by both physical incompatibilities between systems and organizational incompabitilities between the data as required/maintained by the systems.

Physical incompatibilities include differences in word length, character packing, sign bit location, and data encoding (e.g., character sets or use of two's vs. one's complement representation of numeric data). A translator is needed to convert data from the internal format of one host to that of another. Organizational incompatibilities between data bases, on the other hand, result in the need for a transformer to modify the format of files and data items (e.g., reorder and concatenate the data fields of a record before transmitting that data to the requesting host).

The provision of a remote record access capability, then, requires: (1) a mechanism for selecting a record from the file/data base containing it, (2) a record translator to preserve meaning in transmitting the record between dissimilar hosts, and (3) a record transformer to permit the alternation of record structures. Supporting these functions mandates a means for describing the physical and organizational characteristics of the hosts. (It should be noted that the same functions could be performed iteratively for all records, when an entire file is migrated between dissimilar hosts—thus resulting in a file transfer protocol (FTP) for structured files.)

These functional components will now be discussed in greater detail and, to better illustrate the associated information requirements, an example will be described in which a process on one host requests a data record from a dissimilar host on the network. As illustrated in Figuare 4, the host bearing the file containing the remote record is called the Data Host (Dhost) and that bearing the accessing program is the Process Host (Phost).

Record selection

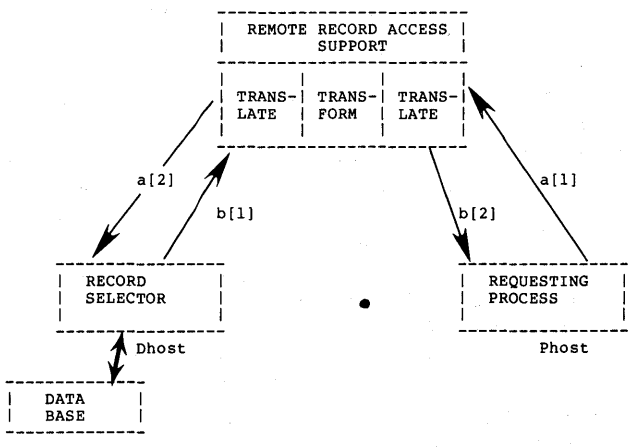
The precise mechanism which supports record selection is dependent upon capabilities existing at the host computer including those provided by a data base management system, if any. The following discussion assumes the existence of a suitable mechanism for retrieving a record based on utilization of a unique key, if random access techniques are being employed or, alternatively, the keyword 'next' if sequential access is being used. Given this assumption, we now describe the basic communication support.

Assume that the Phost issues a request for a record located on the Dhost (path a[1] in Figure 4). This request, when received by the NIM, is forwarded to the Dhost (path a[2], Figure 4), accompanied by any additional descriptive information needed by the selector. Such information would include the host specific file name, as determined by the Network Wide Directory System.

Upon receipt of the request by the Dhost, a record selector is responsible for retrieving the record and transmitting it to the record translator (path b[1], Figure 4). Figure 5 shows such a record, in the format maintained by the Dhost. (The field names are included here for clarity, but would usually not be contained within the actual record.) Although the record in Figure 5 shows all data fields in character notation, it should be understood that these data items are actually in the machine representation of the appropriate data type (e.g., integer, real, logical, character, binary).

Record translation

Record translation preserves the logical record structure and data element type (e.g., real, binary, logical, integer, character) and, for arithmetic data elements, precision. Thus the record translator must know the exact format of the record to be translated down to the data item—a level of detail analogous to that contained in a FORTRAN format statement (e.g., 3I5,2X,5A5,F4.2). In addition, the internal



a[1]: request for data from network-wide data base
a[2]: request for data with access parameters
b[1]: retrieved record in Dhost format
b[2]: retrieved record in Phost format

format of all data types must be known for each computer that is supported on the network.

Placement of the record translator at the host requires its coding for each separate host architecture and increases the impact of the network on the host. For both of these reasons, the record translator has been implemented on the NIM. Although knowledge of the internal data representations of N hosts are still required, only 2N, rather than N(N-1) translators must be implemented (one into and one out of each host format). Since host dependencies are reflected only in the tables being used to drive the translation process, 2N becomes 2. As the process of translating into and out of host dependent representations are very similar, it was initially conjectured that 2 would become 1. However, there prove to be enough subtle differences to justify two separate programs rather than consolidating them into one.

Given that translation is to be supported on the NIM, the remaining issue is whether to map directly from source to destination form or to proceed via a common intermediate form. The substantial simplification in implementation afforded by the intermediate Network Normal Form (NNF) resulted in the selection of this approach. Figure 6 shows the Dhost record as it would appear after translation to NNF format. (Notice that all data types are now in a character representation.) Once the record has been transformed to meet the needs of the requesting process (Figure 7), it is again translated—this time into the bit representation required by the Phost, a process that is essentially the inverse of the original, table-driven translation from Dhost format

Figure 6—Data host record DDR[NNF]

to NNF. Figure 8 shows the record in the Phost format. The resulting record is then transmitted to the Phost (path b[2], Figure 4) and RETURNed to the requesting process.

The communications subnet often supports character translation. Therefore it would at first seem reasonable to have the translation of character data handled by the subnet, thus reducing the translation requirements to a minimum. However, as it is unreasonable to assume the exclusive use of character-oriented data, such subnetwork capabilities cannot be relied upon for the general case. It may be desirable, however, to add to XNOS a capability to default to such subnetwork handling of data when dealing with character-only data.

Record transformation

Record transformation supports modification of both the logical structure of the record and individual data elements. The record transformation function matches the information transmitted to the needs of the receiver or to ensure proper protection of sensitive information (e.g., matching the data to the access rights of the receiver by omitting sensitive information from the record before transmitting it on to the requesting process). Such transformation affects the logical structure of the record through one of three basic transformation types: logical, arithmetic, or string.

Logical transformations such as AND or OR generate Boolean binary strings resulting from the bit by bit ANDing and ORing of two successive strings. Arithmetic transformations such as: $+,-,/,\times$ act as would be expected. String transformations can be quite complex as evidenced by the

Figure 8—Phost data record—PDR[P]

capabilities of string manipulation languages. Initially, a concatenation capability seems desirable. Among the additional transformations that may be needed are algorithms for the compression and/or decompression of textual information.[14]

As with the record translator, support of record transformation is implemented more efficiently on the NIM. This follows through having the transformer operate on the record in NNF format.

In XNOS a Transformation Description Table is used to provide the information that the translator needs to establish relationships between data items in the Phost and Dhost records. In this table each item in the Phost data record (PDR[i]) is expressed as a function of the appropriate item(s) in the Dhost data record (DDR[j]). For example, the concatenation of two character fields from the Dhost record might be expressed as follows:

$$PDR[j]=DDR[i] \mid DDR[k]$$

A record that could be the result of such a series of operations is shown in Figure 7.

Supporting transformation of numeric data types (i.e., integer, real) requires care since precision must be considered. Our approach uses a character based intermediate representation coupled with an arbitrary precision arithmetic package. The character representation directly accommodates varying precision while the arbitrary precision package supports transformations of numeric types. Of course, the precision of the result will never be better than the lesser of that of the source and destination. However, this approach does ensure that precision is not lost during the translation/transformation process.

Secure environments

The enhanced access to system resources provided by a Network Operating System requires a suitable collection of access control mechanisms. Not only must a user's identity be verified at login time, but access on his behalf to NOS maintained accounts on remote systems and to files, records, and fields within those systems must also be controlled.

As part of a continuation of the joint NBS/RADC effort which resulted in the work described in this paper, efforts are currently under way to structure NOS access control requirements and alternatives. This study will result in the incorporation of prototype access control components into XNOS. Since the password has been found to be a relatively inexpensive, but highly effective mechanism for identify verification and access control when used properly[15,16] it will no doubt be an integral part of the effort to enhance XNOS security.

Once the decision has been made to control access to network resources, the ability to protect data during transmission becomes a further requirement. Although it is generally accepted that an algorithm such as the Data Encryption Standard[17] would be suitable for such purposes, an appropriate encryption key management mechanism would have to be determined for the NOS environment. These and other network security related issues will be addressed in subsequent studies and reports.

CONCLUDING REMARKS

In this paper we have provided a perspective on the issues and implementation constraints implicit in providing a general purpose Network Operating System for a heterogeneous collection of host computers. One implementation of an NOS has been described based on utilization of Network Interface Machines to offload NOS support from the host and to facilitate centralized design, implementation and support.

Based upon our experience in the implementation of XNOS we are led to conclude that NOSs are feasible. However, in view of the complexity of the possible error messages, the activities of the general purpose user of such a capability will probably be constrained to minimize unexpected error responses. Thus, we would anticipate that general purpose computing might be confined to one or a few machines while other systems would be accessed to use unique resources known to be fairly well debugged.

Finally, it should be noted that Network Operating Systems only solve part of the problem of simplifying user access to systems—that of providing a uniform viewpoint across systems. The remaining part is concerned with simplifying system access given such a capability and constitutes the area of network access support. In Reference 18 it is shown that such support can be structured into four major components: user and service profiles to simplify and automate user interaction with services; soft user interfaces to eliminate the need for user concern with the precise syntactic structure of commands; expert assistance to reduce the need for entering repetitive information; and dynamic tutorial assistance to provide specific, pinpointed problem solving information online.

INTRODUCTION

With the advent of microcomputers and computer networks, distributed processing (i.e., the sharing of computing by several processors with each processor assigned to perform a certain task) becomes technically and economically feasible. Such architecture also provides system expandability, system reconfiguration, and fault tolerant capability for the system. The performance of such a system is not only affected by its application but also by the system architecture.

One of the important problems that affects system performance is interprocess communication. It is intimately related with the task partition and assignment of various process modules and the system bus structure that provides the interprocess communications. In this paper we will first describe a new system architecture which consists of modules with identical bus interface connected by a unique broadcasting bus structure. In order to reduce bus interface cost, serial broadcasting busses are used. Next, we describe the simulation model for studying the performance of the proposed architecture. Finally, we use the known program characteristics and workload profile of a Naval data communication network as an example of the proposed architecture in order to study its feasibility and performance. The quantitative relationships among process and bus utilization, message delay, and task partitioning and assignments of the distributed processing system are presented. These results provide us with insight and understanding of the behavior of the distributed processing system.

THE DISTRIBUTED PROCESSING SYSTEM ARCHITECTURE

The proposed distributed processing system as shown in Figure 1 consists of three module types: processor, memory and input/output (I/O) modules. Modules may communicate with each other via a unique broadcasting bus structure. Each module has an identical bus interface consisting of a serial send bus and several receive busses. The send bus transmits data serially to all other modules in the system. The receiver receives data serially on its receive busses. For such a bus organization, a system with N modules requires N busses to communicate among the modules.

Every module has an identical hardware bus interface (BI) and a front end processor (FEP). The FEP handles data transfers and protocol between the bus and the module, coordinates data transfers, discriminates between message types, and handles bus transactions for all modules. The FEP of a processor module acts as an input/output controller for the main processor. When it is implemented as a microprocessor or as a bit-slice processor, it provides a reliable and inexpensive approach to handling data transmission and bus protocol. It also provides an inherent distributed system intelligence which can be programmed to control the allocation of hardware resources. A microprocessor is used as the main processor of the processor module.

Data enters the system via the I/O module. The I/O module may store the data temporarily in its own FEP local memory, or it may transfer data directly to any other module via the bus. Similarly, the FEP of a processor module may store data received from the system bus temporarily in its own local memory or transfer it directly to the main processor local memory. The FEP of the memory module may accept data temporarily in its own local memory or transfer data to the common bulk memory. Any module can initiate system output by transferring data to an I/O module.

The processor module

The processor module organization shown in Figure 2 assumes a microprocessor or bit slice processor implementation. The module consists of a main processor, an FEP, local memories, a Direct Memory Access (DMA) facility, a

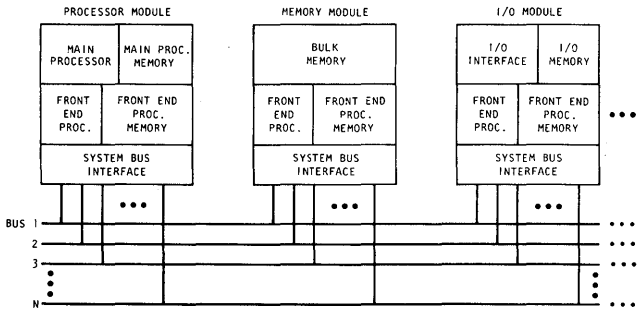

Figure 1—A distributed processing system architecture

bidirectional processor to processor interface and a system bus interface. The main processor executes the application program. The main processor local memory consists of read only memory (ROM) for program storage and random access memory (RAM) for data storage. The FEP has a small amount of local memory programmed to handle bus I/O and bus protocol. Local memory is dedicated to each main processor for program storage to alleviate contention by several processors accessing common memory, thereby reducing the inter-module communications. The FEP transfers data to and from the bus, as relayed to it by the system bus interface, and writes the data in the main processor local memory through the direct memory access. The reverse process occurs when data is read from the main processor local memory.

The DMA facility allows the FEP to store data in and retrieve from the RAM of the main processor. This interface ensures that data transfers are transparent to the interrupt and I/O control hardware of the main processor. The processor to processor communication interface allows word transfers to take place directly between the main processor and FEP without both accessing the main processor local memory. Either the main or the FEP can interrupt the other directly through their respective I/O facilities. The FEP receives or transmits data from or to system busses and provides asynchronous communications to the main processor, I/O control facilities, or to the main processor local memory.

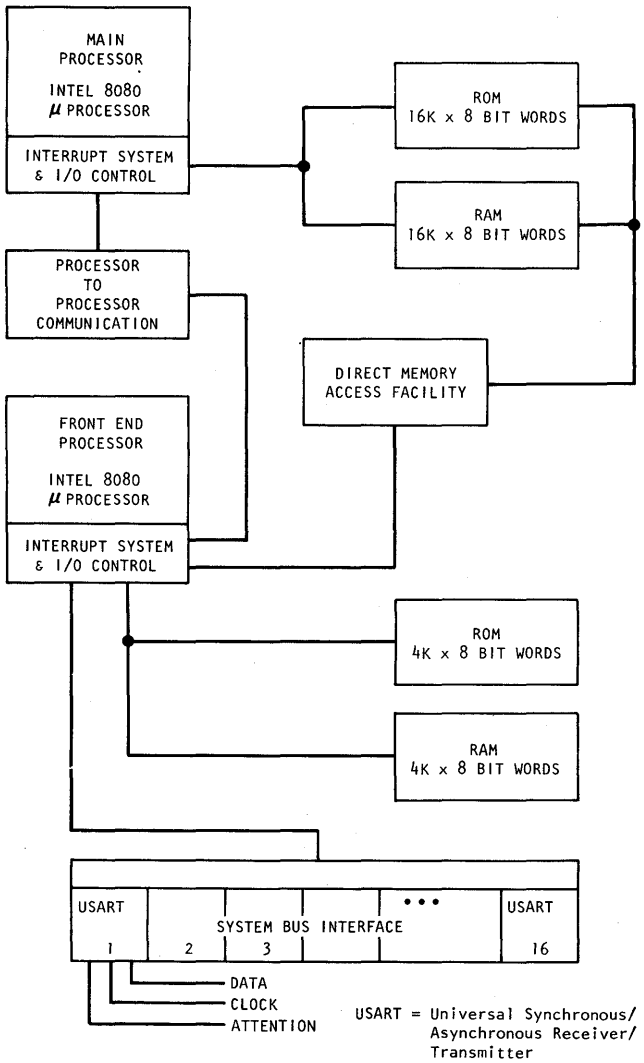

Figure 2—An organization of the processor module

The broadcasting bus structure

The proposed system may be viewed as a network consisting of different types of modules each having its own dedicated send bus which broadcasts information to all other modules. Further, each module can "listen" to the information from all the other modules in the system. Bus bandwidth affects the delay in inter-module communications; a serial broadcasting bus structure is used to both increase the bandwidth and reduce the bus and bus interface complexities.

Further, faults generated by hardware failures in such bus organizations are not likely to affect more than one bus, thus providing a graceful system degradation if software allows. The proposed bus structure can also be arranged to transmit parallel data thereby increasing the bandwidth for inter-module communications. However, system bus reliability decreases as the bus hardware complexity increases, and increasing the number of bus lines also increases the costs of the system bus interface. Hardware allocation schemes for bus hierarchies inherently become more complex as the number of busses increases. For real time applications, contention for a bus among modules is a severe problem when the contention time exceeds a specified time requirement for the system to respond to an external interrupt. Broadcasting bus organizations alleviate bus contention problems.

For the proposed bus organization, a system with N modules requires N busses to communicate among the modules. The system bus interface of each modules consists of N individual bus interfaces. Each bus interface (one per bus) decodes control signals from the FEP, performs serial-to-parallel data conversion, encodes and decodes character parity checks, and stores data for transmit or receive. Commercially available LSI components such as Universal Synchronous/Asynchronous Receive Transmitter (USART) or

Intel microcomputer (e.g. 8048) may be used for such interfaces.

Inter-module communications

Communication between modules is initiated by a module (called the source) transmitting a header, a character, or a block of data at a time. The bus interface of each receiving module of the system receives and temporarily stores the character of data and interrupts its FEP. The FEP of the receiving module honors the interrupt by resetting the interrupt facilities in the bus interface and then reading the identification of the bus request. The FEP of the receiver reads and decodes the destination address. The source begins transmitting data after receipt of an acknowledgment from each of the designated receivers. The receiving FEP disables the bus communication by not resetting the interrupt facility if the data is not addressed to it or if it does not desire to receive the data at that time. The receiving FEP records the time when the transfer request character was recognized. Since a receiver must send an acknowledgment honoring the transfer data request within a specified "time out" period, the source waits to receive an acknowledgment before it begins sending its block of data. All data communication on the bus is in block format. Asynchronous data communication requires DATA and ATTENTION lines for each bus. Synchronous data communication requires DATA, CLOCK, and ATTENTION lines for each bus (Figure 2). The receiving FEP takes one character of data at a time from the bus interface and stores the data temporarily in its own local memory or stores the data, via the DMA interface, directly at a predetermined memory location in the main processor local memory. After a receiver acknowledges the header character (which may consist of destination ID, word count, priority and message types), additional characters are transmitted by the source as specified by the word count of each message block.

In order to transfer data from the main processor to the bus output the main processor interrupts the FEP via the processor to processor interface. The data transfer flag for each receiver is stored in the RAM of the main processor. After the FEP acknowledges the interrupt, it reads the data transfer table if there is a request for a data transfer. The FEP initiates the output of that data block to the system bus interface. Transferring input data to its main processor is accomplished in a similar manner. Since program and local variables are stored in the local memory of each main processor, interprocess communication is greatly reduced.

Input/output module and memory module

Both the I/O module and the memory module (Figure 1) have an FEP for handling data transfers to and from the bus, and have identical system bus interface, FEP, and local memory. The memory interface in the memory module performs the function of interfacing the FEP with the bulk memory. The channel interface in the I/O module asynchronously multiplexes the channels and provides asynchronous communication with its FEP, I/O control, and interrupt facilities.

The I/O module interfaces the system with the user and with a variety of peripheral devices that include various hardware interfaces. The I/O module stores the data in its own local memory which queues the data for output to an I/O channel interface. In a similar manner, the FEP retrieves data from its local memory and sends the data to the bus. The interconnection of the FEP of the I/O module to the channel interface depends on the specific application and channel interface characteristics.

PERFORMANCE EVALUATION

In examining the performance of a distributed computer system, we are interested in the study of inter-module communications, processor and bus utilization, and response time and throughput of the system. Since these performances are program and application dependent, analytical models that can accurately predict the system performance are difficult to devise. An alternative method is to construct a prototype and measure these performance values. This approach not only requires the development of hardware prototypes, software system, data reduction and measurement facilities, but also encounters difficulties in evaluation of the system performance at different parameter values. We therefore use simulation techniques which enable us to use the actual program behavior and workload profile in studying system performance.

The simulation model

In order to provide a general yet accurate simulation model for our study the model is based on events. Events are generated at each processing module according to a given arrival distribution and enter into multi-level queues waiting their turn to be processed. The processing time of each task is known. In evaluating the performance of the system we are only interested in the task processing sequence, the task time and the bus occupancy time. The information of processor instructions and bus traffic contents is not required. As a result, the model does not require the detailed knowledge necessary for the applications program and system software. This greatly simplifies the simulation. The accuracy of the result depends on the accuracy of the estimates of processing times, bus occupancy times of various tasks, and the workload profile.

The simulation model for a module is shown in Figure 3. The bus occupancy time of a task can be estimated from the number of bits transmitted and the bus bandwidth. All the queues are of a multi-level queueing system, with entry level determined by the priority of the messages. The model also has facilities to gradually increase the message priority as a function of the amount of time since it entered the system. The simulation is event-driven. That is, it advances the clock to the next event which is to occur, rather than stepping

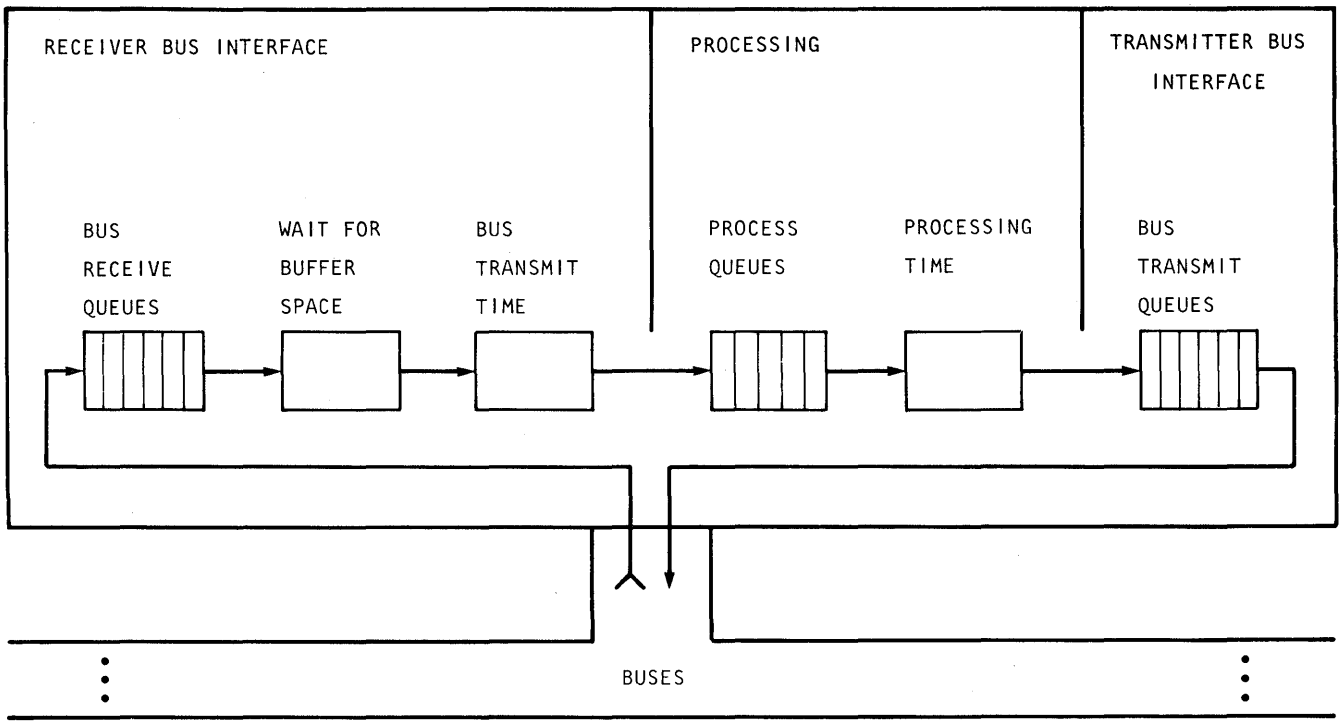

Figure 3—Simulation model for a module

through every clock interval and checking for events. Thus the time required for a simulation run depends on the number of events which occur during the simulated interval rather than the time span of the simulated interval. The internal unit of time is expressed in terms of bus clock time. Inputs and outputs are represented in milliseconds.

A module can receive data simultaneously from several busses, but can send data only on its designated send bus. The number of received busses, the number of modules in the system, as well as the buffer space can be easily varied in the simulation.

Input parameters for the simulation are message arrival rate, which corresponds to the satellite communications channel bandwidth, effective processor execution time, which reflects both instruction execution time and the power of the instruction set, bus bandwidth, assignment of processing tasks to the modules, and number of processing modules.

The performance measures used in the simulation are utilization of the processors, busses, and peripheral devices, delays at each module such as processing queues, sending queues to the bus, receiving queues from busses, and message response time.

The simulation program creates a message control block for each network message to be handled by the system (send or receive). Each block is composed of sub-blocks which specify the details of processor and bus usage and contain time stamps applied at the times of queue entry and departure. After the processing of the message has been completed, the time stamps in the message control block are used to calculate the delay statistics.

The simulation is written in PL/C, Cornell University's compile-and-go version of PL/1. Because subroutine calls have a high executed time overhead, no subroutines are used. Integer variables were used whenever possible in order to save execution time. The processing time required on the IBM 360/91 for a typical simulation run ranges from one to two minutes.

EXAMPLE FOR SIMULATION

The application selected for simulations was a communications processor (at a ground station) in a military satellite-based communications network. This is mainly because reasonable estimates of the computational requirements, workload profile, as well as program structure (program size, execution sequence and times) were available from a previous study that was implemented with a military computer (AN/UYK-20).[1,2]

The communications network shares a single half-duplex channel of a satellite in stationary earth orbit. Reservation time division multiplexing (statistical multiplexing)[3,4] is used for multiplexing the communications from all the stations. There are two types of stations: master station and slave station. The master station not only handles all the slave station tasks but also it handles time slot reservation for all the slave stations. In our investigation we shall study the performance of the communication processor in a master station. The basic time unit (time slot) is the time required to transmit a 4,164 bit block. These time slots are grouped into a frame which consists of 15 to 32 consecutive time

slots. The first time slot of each frame is for reservation of the remaining time slots in that frame. The master station makes the time slot assignments on the basis of requests received from all the other stations (slave stations). These requests, which indicate the priority and number of messages a slave station is waiting to transmit, are sent during designated assignment request time slots. An assignment permits a designated station to broadcast a message block to all other stations. The stations addressed by the header (part of the 4,164 bits) need to fully process the message. For our application, we always keep the channel busy. Therefore, dummy messages are transmitted (assigned by the master station) when there are not enough real messages to occupy all the available time slots. The amount of work involved in handling these dummy messages by the communication processor at the received station is similar to the handling of those messages that are forwarded to the other stations. Each block of data consists of a 16 bit cyclic redundancy check code. Error detection and retransmission are used for error control.

Assumptions used in the simulation example

In the simulation example, we assume the round trip propagation delay between the radio (ground station) to the satellite is 260 msec. All the peripheral devices are assumed to have constant service times: Disk=90 msec; Printer=200 msec (at 6000 lines/min.); Magnetic tape drive=150 msec. Processor execution time ratio is relative to a typical military minicomputer (AN/UYK-20) with instruction execution time of 1.5-2.3 msec. Execution time includes the effects of both instruction execution cycle time and the power of the instruction set. Each module has 16K bytes of buffer space available for bus traffic and can receive data from three busses (i.e., three other modules) simultaneously. A message fits exactly into one message block (4,160 bits including message header and cyclic redundancy check bits). Processing of a send message has a higher priority than the processing of a received message. This quarantees that send processing suffers minimum of delay, which assures that messages to be sent will be ready for transmission in their assigned time slots (as required by the network protocol) with a reasonable processing scheduling scheme. The bus bandwidth is assumed to be 50 kHz/bus.

Task partition and assignment for the example

The two main tasks of the communications processor at the master station are to perform send and receive message blocks. Their task flow sequence is shown in Figures 4 and 5. Additional tasks such as generation of network and station status reports for the operator, creation of checkpoint tapes for system recovery in case of failures, etc. occur relatively infrequently. For purposes of simplicity they are not included in the simulation.

The basic principle of a good assignment of processing tasks to processing modules is to balance the processing load and minimize the amount of inter-module communica-

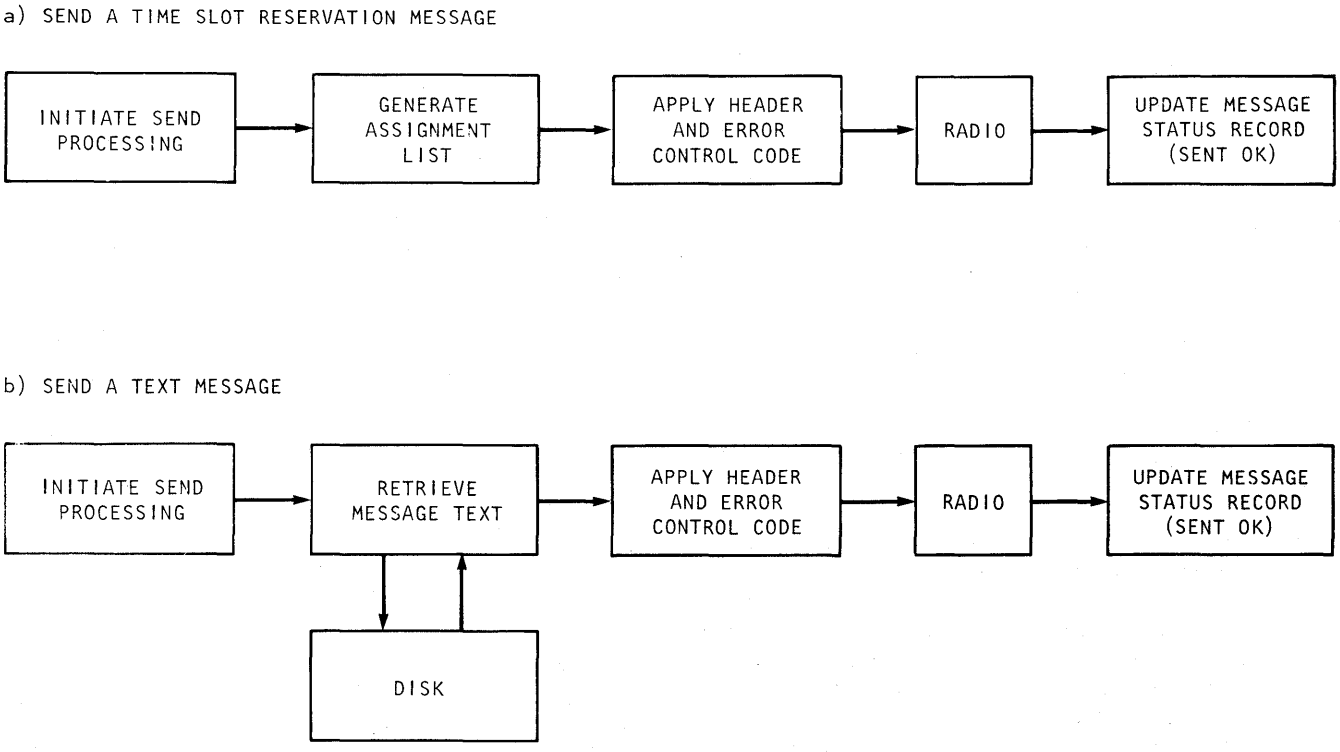

Figure 4—Sequence of processing tasks for handling a send message

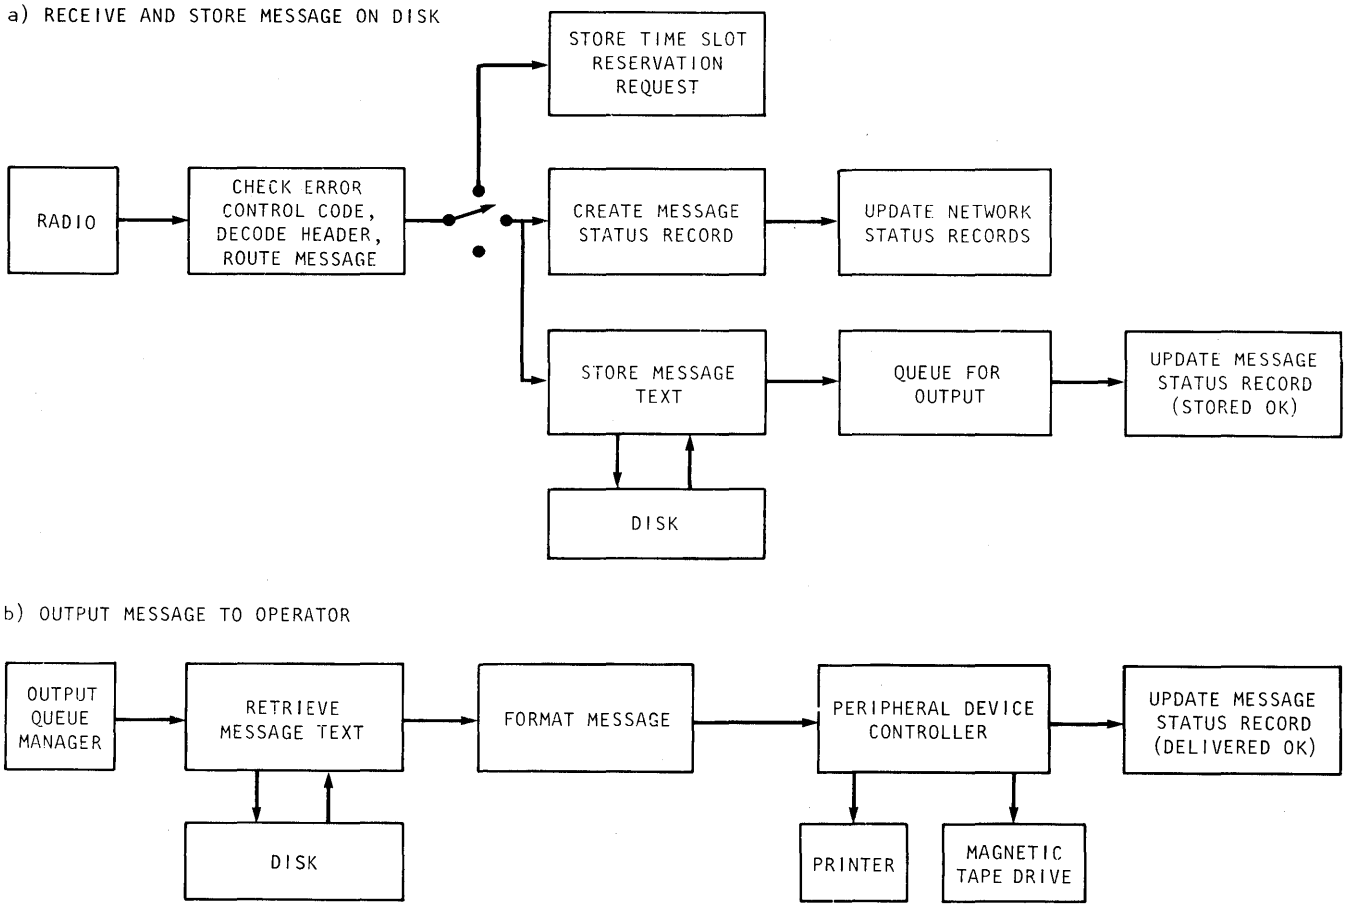

Figure 5—Sequence of processing tasks for handling a receive message

tion. Assigning all the tasks to one module requires the least amount of inter-module communication but may result in long queueing delays due to processor overload. On the other hand, assigning each task to a module yields short queueing delay for the processors but requires a large amount of time for sending intermediate results between modules. Because of the inter-module communication, processing requirements are rather complicated and may vary from one application to another. We shall use the simulation model to compare the performance of two task assignments.

The first assignment consists of assigning the tasks to a five-processor module system as shown in Figure 6. The task for sending a message on the communication network is largely independent of the task for receiving a message from the network. To minimize inter-module communication between the send task and the receive task, they are assigned to separate processor modules. We assigned one module for status record updating and time slot reservations, one module to serve as peripheral device controllers, and one module for file management and system recovery.

The second assignment consists of assigning the tasks to a three-processor module system as shown in Figure 7. Both sending and receiving processing require access to status records, but usually there are more receive messages than send messages. In order to minimize the amount of inter-module communication, status record updating and time slot reservation operations are combined with the receive processor. System recovery and report generations are combined with the send processor. The file manager and disk controller are combined, along with the peripheral device controllers, into a single module.

Table I displays the performance comparison of the three-processor and five-processor module systems. We notice

TABLE I.—Performance Comparison between the Three-Processor Module and the Five-Processor Module Systems

Number of processor modules	5	3
Virtual time to process a received message (msec)	1601	1510
Average queueing delay to receive a message (msec)	14	13
Total # of bits transmitted on buses to process one received message	13504	8736

The system is operated at the following condition: 59 percent of the received messages are addressed to the master station and require complete processing; Network data rate=9600 bits/sec.; Bus bandwidth=50kHz; processor speed equal to a minicomputer.

that the average delay in processing received messages is almost the same in both of these configurations. Due to less inter-module communication in the three-processor module system, less bus traffic is required to transmit the intermediate results and less processing time is required to prepare and interpret these inter-module communications. As a result, the three-processor module system yields better performance than that of the five-processor module system.

It is interesting to note that due to the excessive inter-module communication and the overhead in handling these

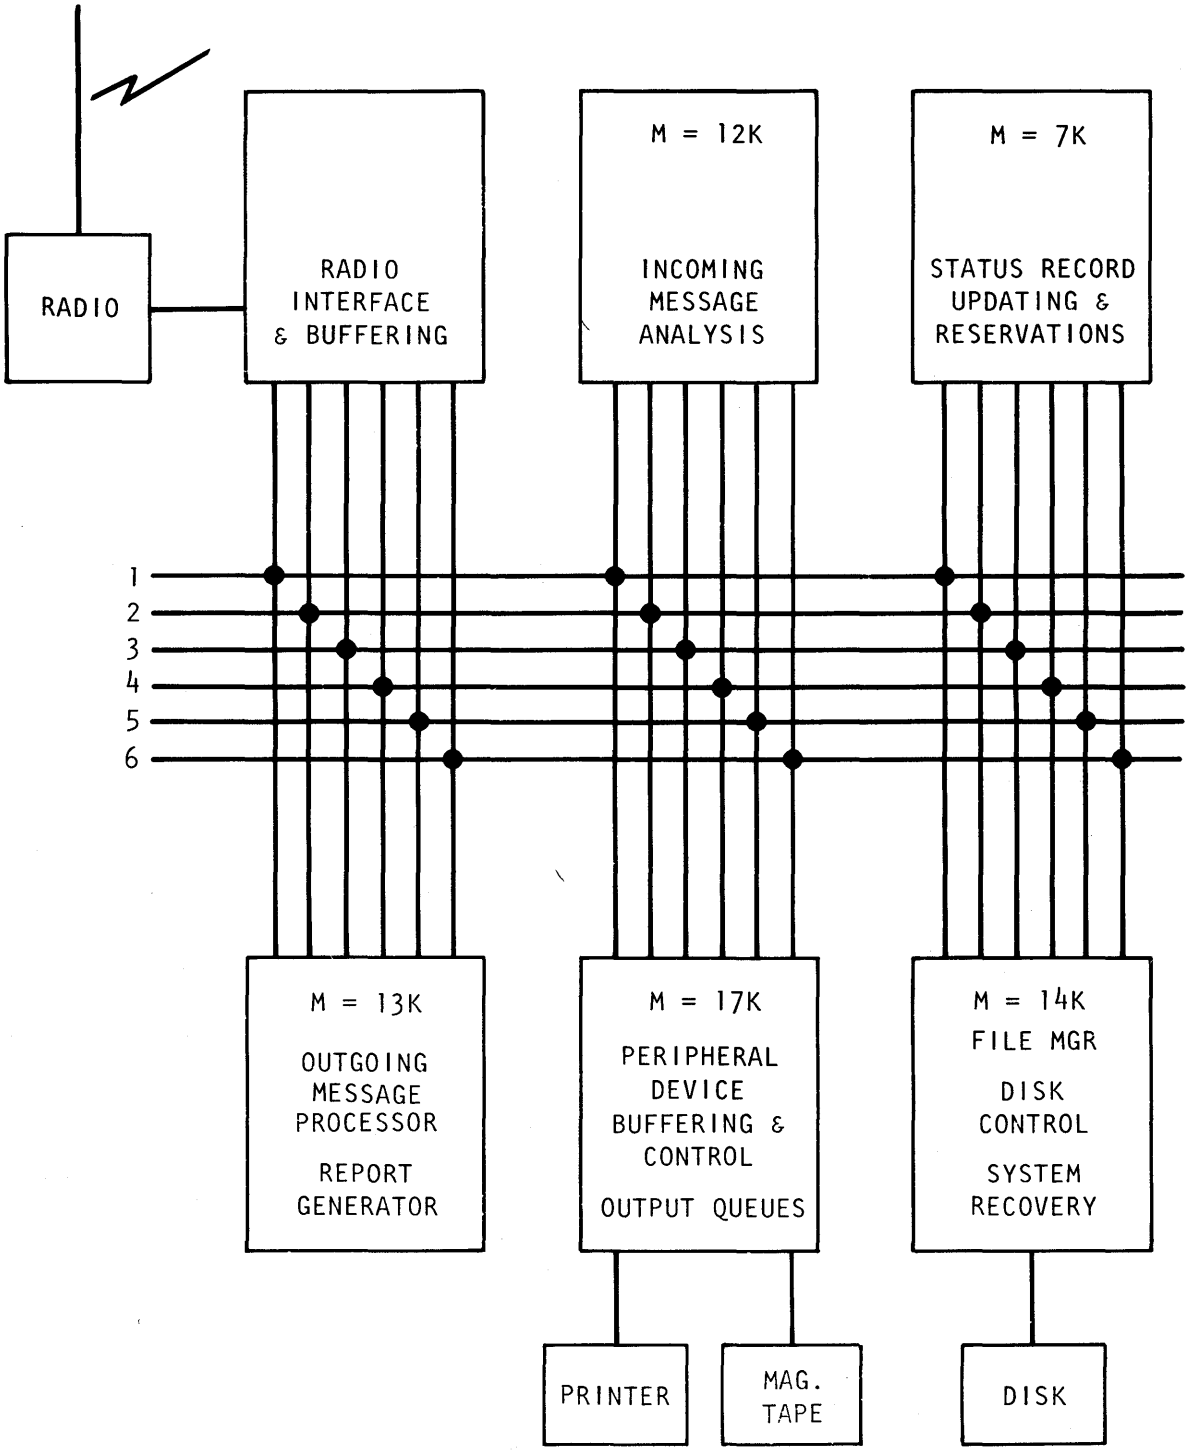

Figure 6—A five-processor module organization for the example.
M=Memory requirements for program storage (in bytes)

TABLE II.—Processor and Bus Utilization Comparison between the Three-Processor Module and the Five-Processor Module System

Utilization	Processor		Bus	
Number of processors	5	3	5	3
	Percentage		*Percentage*	
Receive processor	5	5	9	9
Status tables	2		1	
Send processor (SP)	4	4	7	7
Output queues and printer, tape controller	1	5	1	6
File manager and disk controller	5		15	

inter-module communications in the five-processor module configuration, the throughput as well as response time of the three-processor module are better than that of the five-processor module system. Therefore, in the planning of a distributed computer system, using more processors does not necessarily always yield better throughput. In fact, one of the important problems in the planning of a distributed processing system is how to partition the tasks and optimally assign them to the processor modules such that they yield minimum interprocess communications and high system throughput, and yet satisfy the cost and response time requirements.

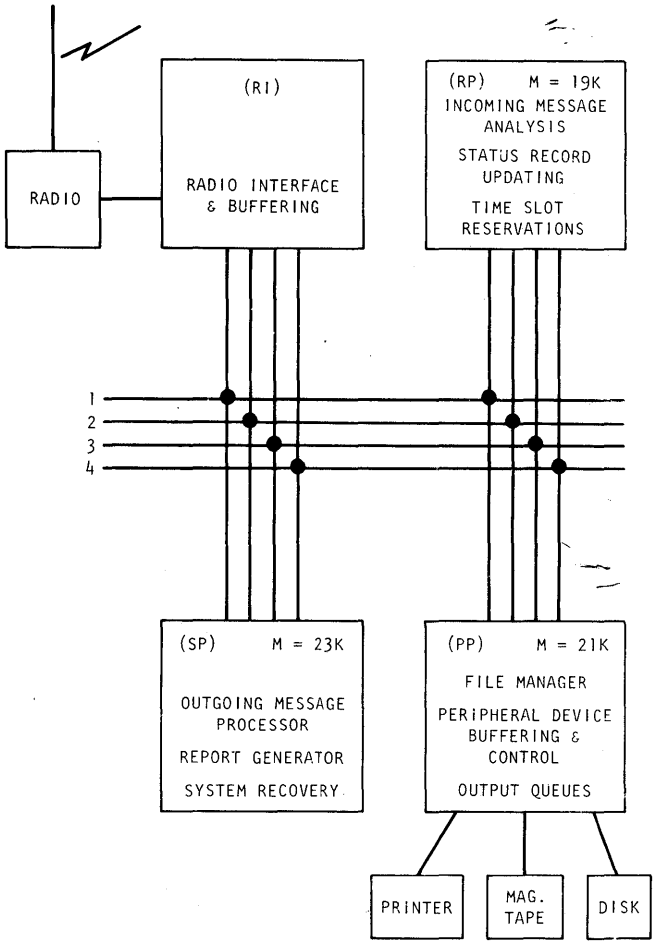

Figure 7—A three-processor module organization for the example. SP=Send processor, RP=Receive processor, RI=Radio interface. M=Memory requirement for program storage (in bytes)

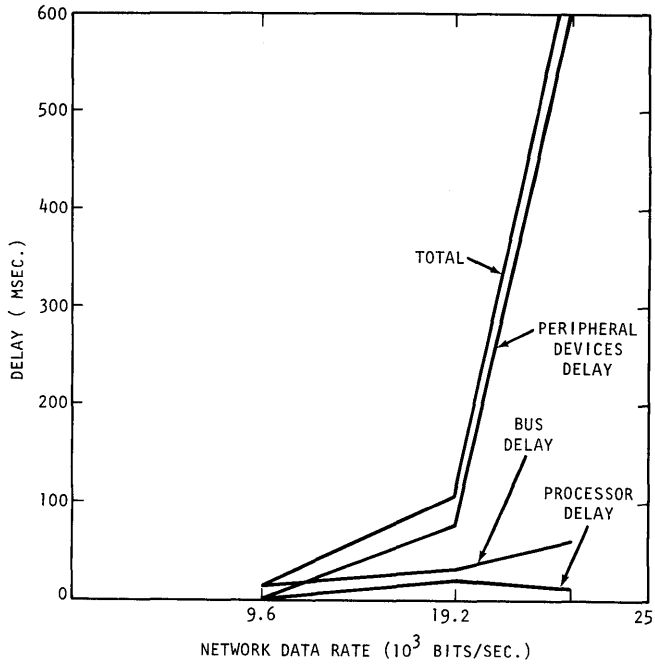

Figure 8—Average delay to process a receive message. Note that the sum of the delay components is greater than the total delay because some delays occur at the same time. Relative processor execution time=1. Bus clock period—20 msec (50 kHz/bus)

Discussion of results

Total delay is defined as the time difference for processing a message with and without any queueing delay. Total delay is not necessarily equal to the sum of all the queueing delays encountered in the processing of a message, since some processing (and delays) occur in parallel execution branches. Delays are shown only for the processing of received messages, since the processing of send messages has a higher delay allowance than that of the receive messages. Since the message arrival and departure process are deterministic and there is a long radio propagation delay, there is no interference between network cycles.* And since the processing of received messages is completed before the processing of send messages begins, we only need to simulate one complete network cycle. We studied the simulation variations of the network input data rate and relative processor execution time with the three-processor module configuration. The system performance (with processor execution time equiv-

* A network cycle consists of 32 time slots: 1 for time slot assignments by master station, 9 slots for sending messages, and 22 slots for receiving messages.

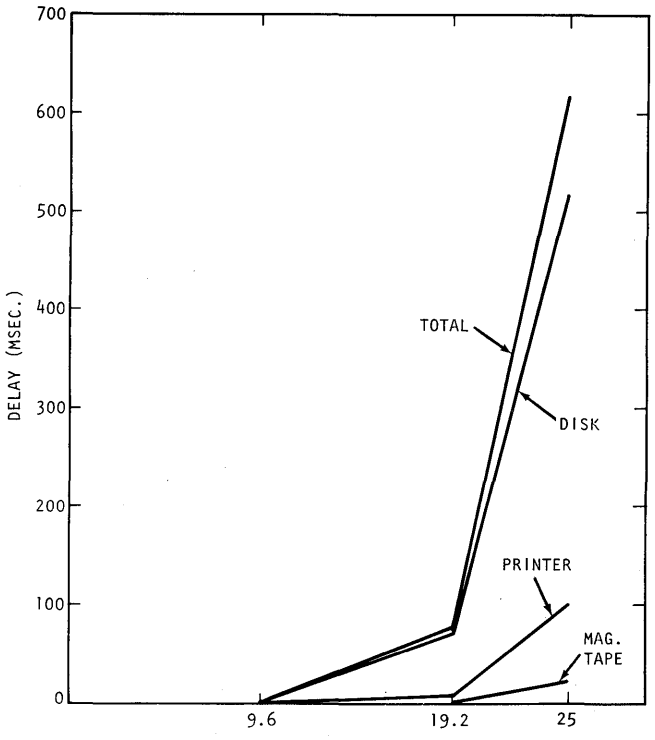

Figure 9—Peripheral device delay for processing a receive message vs. network data rate (10^3 bits/sec). Note: mag. tape drive delay is not included in total because it always occurs at the same time but is shorter than the printer delay. Relative processor execution time=1. Bus clock period=20 msec (50 kHz/bus)

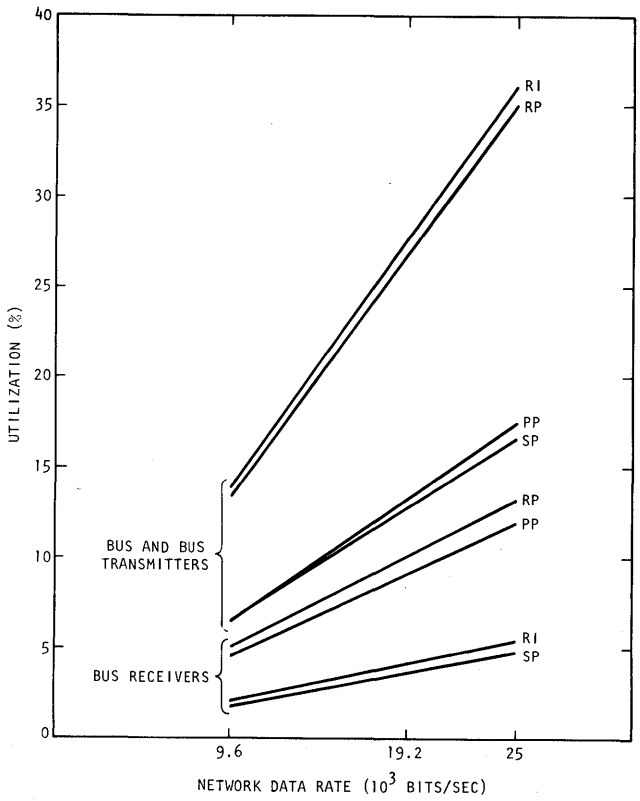

Figure 10—Utilization of busses and bus receivers vs. network input data rate. The bus transmitter utilization is the same as the bus utilization. Bus clock period=20 msec (50 kHz/bus)

alent to a minicomputer) for different network input data rate are portrayed in Figures 8, 9 and 10. From Figure 8 we notice that the largest component of total delay is due to queueing at the peripheral devices, to which the disk contributes the largest amount (Figure 9). The disk delay is large because it has a high utilization. From Figure 10 we notice that the bus utilization is only 5 percent at input rate equal to 9,600 bit/sec. Thus the bus delays (Figure 8) are small compared to an average bus occupancy time* of 44 msec. From Figure 10 we noticed that the bus receiver utilization is lower than the bus utilization because the bus receiver utilization is computed on the basis of each module being able to receive from up to 3 busses simultaneously. Since no module is addressed by more than three other modules, there is no queueing delay for bus receivers. Due to the low processor utilization (Figure 11), the processor delay is very small compared to the longest uninterrupted processing time of 38 msec for the SP module and 13 msec for the PP module. Next we studied the performance as a function of relative processor execution time. A network data rate of 19,200 bits/sec was used. The simulation results are portrayed in Figures 12, 13 and 14.

For the relative processor execution time exceeding 5 (Intel 8080 has a relative processor execution time of approximately 4 in this application), the total delay for processing a receive message exceeded the maximum allowable time which is 218 msec for 19,200 bit/sec and 436 msec for 9,600 bits/sec. From Figure 12 we noticed that for the system with large relative processor execution times, the delay of a received message is dominated by the processor delay. The increase in link queueing delay with increasing processor execution times is due to the increases in the effective peripheral device service resulting from the reduction in processor speed. The decrease in disk queueing delay at high processor execution times is due to the stretchout of

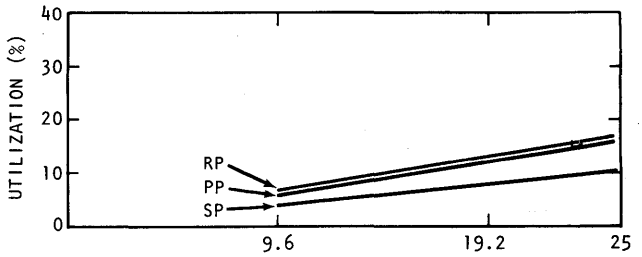

Figure 11—Processor utilization (for both send and receive messages) vs. network data rate. Relative processor execution time=1.

* Based on approximately equal numbers of large blocks of 4,192 bits each (about 85 msec) and small blocks of 192 bits each (about 4 msec) are sent on the busses during the processing of messages.

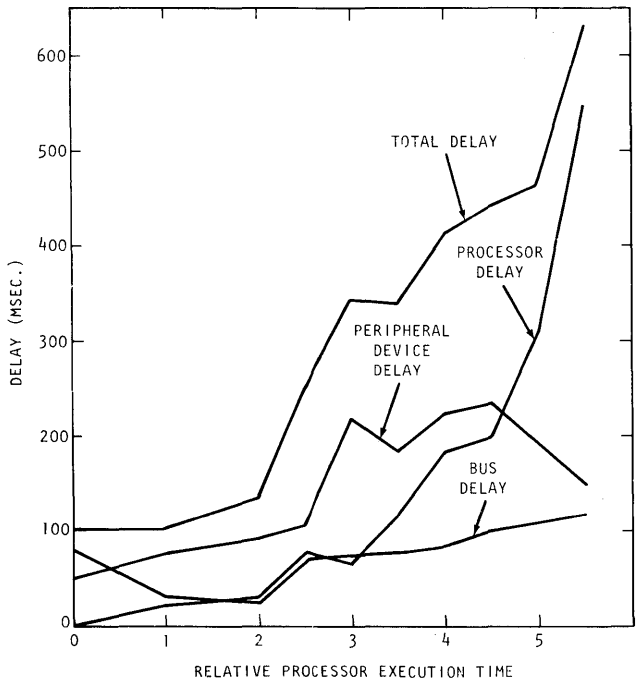

Figure 12—Average delay to process a receive message vs. relative processor execution time. Note that the sum of components delay is greater than total delay because some delays to a message occur at the same time. Network data rate=19,200 bits/sec. Bus clock period=20 msec (50 kHz/bus). The relative processor execution time for a minicomputer=1, Intel 8080 type processor=4.

access request arrivals resulting from the increased processor queueing delay. The variation in bus delay to received messages is the result of specific timing relationships between the processing of send and receive messages that occur at certain processor rates, which is due to the variations of starting time for processing of send messages. The queueing delay at the Receive Processor for processing a receive message is approximately equal to that of a PP module (i.e., balanced delay). The delay from the PP module is due to the larger number of processing tasks, each of shorter duration that for the SP module. Processor utilization (Figure 14) is the overall utilization average for the whole network cycle. When the processor execution time is large, the demand for processing may be higher than 100 percent during part of the time. This yields a very large queueing delay.

With the three-processor module configuration with Intel 8080 type microprocessors, the system performance is adequate for handling of the example network with a data input rate of 9,600 bits/sec. Since three-processor modules are just adequate, it is very unlikely that a system with a two-processor module configuration could do the job satisfactorily. The response time for the two-processor module is likely to be much larger because the processing tasks cannot be easily divided into two equal parts. Consequently, additional delays will be caused by increases in contention between processors and by unbalanced processor loading.

Simulation results reveal that the serial broadcasting bus structure is viable. The bus delays for receive messages are lower than the processor delays for a relative processor execution time greater than 3 and are comparable to the processor delays for a relative execution time in the ranges between 1 to 3 (Figure 12). Bus delay can be reduced con-

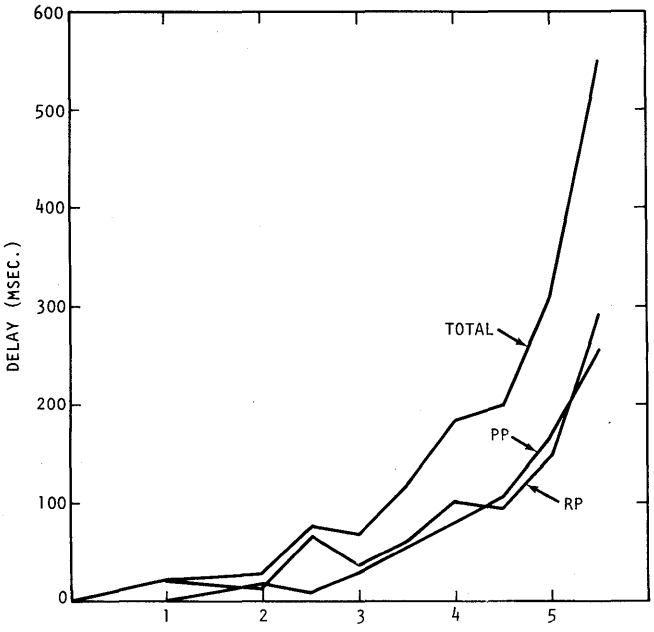

Figure 13—Average delay at the processor module for processing a receive message vs. relative processor execution time. Network data rate=19,200 bits/sec. Bus clock period=20 msec (50 kHz/bus)

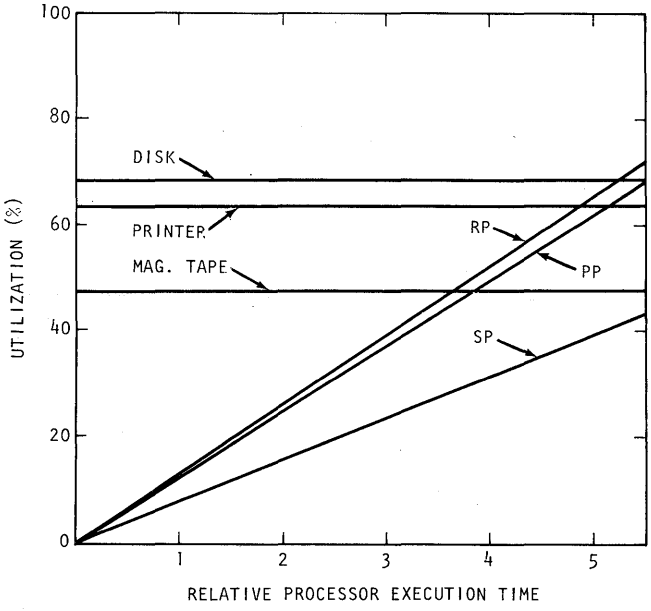

Figure 14—Processor and peripheral devices utilization (includes processing of both send and receive messages) vs. relative processor execution time. Network data rate—19,200 bits/sec.

siderably with a higher bandwidth bus. A much higher bus bandwidth interface with 2.5 MHz (50 times higher than the bus bandwidth used in the simulation) is available commercially.

We also noticed that increasing the network data rate causes a higher bus and processor utilization, while increasing relative processor execution times increases only the processor utilization.

CONCLUSIONS

Simulation study revealed that the proposed distributed processing architecture with three processor modules provides adequate processing capability for handling the Naval data communication network processing tasks. Further, the serial broadcasting bus structure provides sufficient bus bandwidth for the application.

We also found that task partition and task assignment to various processor modules has great influence on interprocess or intermodule communications and thus affect the system throughput. A good rule for optimal task partition and assignment is to balance the workload among the various modules and yet keep them as independent as possible so as to reduce inter-module communication. Excess intermodule communication not only requires excess bus bandwidth but also requires extra processing time for handling these inter-module communications. This degrades system throughput.

The low bus and processor utilization for the system indicates that our proposed distributed processing architecture would be useful for other applications as well. Distributed processing architecture not only is more flexible for system reconfiguration and system expansion, but it also provides greater fault tolerant capability. Because of these capabilities and its low implementation cost, distributed processing architecture should find its place in many future applications.

ACKNOWLEDGMENT

The authors wish to thank Mr. Howard Wong and Ms Dana Small of Naval Oceanic System Center, San Diego, and Joel Trimble of the Office of Naval Research, for their encouragement and support in carrying out this joint project between NOSC and UCLA.

INTRODUCTION

During the next decade, in the wave of microelectronics and digital revolution, we can expect to witness fast growth in the number of communication-based distributed data processing systems. A communication-based distributed data processing system is a decentralized data processing system in which data processing facilities or computer resources are geographically distributed and communicate with each other through a data/computer communications network. Figure 1 typifies such an environment. The most common data/computer communication network architectures used in the distributed environment are those illustrated in Figures 2, 3 and 4. These are the tree-shaped hierarchical, the packet and the ring-shaped architectures, respectively. These architectures are not new and heuristic algorithms have been widely available for their optimization. However, the emphasis on the distributed data processing systems shifts the application environment and objectives of the optimization problem and hence lessens the applicability of these earlier algorithms. This paper presents a set of integrated algorithms more appropriate for network optimization in this new environment. Some of the algorithms are newly developed; some are modifications of the earlier ones.

Figure 2 depicts the tree-shaped, hierarchical architecture, in which the local access network defined as the circuits interconnecting the terminals and/or terminal control units, are connected to, and controlled by, the concentrating devices. The concentrating devices are in turn connected to, and controlled by, the host computer. The concentrating functions may be performed as part of a remote processor's responsibility. The circuits shown interconnecting the concentrating devices and the host computers are called the backbone network. Both the local access and the backbone networks may be point-to-point or tree-shaped connections. Occasionally, ring-shaped terminal connections may also occur.

The mesh-shaped packet switching architecture is illustrated in Figure 3. In this architecture the local access network comprises both the terminal devices and the host computers connected in either a point-to-point or multipoint configuration. The local access networks are connected to the packet switches. The backbone network for this architecture is defined as the interconnecting circuits between the packet switches.

Figure 4 presents the architecture associated with a ring-shaped, ring-switching design. The local access network in this case is the same as that defined earlier for the packet network architecture. Similarly, the backbone network is defined by the circuits interconnecting the switches, in this case specified as ring switches. For completeness, it should be noted at this point that terminals controlled by a Terminal Control Unit (TCU) usually form, on a second order local level, a star or ring network as shown in Figure 5.

As evident from the figures, interfacing the local access and backbone networks are the concentrating devices, the packet switches, and the ring switches. In this paper, these devices will be generically referred to as the Network Access Facilities, or NAF's. (For more detailed descriptions of the data network architectures, see Reference 1.)

The network optimization problem of a distributed system, therefore, consists of the determination of the number and locations for NAF's; the configuration of the local access networks, including point-to-point, tree-shaped multipoint and ring-shaped multipoint; and the configuration of the backbone network, including point-to-point, tree-shaped multipoint, ring-shaped multipoint, and mesh-shaped packet switching architectures. Of course, the optimization of each of these network problems is not new, and good heuristic algorithms have been widely used in many data/computer communication networks. However, new emphasis on the distributed data processing systems has lessened the applicability of these algorithms. The following sections of this paper discuss the algorithms and implementation approaches that are felt to be more suitable to the new distributed processing network environment.

For local access networks with geographically dispersed terminal devices, "effective" algorithms for optimization have existed for over a decade.[2,3] The term "effective" implies nearness to the theoretic optimum. With the number

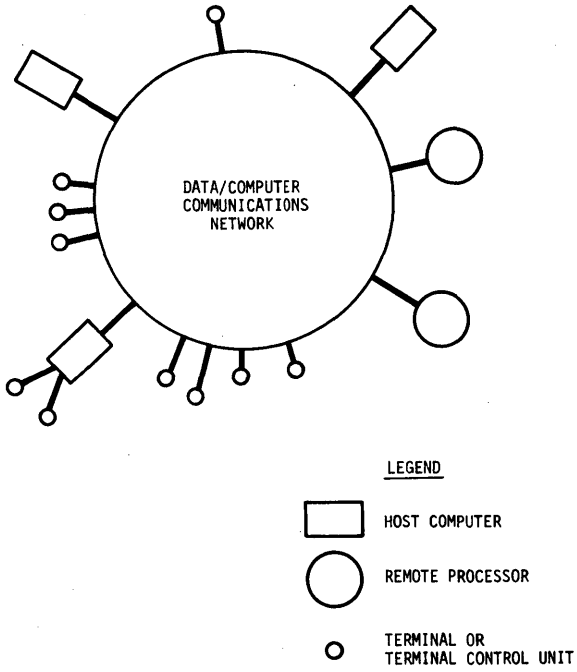

Figure 1—Communication based distributed data processing system

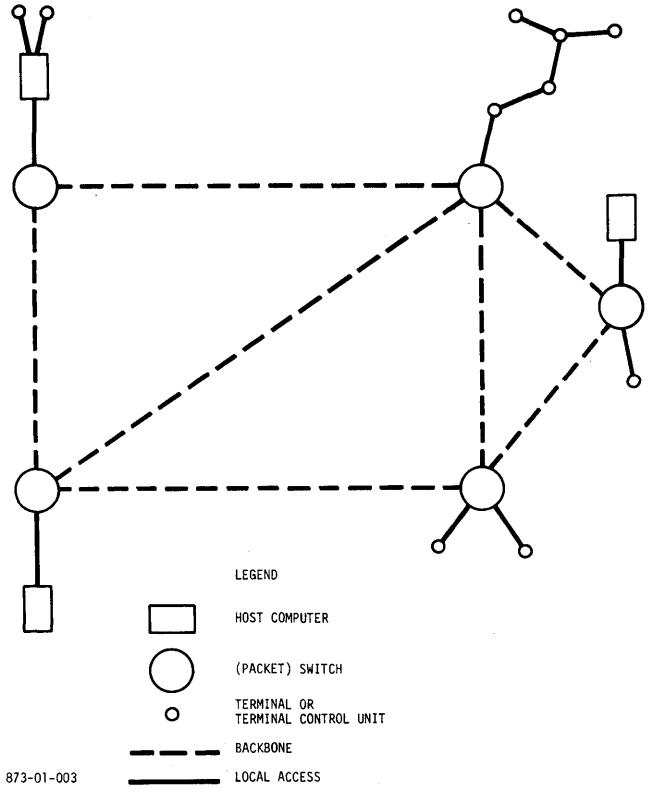

Figure 3—A packet switching architecture

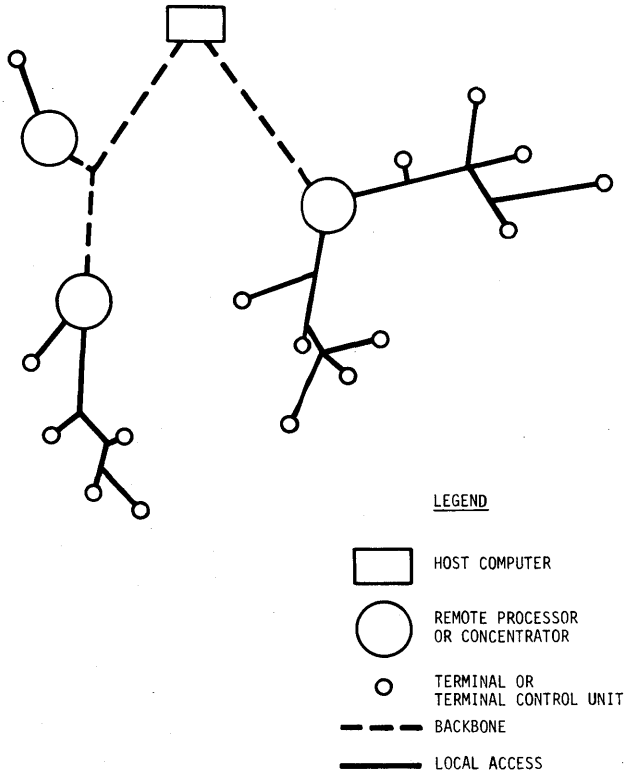

Figure 2—Tree-shaped hierarchically controlled data communication network architecture

of terminals on the order of hundreds or even thousands, the efficiency in terms of computer memory and running time requirements for executing the algorithms becomes important. Otherwise, however effective, implementation of the algorithms may become too expensive. The second section describes a currently most effective algorithm for the optimization of tree-shaped multipoint networks and shows how it can be modified to improve its implementation efficiency.

The concept of ring-switching has been proved workable for quite a few years,[4] and there are ring-shaped local access networks in operation; e.g., IBM 3600. However, with few exceptions, devices on a same ring are generally located in the same proximity. Therefore, topological optimization has never been a concern and there has not been direct published work in this area. Nevertheless, it is expected in the distributed data processing environment that in some applications, the ring network may be more desirable than the tree network even for geographically dispersed devices. The third section describes algorithms for designing ring-shaped networks, based on the modifications of graph-theoretic results.[5,6]

Dominating the backbone network optimization problem is that of the packet switching network. The bulk of the research in the optimization of packet switching networks has been supported by the Advanced Research Project Agency from 1969 through 1976. Naturally, the algorithm that has been widely used and has been verified by real

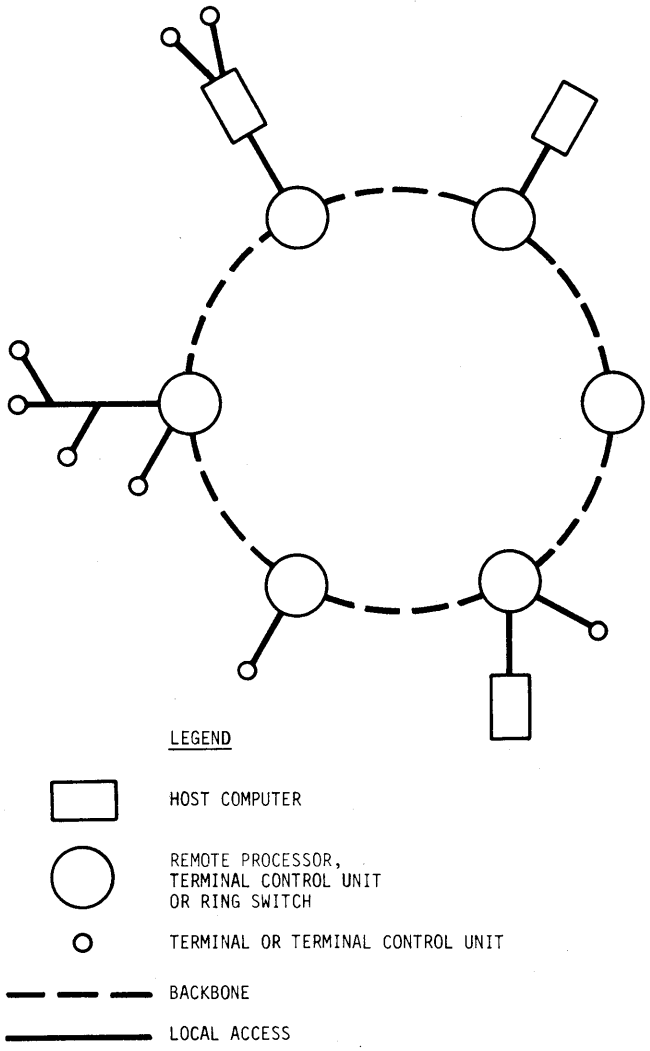

Figure 4—Ring architecture

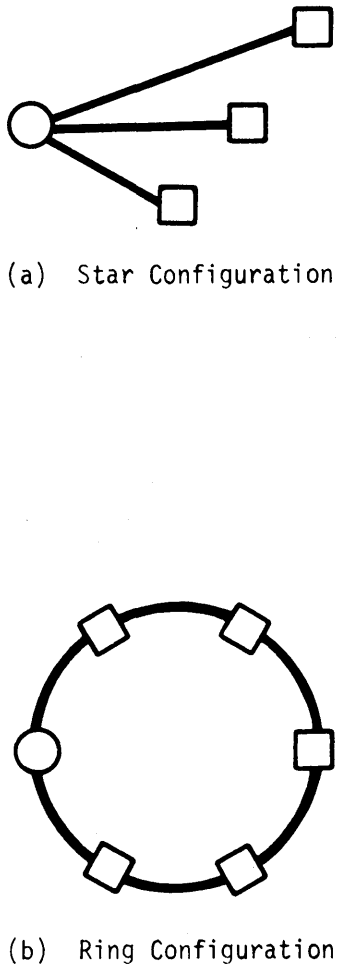
networks is the one sponsored by the ARPA, and just as naturally, these algorithms have been biased by the ARPANET environment during that period. The fourth section describes these biases in the algorithm, and specifies a modified algorithm that eliminates these biases and improves both their effectiveness and efficiency.[7]

In the past, the number and locations of the NAF's have not been an important consideration for optimization. They are more constrained by users' organizational structure than costs. As a consequence, algorithms developed to date are more of an academic interest than for real network optimization. Hence, definite room exists for the improvement in these algorithms' effectiveness and related efficiency. In particular, even though the costs of the local access and backbone networks depend on the number and locations of the NAF's, these algorithms have not sufficiently considered these configurations in making decisions on the number and locations of the NAF's. The fifth section develops an effective and efficient algorithm for the determination of the number and locations of the NAF's.



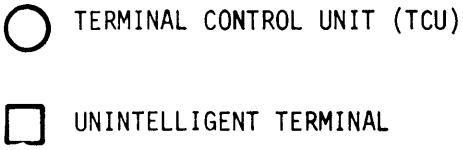


Figure 5—TCU-terminal configurations

Using conventional approaches to design a distributed network as shown in Figures 2, 3, or 4, the number and locations of the NAF's, the configuration of the local access network, and the configuration of the backbone network are each treated as a separate optimization problem. The optimal network cannot be realized by simply overlaying three optimized subnetworks. To avoid such a suboptimum design, it is necessary to integrate consideration of the subnetworks in the final and overall optimization process. The fifth section, in conjunction with the determination of the number and locations of NAF's, introduces an integrated approach that combines the three optimization problems

into one. This integrated approach, together with the algorithms given in earlier sections, has been implemented as a computer program. It is capable of designing in one single execution, a distributed network of the form shown in Figures 2, 3, or 4. In addition to the integration of three optimization problems into one process, the program which has been developed also integrates into the same process the different network shapes (tree, ring, mesh) and variations associated with differences in line circuit tariffs.

LOCAL ACCESS NETWORK OPTIMIZATION—TREE-SHAPED MULTIPOINT CONFIGURATION

The basic problem of tree shaped multi-point line design can be stated as: given a geographic distribution of terminals, locations of roots (network access facilities, host computers), line speeds or capacities and constraints (such as maximum number of terminals permitted per line, maximum traffic permitted per line as a function of the terminals on the line), design a least-cost network connecting the terminals to the roots.

Many, mainly heuristic, techniques have appeared in the literature for the optimization of tree-shaped networks in data communication systems.[2,3,8–11] The techniques, though differing, are all constrained minimum spanning tree algorithms. They design minimum cost tree-shaped networks satisfying the constraints. Each of these algorithms starts with the terminals in separate components and subsequently joins pairs of components. They differ only in the order in which they consider joining components. If no constraints are imposed, they all yield a least-cost tree-structured network. Since the grouping of a given set of terminals into one component (i.e., placing them on the same multidrop line) restricts subsequent merging with other components because of the constraints, these algorithms, in general, yield different solutions. For example, Prim's algorithm[9] chooses a terminal whose distance to any terminal already in the tree is minimal as a basis for joining components to the tree. Kruskal's algorithm[8] evaluates a least-cost line connecting a pair of components and joins the components by that line. (See Reference 3 for more details.)

Based on the above principle, Chou and Kershenbaum[3] have developed a unified algorithm which, with the proper choice of parameters built into the algorithm, allows one to emulate a specific algorithm and to take advantage of the precepts forwarded by many of the existing algorithms. The network designer, using the Chou-Kershenbaum algorithm, can take advantage of features offered by other algorithms or experiment with new algorithms by simply varying parameters. In addition, while most techniques allow only one root for all the tree networks during the execution of the algorithm and, in the case of multiple roots or NAF's, require a preprocessing step of clustering terminals for each of the roots or NAF's, the Chou-Kershenbaum algorithm allows multiple NAF sites to be considered during the execution of their algorithm. A modified version of the algorithm is given below.

CHOU-KERSHENBAUM'S UNIFIED ALGORITHM FOR TREE NETWORK OPTIMIZATION

STEP 0 INITIALIZATION

$A \triangleq \{1,2, \ldots, N_t\}$	(Set of all yet unconnected terminals, N_t=Number of terminals)
$B \triangleq \{N_t+1, \ldots, N_t+N_{NAF}\}$	(Set of all concentrators, N_{NAF}=Number of concentrators)
$C_i \triangleq \{i\} \forall\, i \epsilon A \cup B$	(Initially, each component C_i contains one node)
Define W_i	(Weighting function associated with C_i. e.g., min. connecting cost from C_i to any concentrator)
$t_{ij}=W_i-d_{ij},\ i \epsilon A,\ j \epsilon A \cup B$	(Cost trade-off function of connecting C_i and C_j, d_{ij}=cost of connecting i and j)
$N_L=0$	(Number of connected links=0)

STEP 1 DEFINE MAX COST TRADE-OFF FUNCTION

$t_{i^*j^*} \triangleq \text{Max } t_{ij}$	
$i \epsilon C_i \cap A$	(i must be a terminal)
$j \epsilon C_j$	(j may be either)
$C_i \neq C_j$	(i and j not in same set)

STEP 2 ADD LINKS

If $C_{i^*} \cup C_{j^*}$ does not violate constraints,

Add (i^*, j^*)	(Adding a link)
Let $C_{j^*} \leftarrow C_{i^*} \cup C_{j^*}$	(Merging two components)
$N_L \leftarrow N_L+1$	(Increment N_L)
Update W_i and t_{ij},	(W_i may vary with configurations)
Otherwise, let $t_{i^*j^*}=\infty$	((i^*, j^*) are not allowed)

STEP 3 CHECK NUMBER OF CONNECTED LINKS

If $N_L<N_t$, go to Step 1	(End of the algorithm if the number of links equals to the number of terminals)
Otherwise, stop.	

The algorithm does not restrict the definition of the terminal weight, W_i. However, Chou and Kershenbaum[3] suggests the following definition:

$$W_i = a(b \times d_{i0} + (1-b) \times d_{i2})$$

Where,

d_{i0}=Cost of connecting terminal i to the closest NAF
d_{i2}=Cost of connecting i to the second nearest neighbor
a,b are parameters of the algorithm such that $a>0$, $0 \leq b \leq 1$

The parameters, a and b, when varied allow the Chou-Kershenbaum algorithm to essentially perform operations similar to other algorithmic processes. For example, by setting $a=0$ Kruskal's algorithm is simulated; or by setting $a=b=1$ Esau-William's algorithm results.

Before, the publication of References 3 and 12 proved that most prior published heuristic algorithms achieve near-theoretic-optimum results, particularly so of the Esau-William algorithm.[2] Cain[13] then showed that Chou-Kershenbaum algorithm always outperforms Esau-William algorithm. Thus, the effectiveness of the algorithm is well recognized. However, the efficiency of the algorithm, i.e., the computer memory size and running time required to execute the algorithm, has not been shown to be optimized.

In a large network with many terminals, large memory requirement and long execution times are primarily the result of determination and updating of t_{ij} values. Technically, determination of minimum t_{ij} implies the computation and storage of (t_{ij}) for all i and j. With 1,000 terminals, this means that almost 1,000,000 lines have to be considered for costing, at each stage of the algorithm. The memory and computation time requirements can be expressed as, for large N, $K_m N^{a_m}$ and $K_t N^{a_t}$, where K_m, a_m, K_t, a_t are constants, and N is the number of terminals. With a straightforward implementation, a_m is 2, a_t is 2 or 3.[14] The computation time could be horrendous and the algorithm becomes impractical to use even if N is in the low hundreds.

In order to improve the efficiency computation time, we must lower the value of a_m and a_t. It can be observed that by proper preprocessing, the value of K_t is increased with companion consequence of lowering the value of a_t. With the following two schemes, it can be shown that we are able to reduce a_m and a_t close to "1". For large practical networks, a_m and a_t can actually be reduced to a value less than "1." (The net result is that, memory storage size and computation time are increased by the schemes for small N due to the increase in K_t, K_m; but are reduced for large N.)

SCHEME A—ONLY TERMINALS WITHIN A NEIGHBORHOOD BEING CONSIDERED FOR CONNECTIONS

Without significant degradation in the resulting solution the evaluation can be reduced to consideration of only a few t_{ij}, based on the premise that in the optimum design network, it is very unlikely that a terminal will be connected directly to a very distant terminal.

Significant execution time savings can be obtained in determining the nearest neighbors if, instead of evaluating all inter-terminal costs, the area containing the terminals is partitioned into grids. Then, for each terminal, the nearest neighbors are found by considering only the terminals contained either within the same grid or in the next adjacent grid area.

The evaluation and updating of t_{ij} can be speeded up by maintaining the neighbors as a list-data structure with associated nearest neighbor trade-off parameters. This structured list is referred to as a "heap." Updating a "heap" structured array can be shown to be much more efficient than re-sorting an identically sized array. This is due in part because the least element is always located at the top of the heap. Maintaining the neighbors in a linked list has the advantage that after merging link (i) with its immediate neighbor link (j), by simply adjusting appropriate pointers, immediate neighbors of link (j) can be assigned as link (i)'s immediate neighbor. Note, once link (j) has been merged with link (i), it is no longer necessary to consider the link (i, j).

This scheme has been implemented with FORTRAN in an IBM 370/158. Figure 6 illustrates the relationship between computation time and the number of different terminal locations. As shown, the curve is practically linear. Superimposed on the Figure is the predicted curve that would have occurred had this scheme not been employed. Let K_t, for the curve representing the implementation with Scheme A be K_t', and for the curve representing the implementation without Scheme A, be K_t''. We *conservatively* assume $K_t'=50K_t''$, and, *optimistically* assume $a_t=2$ for the curve without Scheme A. (K_t' is found to be 0.75).

With Scheme A, the computation time can be expressed as $C_0+C_1 \log N+K_T' N$. For large N, the term $C_0+C_1 \log N$ is insignificant.

SCHEME B—PREPROCESSING TERMINALS IN A SAME LOCALITY

When terminals served by the same exchange are interconnected often no mileage charges are levied. Thus they can form components and be interconnected based only on traffic constraints. By only increasing the number of terminals in each locality without increasing the number of localities, the value of "N" in $K_t N^{a_t}$ is hardly increased and the computation time is only increased slightly. For systems with more than a couple of hundred terminals, it is likely that many locations have multiple terminals. The multiplicity of terminals per location increases as the total number of terminals increases. Thus for systems with several hundred terminals or more, the computation time goes up much less than linear as the terminal size goes up. Figure 7 illustrates this relationship.

LOCAL ACCESS NETWORK OPTIMIZATION—RING NETWORKS

At the present, only a very small percentage of data and computer communication networks are ring-shaped. For those that are, the nodes on the ring network are concen-

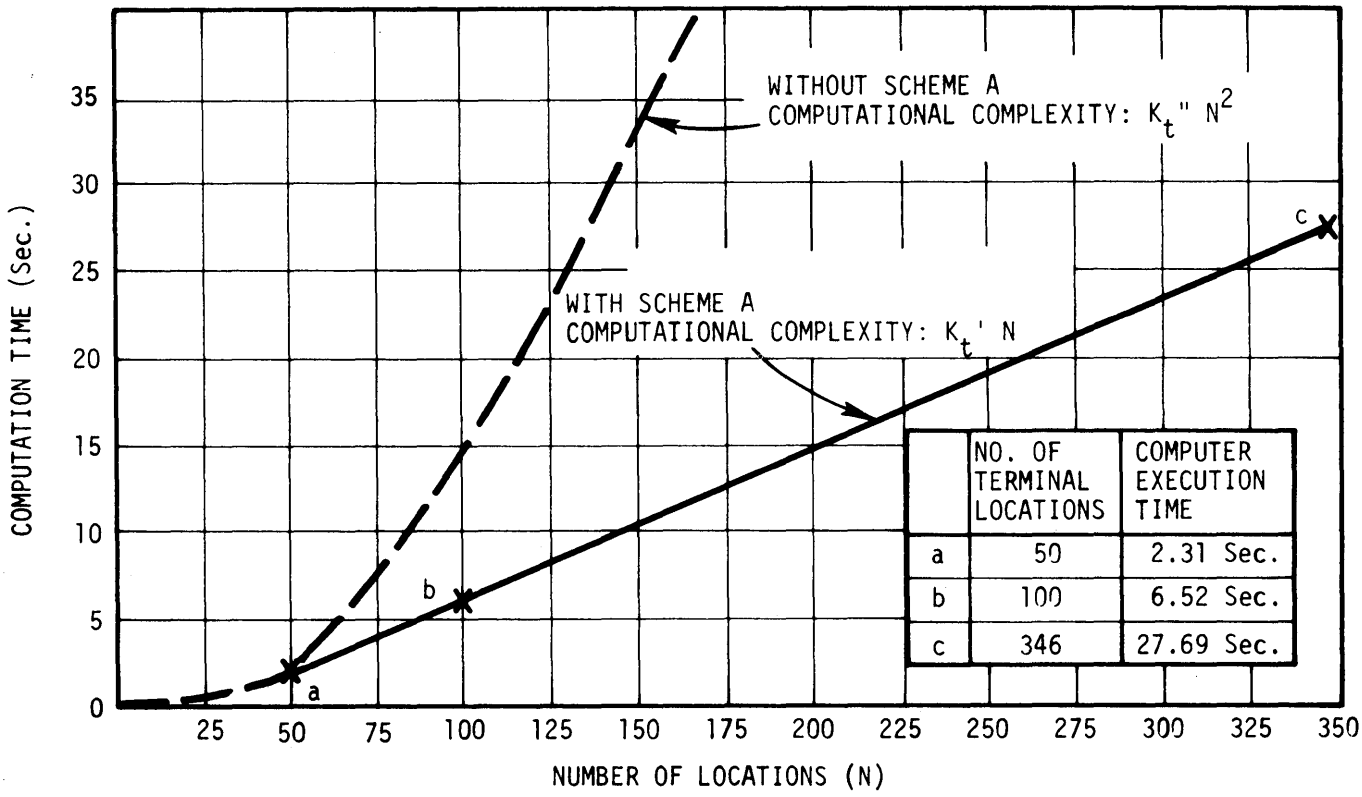

Figure 6—Computation complexity of Chou-Kershenbaum algorithm with Scheme A

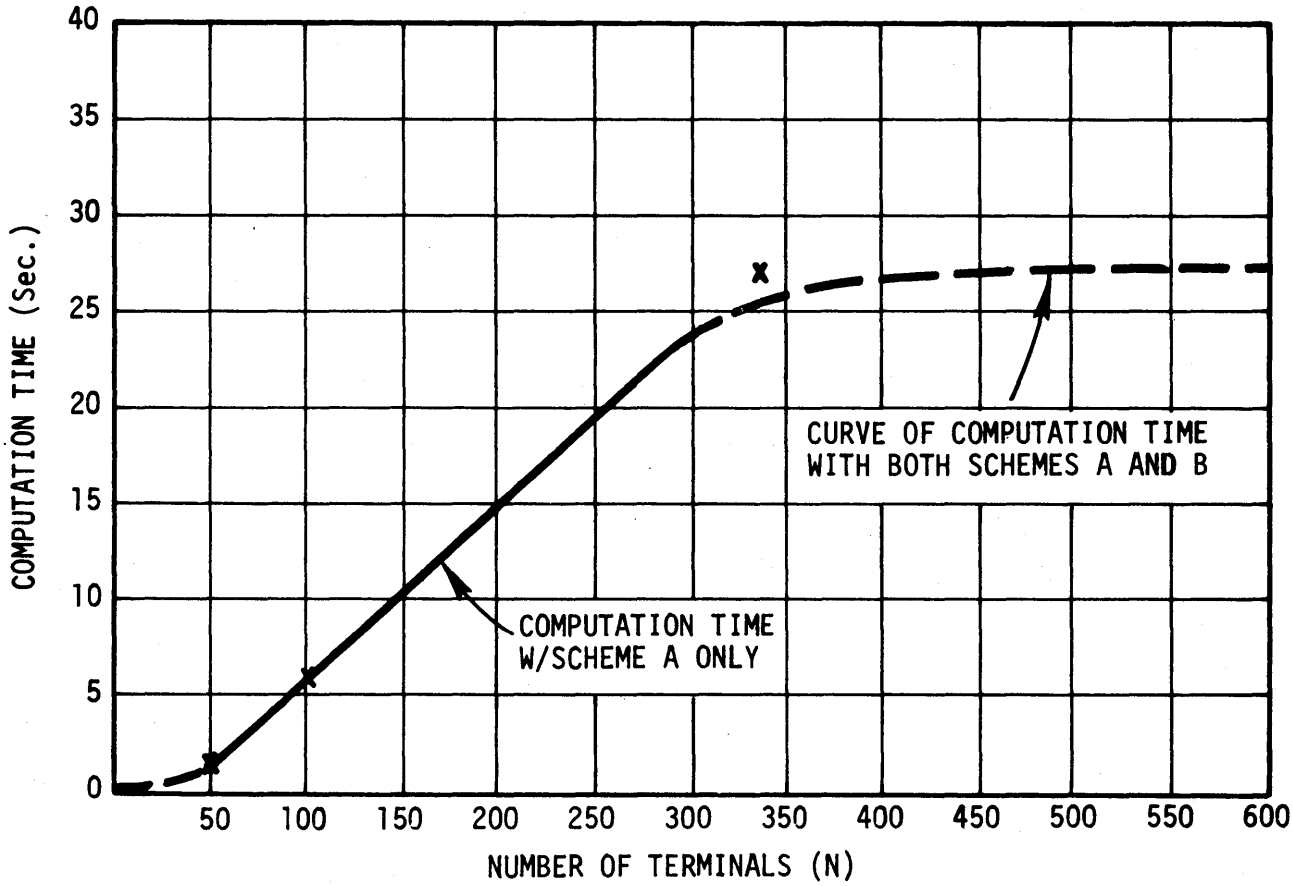

Figure 7—Computation complexity of Chou-Kershenbaum algorithm with Schemes A and B

trated within a building complex, or the number of nodes is small. Eyeball design of such networks has been adequate. And no algorithm has been published for the design of ring-shaped computer communication networks. To consider ring-shaped networks covering larger geographical areas, good algorithms are needed. Good algorithms do exist; however, they were not inspired by data and computer communication networks, but are directly applicable to the layout of ring-shaped data communication networks.

The topological layout problem for the ring-shaped data networks can be classified into two problems. One problem is to connect terminals or communication devices into a ring (loop) shaped network with minimum total transmission line cost, given the locations of the devices. This problem is equivalent to the traveling salesman problem of determining a minimum cost tour for a salesman visiting every city exactly once. It can be effectively solved by following steps: start from an arbitrary initial ring interconnecting the nodes; interchange one or more pairs of links while keeping the network in the ring-shape; if the exchange does not result in a net cost saving, restore the original network; otherwise, use the new network and repeat the interchange process until no appreciable improvement can be made.[5]

A second problem involves the layout of multiple ring-shaped networks. In this case, the number of terminal devices that can share a loop is often constrained by the terminal generated traffic and by the link capacities. This second problem is the constrained loop problem, and can be considered an extension of the traveling salesman problem. Instead of having one salesman visiting all the cities, there are now several salesmen visiting different cities. Each salesman must start from the central office. The number of salesmen and the number of cities to be visited by a salesman depends upon the sales load at the cities. The problem can be solved effectively by partitioning the terminals into separate rings and then optimizing each of these rings as a separate traveling salesman problem.

A very good algorithm for partitioning the terminals is the following one given by Clark and Wright.[6] Initially, consider every terminal as forming a separate ring connected to the central node (communication device or host computer) by two links. Merge the two rings which result in the largest cost saving without violating constraints. Each time two rings are merged, two of the four links connecting them to the central node are removed and one link connecting the two individual rings is added. This process continues until no more rings can be merged without violating the constraints. This Clark-Wright algorithm gives good results for the terminal layout design problem even without the link exchange reoptimization of the individual rings. It is also interesting to note that their algorithm is quite similar to the one for tree network design. The Clark-Wright algorithm is presented below in a form similar to tree network design algorithms.

MODIFIED CLARK-WRIGHT ALGORITHM FOR RING NETWORKS

STEP 0 INITIALIZATION

$A=\{0,1,2,3,\ldots,N_t\}$ (Set of all nodes, N_t=Number of terminals)

$C_i=\{i\}\quad \forall i\epsilon A$ (Initially, each component C_i contains one node)

$i_1=i_2=i\quad \forall i\epsilon A$ (i_1 and i_2 denote the two end points of the chain formed by C_i)

$d_{i_1}=d_{i_2}=d_i\quad \forall i\epsilon A$ (d_k=the cost connecting k to NAF)

$t_{ij}=\underset{k=1,2,\ h=1,2}{\text{MAX}}\{d_{i_k}+d_{j_h}-d_{i_k j_h}\}\forall i,j,\epsilon A$ (Det. the cost trade-off functions of merging C_i, C_j)

$N_L=0$ (Number of links=0)

STEP 1 DET. THE MAX COST TRADE-OFF FUNCTION

$t_{i^*,j^*}\triangleq \text{Maxt}_{i,j}\quad i,j\epsilon A$

STEP 2 MERGING TWO LOOPS BY ADDING A NEW LINK

If $C_{i^*}\cup C_{j^*}$ does not violate constraints, (e.g., no more than certain number of terminals per ring)

Add (i^*, j^*)

$C_{j^*}\leftarrow C_{i^*}\cup C_{j^*}$

$A\leftarrow A-\{i^*\}$

Det. j_1^*, j_2^*, $d_{j_1^*}$, $d_{j_2^*}$

Update t_{i,j^*}, or $t_{j^*,i}$ for $i\neq j^*\epsilon A$

$N_L=N_L+1$

Otherwise, $t_{i^*,j^*}=-\infty$

STEP 3 If $N_L<N_t$ Go to Step 1

Otherwise, add a link from 0, the NAF, to the free end point of $C_i\forall i\epsilon A$,

STOP

BACKBONE NETWORK OPTIMIZATION—PACKET SWITCHING NETWORKS

A backbone network can be point-to-point, tree-shaped, ring-switched, or packet switched. For the first three types techniques and algorithms given in earlier sections apply. This section discusses the optimization of packet switching networks.

The topological design of distributed packet switching network was first discussed by Frank, Frisch, and Chou.[15] They described the application of branch exchange techniques in conjunction with branch deletion and addition techniques to the optimization of ARPANET. A summary of experience with branch exchange techniques for ARPANET optimization is given in Reference 16. Similar techniques are discussed in Reference 17. Basically, these techniques seek repetitive cost or throughput improvement by adding, deleting, or simultaneously adding and deleting links, (branches, lines) to a starting network until there are no modifications that result in an appreciable improvement. An evolution from the branch addition, deletion, and exchange is the cut-saturation algorithm[7] which improves both the effectiveness of the design and the efficiency of the computer running time. A cut is any set of lines whose removal will disconnect the network. A cut is saturated if the traffic load of every link in the cut is at capacity. There are, typically, a large number of cuts in a network. When traffic load grows, one of the cuts approaches saturation. Then the only way the capacity of the network can be increased is by increasing the capacity of at least one link in the cut or by adding links across the cut. These ways form the basis for the cut-saturation algorithm. The algorithm attempts to satisfy throughput and response time requirements while keeping overall cost low. It has been successfully applied to the various stages of the ARPANET and the AUTODIN II, among others, and has been shown to be near optimum for problems under consideration.[18]

Another class of heuristic algorithms for designing packet switching networks are called concave branch elimination algorithms.[7,18,19] However, their limited applicability makes them less useful than the cut saturation approach.

However, the cut saturation algorithm as given in Reference 7 is somewhat biased by the ARPANET environment and is limited in its applicability to more general packet switching networks. Specifically, (1) it always starts with a good starting design and uses the optimization algorithm to improve upon it, (in a general environment, a "good" starting design is not always available.); (2) it pays little attention to the applicability of multiple capacities and parallel links, (with the proliferation of line tariffs, such considerations are a must.); (3) the criterion to determine the locations to add links across a cut is derived purely from the experience of ARPANET network structure, (therefore, it is likely not well suited to other environments). A unified algorithm for packet switching network optimization has been developed with those deficiencies eliminated.[20]

Step 1—Generating a starting network

(a) Let TRM(k)=kth largest element in {TR(i,j)} where TR(i,j) is the traffic requirement from packet switch i to j.
(b) Reorder first N_1 elements in TRM according to ascending link costs. (N_1 is determined by a prespecified parameter A, such that TRM(1)/TRM(N_1)≤A< TRM(1)/TRM(N_1+1). Let the vector be TRCOST.
(c) Let the end points of the line represented by TRCOST (1) be i and j. If the sum of the line capacity connected to k divided by ΣTR(k,i), $k=i$ or j, does not exceed a preset limit, B, line (i,j) is added. Otherwise, eliminate this link from the list and a new link is picked from TRM and TRCOST is reordered.
(d) Process (c) is repeated until all the nodes are connected.

Parameters A and B impact on computer running time. For small network, they may be set to infinity. For large network, they should be set small. But if too small, a feasible network cannot be realized.

Step 2—Define generalized link capacities

Let ($S_i \mid i=1, \ldots N_S$) be the set of available link speeds (capacities). The set of generalized capacities ($C_m \mid C_m<C_{m+1}$, $m=0,1,2, \ldots$) are defined as:

$$C_0=0$$

$$C_m=\sum_{i=1}^{N_s} m_i S_i \qquad m=1,2,3, \ldots$$

A link can assume a generalized link capacity C_m. C_m, in general, consists of parallel lines of different speeds or capacities. Among them there are m_i parallel lines with speed S_i, for $i=1,2, \ldots, N_s$. The value of m_i can be zero.

Step 3—Routing

The routing operation checks whether a network can support the required throughput or can support more traffic than the original network. It is performed after each network modification and is used to generate a new optimal link flow. The routing operation is a necessary step regardless of which topological optimization technique is used.[21]

Step 4—Saturated cutset determination

The cutset that has been newly saturated must be determined after each operation. Link flows are calculated. The minimal cutset that has the highest utilization is the saturated cutset.

Step 5—Add-only algorithm

If the network structure under consideration cannot accommodate the required throughput, an add-only algorithm determines the "best" link to be added across the two components separated by the saturated cutsets.

Let C_{n_k} be the generalized capacity on link k. The 'adding' of a link is used in a generic sense to mean the upgrading of the value of capacity for link k from C_{n_k} to C_{n_k+1} or higher. If link k did not exist before, this operation becomes the addition of a new link. Otherwise, this operation may upgrade the capacity of individual lines in link k or add parallel lines to link k.

Let $D_k(C_m)$ be the line cost of link k if link k assumes a capacity value of C_m. Link k must be either an existing or a potential new link across the saturated cut. Either of the following two criteria may be used:

Criterion 1. Upgrade the link whose upgrading results in minimum additional costs, that is, upgrade link K if

$$D_K(C_{n_K+1})-D_K(C_{n_K}) = \min_k\{D_k(C_{n_k+1})-D_k(C_{n_k})\}$$

Criterion 2. Upgrade the link whose upgrading appears to result in minimum additional costs per bit, that is, upgrade link K if

$$((D_K(C_{n_K+1})-D_K(C_{n_K}))/(C_{n_K+1}-C_{n_K}) = \min((D_k(C_{n_k+1})-D_k(C_{n_k}))/(C_{n_k+1}-C_n)$$

For computer running time efficiency, only a subset of possible k's should be considered. In particular, choose only those links whose end points have high unsatisfied traffic requirements for nodes across the saturated cut.

Step 6—Delete-only algorithm

This algorithm may be applied if the throughput supported by the network structure under consideration is higher than the requirement. The Delete-Only operation begins with a highly connected topology and "deletes" one "link" at each iteration, continuously reducing cost and throughput. The deleting of link k is used in a general sense to mean the degrading of link k's generalized capacity from C_{n_k} to C_{n_k-1} or lower. If C_{n_k-1} is zero, this operation eliminates link k. Otherwise, this operation reduces the capacities of individual lines in link k or reduces the number of parallel lines in link k.

Either of the following two criteria may be used for "degrading."

Criterion 1. Degrade the link which has the most residue capacity, that is, degrade link K if $C_{n_K-1}-f_K=\max_k(C_{n_k-1}-f_k)>0$ where f_k is traffic flow on link k.

Criterion 2. Degrade the link whose degrading will result in the maximum costs per bit savings, that is, degrade link K if

$$(D_K(C_{n_K})-D_K(C_{n_K-1}))/(f_K-C_{n_K-1}) = \max\{(D_k(C_{n_k})-D_k(C_{n_k-1}))/(f_k-C_{n_k-1})\}$$

for $f_k<C_{n_k-1}$

Step 7—Exchange

This operation combines Add-Only and Delete-Only operations and is used to improve the throughput or the cost. One link is introduced according to the Add-Only algorithm and one link is removed according to the Delete-Only algorithm. Perturbation is performed when the Add-Only algorithm cannot further improve appreciably, the throughput and the Delete-Only algorithm cannot further improve appreciably the cost.

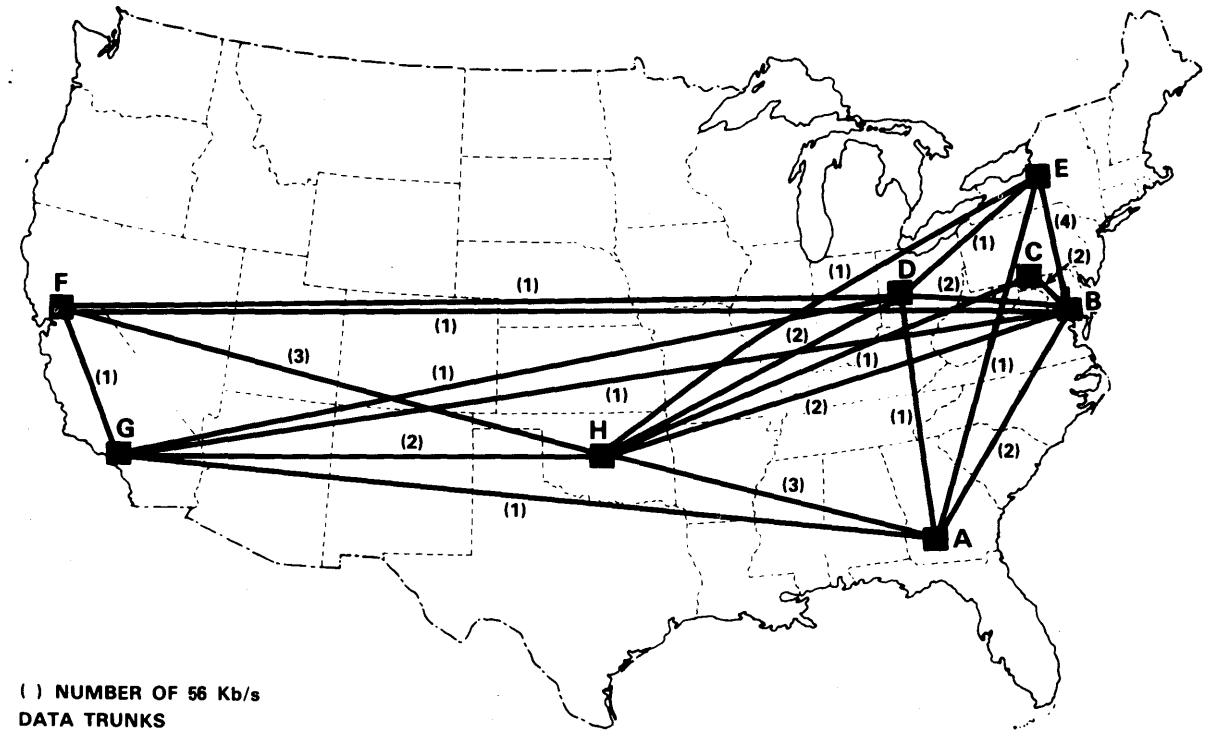
Figure 8 demonstrates the efficiency and effectiveness of the unified algorithm. Figure 8(b) is an AUTODIN II network design that is designed with several executions of ARPANET-based optimization algorithm, and with substantial amount of human interface, including the human configuration of starting network design. Under the same throughput and response time requirements, Figure 8(a) is the design obtained by a single execution of the unified algorithm without input specifying a starting network. It was designed with 28 sec of CPU time on an IBM 370/168 machine which results in a computer charge of $2.20. Yet this design realizes savings of over $200K (11 percent) annually. Figure 8(c) summarizes the comparison.

INTEGRATED OPTIMIZATION AND NAF PLACEMENT

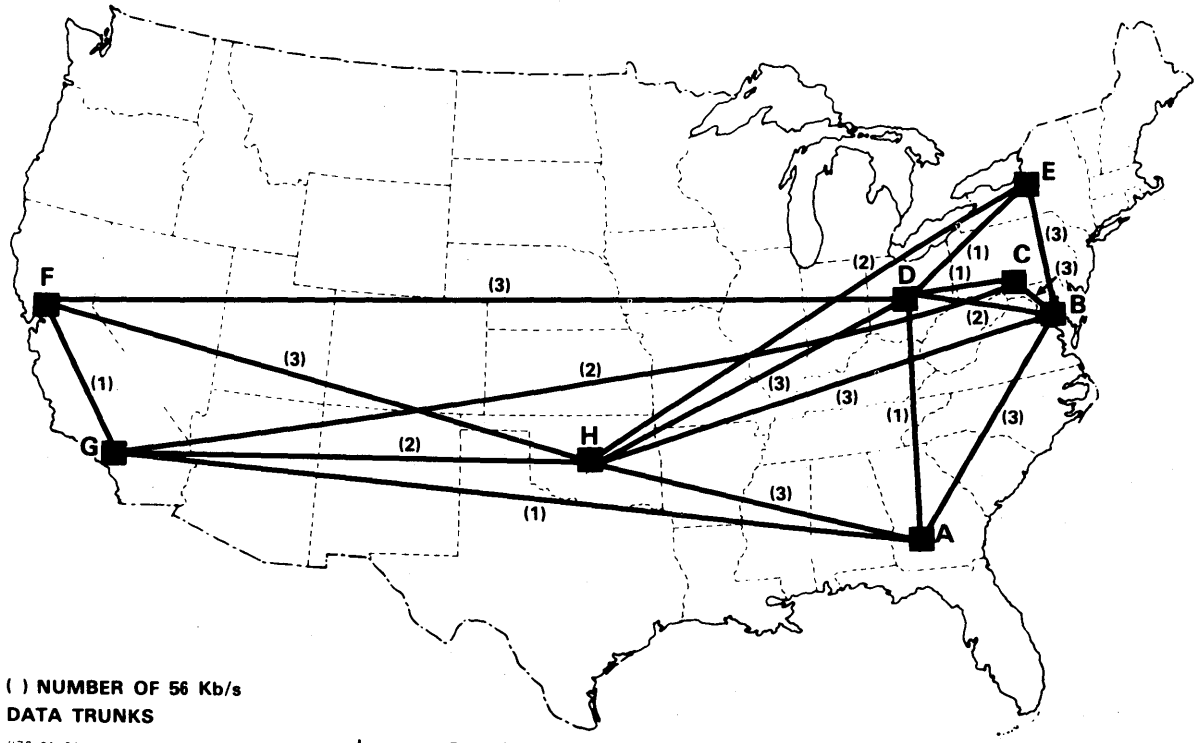
Integrated optimization process

The communications cost for a distributed system in general consists of the costs of NAF's, local access network, and the backbone network. Minimizing the costs for one of the three elements is likely to increase the overall cost. It is important that to optimize the overall communication network costs, the three design problems should be treated as an integrated one. All conventional approaches, however, have treated them as separate sub-optimization or design problems resulting in potentially an overall non-optimized network. We present here an integrated approach.

Since the number and locations impact directly on the costs of both local access and backbone networks, it is only logical to implement the integrated optimization process in conjunction with the optimal placement process of the NAF's. Figure 9 is a simplified version illustrating the interrelation of the integrated process and the three optimization processes. Basically, whenever a set of locations are considered as potential NAF sites, the integrated process interfaces the local access optimization and the backbone



a. Design with Unified Algorithm



b. Design Using ARPANET-based Algorithm and Human Intervention

Figure 8—Comparison of network design with and without the unified algorithm

	Unified Algorithm	ARPANET Algorithm
Network Throughput	1529.2kb/sec	1635.434kb/sec
Avg. End-to-End Delay	0.1233 sec	0.1233 sec.

Computation Time	28 sec (IBM 370/168)	Substantially More
Computer Time Charge	$2.20	Substantially More
Human Interface	None except input preparation	Substantially More

c. Comparison of Designs (a) and (b)

network optimization process to determine the costs of the two subnetworks under this set of NAF's. The network costs may either be determined by a complete optimization procedure or by heuristic estimation. The next section describes the algorithm combining the integrated process and the NAF optimization process.

Optimization of NAF placement

The problem of determining the number and location of NAF's is very similar to the classic warehouse (or plant) location problem. The warehouse location problem is to determine the number, location, and capacity of source sites which minimize the cost of satisfying shipping requirements.[31] A "warehouse" corresponds to an "NAF," and shipping requirements correspond to traffic requirements. Many techniques and algorithms for warehouse location problems have been applied by many authors to the NAF problem.

A general NAF location algorithm has (heuristic) procedures for as many as four problems: determining potential sites, iteratively placing NAF's at the potential sites, estimating the cost of local access networks, and estimating the cost of backbone network.

If the number of sites on which NAF's may be placed is small, every one is designated as a potential site. If not, only a subset of all the possible sites are designated as potential sites to reduce the computational complexity. Iterative procedures are then used to determine the number of NAF's and the eventual NAF sites among the potential NAF sites. The optimal number and locations of NAF's depend on the costs of the network because NAF's interface local access networks and backbone networks. These network costs are sometimes estimated instead of being determined exactly.

Many algorithms have been developed and published, e.g., References 22 through 28. However, they all have only limited applicability. This is probably because there has been very little demand for using algorithms to place the NAF's. There are very few network designs in which the NAF locations have been determined by any of the algorithms referenced above.

For large communication based distributed data processing systems, more flexible and more effective algorithms are needed. In particular, there are the needs for better evaluation of both local access and backbone network costs, and the needs of more flexible algorithms in considering the alternative NAF site. Described below is an algorithm that has incorporated these needs.[29]

The integrated NAF location algorithm

Step 1—Select a subset of permissible sites as potential NAF sites

a. Check the size of locations permissible as NAF sites. Certain locations may be designated as mandatory NAF sites and certain others as permissible. If the sum of the two sets is reasonably small, they are all designated as potential NAF (PNAF) sites and go to Step 2.

b. Cluster Terminals—If the input specified PNAF set is large, the magnitude of the design problem may be reduced by initially clustering the terminals. Intuitively, a good location for a NAF is the center of a cluster of terminals. Thus, by only considering the centers of a set of clusters, the magnitude of the initial problem may be significantly reduced. The number of initial clusters and the cluster size is either input or

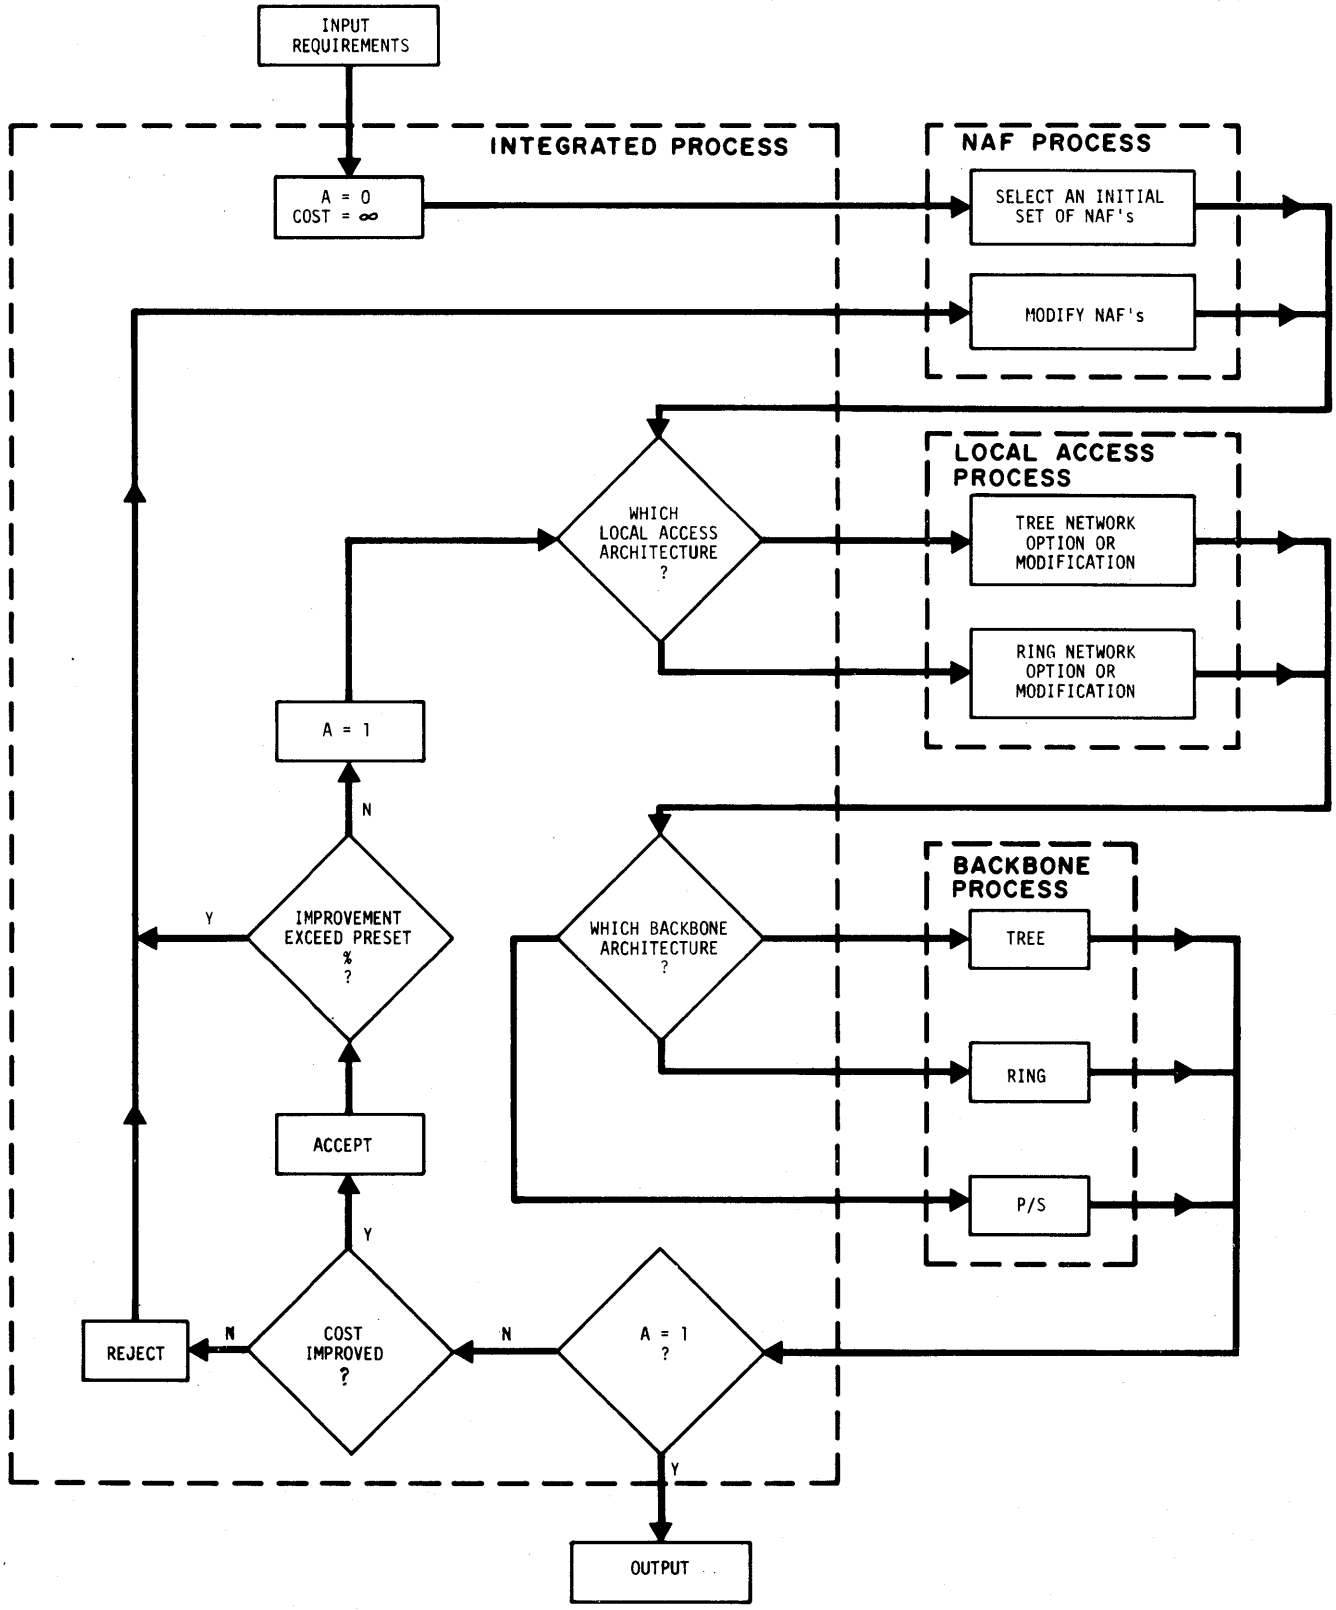

Figure 9—Integrated optimization process

estimated by the program. Then, using Kruskal's algorithm,[8] the clustering is performed.

c. Determine Center of Mass of the Clusters—The center-of-mass (COM's) for the clusters are determined. Only those clusters that have permissible NAF sites but not mandatory NAF sites need be considered. For each such cluster, define the COM by:

$$\text{V Coordinate of COM} = \sum_{1}^{Nc} t_i V_i / \sum t_i$$

$$\text{H Coordinate of COM} = \sum_{1}^{Nc} t_i H_i / \sum t_i$$

where t_i=traffic from Node i

V_i, H_i=(V, H) coordinates of Node i

N_c=Number of nodes in cluster

d. Refine the Center of Mass—The COM as defined above is a mathematically defined location and, hence, may not correspond to any physical node location. Determine a permissible NAF site closest to each COM and assign it as a PNAF.

Step 2—Design or estimate local access network

This step designs the local access network. Initially, assume that all PNAF locations are NAF locations. Using algorithms in earlier sections, the local access network is designed.

Step 3—Design or estimate backbone network

Having designed the local access network, the traffic emanating from each PNAF can be assessed. Four distinct types of backbone network designs are considered: (a) Point-to-point (b) Multipoint (c) Packet-switched (d) Ring.

In (a), for each NAF, the closest CPU is connected.

In (b), the NAF's are connected to the CPU's via multipoint trees using similar algorithms defined earlier.

In (c), Packet-switching techniques are used for the backbone network using algorithms defined earlier.

Step 4—Select the NAF sites

a. Drop Algorithm—In this step, for each PNAF that is non-mandatory and has been selected as a NAF site in the current design step, the potential cost-savings to be obtained by dropping it is evaluated. This savings consists of: (a) savings in backbone network, (b) savings in local access network. A PNAF that yields maximum positive savings is permanently dropped from the network. If the savings is negative, this step is concluded. The savings (a) and (b) can be either evaluated exactly or estimated using heuristics.

- Heuristic Cost Estimate for Backbone
  If the PNAF considered for dropping is singly connected to another node, the backbone cost saving simply equals the line cost plus the physical cost of the NAF. If the PNAF is multiply-connected, consider all the nodes directly connected to this PNAF. Consider, in turn, each of these nodes for direct connection to the rest of the nodes. Whichever of these yields the least cost is considered the alternative. The cost-saving equals the line cost of the new configuration minus the line cost of the previous configuration plus the NAF cost.
- Heuristic Cost Estimate for Local Access
  Consider all the lines that were connected to this PNAF. For each of these lines determine the closest NAF (other than the NAF under consideration) and check if this NAF can accommodate one additional input port. If not, dropping the NAF is infeasible. If it can, consider this the alternative local access configuration. As before, the cost savings equals the new line cost minus the previous line cost.

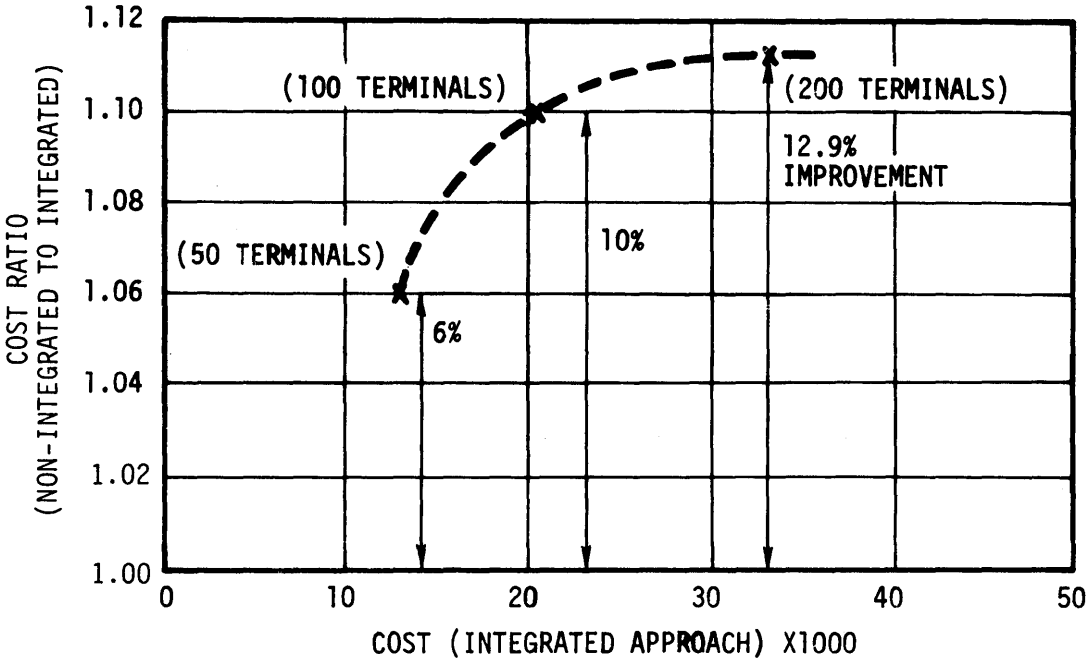
After each K ("K" is an input parameter) iterations, the local access and backbone networks are reoptimized.

b. Add Algorithm—This step considers the cost savings to be obtained by adding an NAF site. For this purpose, PNAF's that are not selected for the current design and that are farthest from the current set of PNAF's are considered for potential addition. The cost savings are heuristically estimated. The PNAF whose addition results in the greatest positive saving is added to the network. If the saving is negative, conclude this step. If the number of iterations equals K, the local access and backbone networks are redesigned.

c. Split Algorithm—This step considers the cost saving that results if a PNAF having a large number of terminals is replaced by two PNAF's. Consider "KS" (input parameter) PNAF's that have the most number of terminals. For each of these, heuristically estimate the cost saving by replacing it with two NAF's. If the maximum cost saving is positive, the split is made permanent; if not, conclude this step. After K iterations, the local access and backbone networks are redesigned.

d. Exchange Algorithm—This step examines the cost saving obtainable by exchanging NAF locations. It considers unselected PNAF locations that are farthest from the current set of selected PNAF's; each of these locations is examined for the effect of exchanging it with a selected PNAF closest to it. As before, an exchange which yields the most positive heuristic cost saving estimate is made permanent. After each K iteration, the local access and backbone networks are redesigned.

e. Merging Algorithm—This step examines the cost saving obtainable by merging a PNAF which has a small number of terminals associated with it, with a neigh-



(a) Cost Comparison Curve

	INAF DESIGN	COM DESIGN	ATD DESIGN

NO. OF SWITCHES	1	1	1
NO. OF TERMINALS	100	100	100
ANNUAL TOTAL COST	$159,120	$175,536	$187,344
NO. OF SWITCHES	1	1	1
NO. OF TERMINALS	200	200	200
ANNUAL TOTAL COST	$247,860	$276,876	$277,956

(b) Cost Comparison Table

	COST BASIS
CONCENTRATOR (NAF)	$200/MONTH
LINE CHARGES/MI.	$0.50/MILE
TERMINATION CHARGE	$$40/TERMINATION

(c) Charges Considered in Determining Communication Cost

Figure 10—Cost comparison information

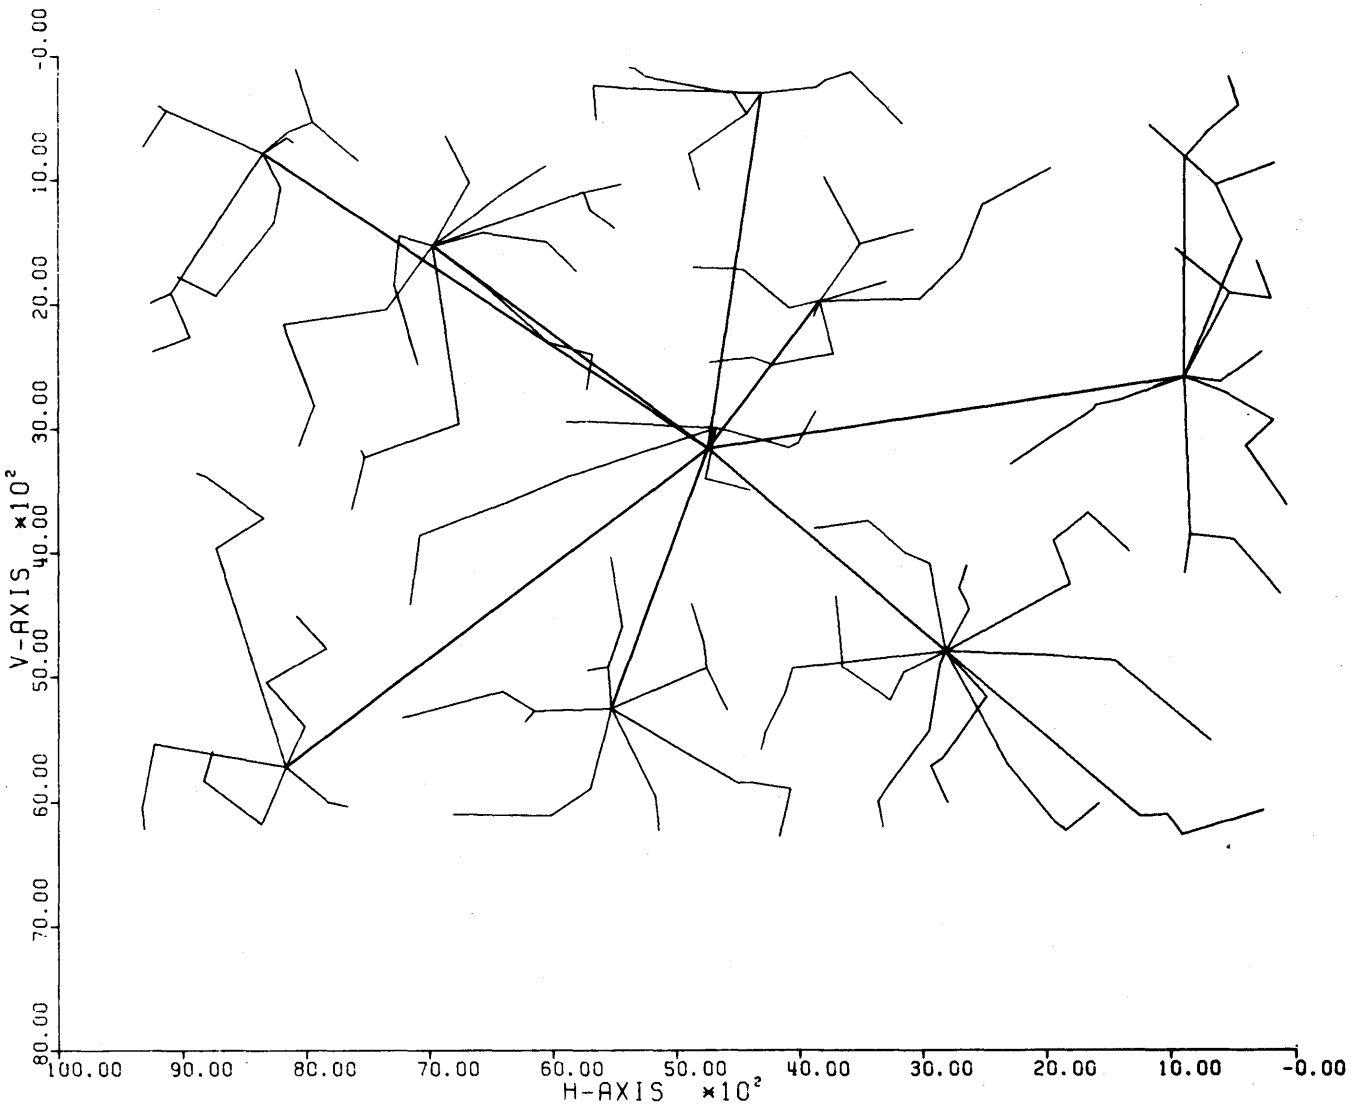

Figure 11—Integrated algorithm network design (200 terminals)

boring PNAF which can accommodate these additional terminals.

In any one design run, all substeps need not be executed. For a given design problem one of these steps may be more useful in achieving low cost networks than others. The designer can experiment with the order and number of these heuristics that need to be called to yield a near-optimum design.

Step 5—Refinement and reoptimization

If any network adjustments have been made since last redesigning the network, reoptimize both the local access and backbone networks.

Figure 10a compares the costs between the designs obtained from the integrated and non-integrated approaches. Cost information for the non-integrated approach was derived from data presented in the recent McGregor-Shen paper.[28] Only local access, backbone line cost, and concentrator costs were considered in doing the comparative evaluation, since these costs are used primarily in our optimization process. Fixed termination charges of $40/termination were subtracted from the McGregor-Shen data in order to provide a basis for comparison.

Locations of terminals used in the data presented in Figure 10 were obtained from a uniformly random distribution of sites taken over a 2000 by 3000 mile rectangle. This distribution of terminals was provided again in order to have a basis for comparison between our integrated algorithm and the algorithm presented in the McGregor-Shen paper.[28]

The specific cost comparisons of the two approaches for three network designs are given in the table in Figure 10b. Figure 10c gives the cost information on lines and devices. Figure 11 is the plot of one of the network designs (200 terminals design). In the above comparisons it should be noted that the reason for using McGregor-Shen's data is that

the authors felt that the McGregor-Shen COM algorithm was demonstrated to be the best heuristic algorithm published to date. Based on our comparative analysis we feel that our integrated algorithm approach improves upon the McGregor-Shen algorithm and uniformly outperforms all other non-integrated approaches published to date.

CONCLUSION

With the fast growth in the communication-based distributed data processing systems, the emphasis on the objectives of the optimization has shifted. We have presented a set of integrated network optimization algorithms that are best suited for this environment. Some of the algorithms are newly developed; some are the modifications of the existing ones.

There are needs for reducing, substantially, the computation time for local access networks with a large number of terminals. We have developed two implementation schemes, heuristic in nature, to satisfy these needs. The computation time, with these schemes, grows practically linearly as the number of terminal locations grows; and, in practical networks with more than two or three hundred terminals, the computation time actually grows less than linearly.

There are some needs for topological optimization algorithms for ring networks, which have not been available in the open literature in the data communication field. We presented such algorithms, developed by modifications of works in the graph theory area.

There are needs for improvements on the widely used packet switching network optimization algorithms that were developed with ARPA support. The improvements are to eliminate its bias from the ARPA environment and to improve the design results and computation times. We presented a generalized algorithm to achieve these improvements.

There are needs for more effective algorithm than currently available on the determination of the number and locations of network access facilities. To realize these needs, we presented an algorithm that adopts many good features of the existing algorithms and is augmented with new ones.

Finally, there are the needs for integrating the different optimization processes into one unified process, which would turn out better design results. We presented such a process in conjunction with the NAF algorithms. In the program that we have developed with the implementation of these algorithms we were also able to integrate into the same process the different network structures (tree, ring, mesh) and variations associated with differences in line tariffs.

ACKNOWLEDGMENT

The authors wish to express their appreciation to J. McLeod and R. A. Pickens for their encouragement, to D. Sapir for informative discussions on Backbone Network design and L. Gerke for her efforts in the development of the computer programs.

An extensible distributed data base system*

by MAMORU MAEKAWA and SATORU ISHII
Toshiba Research and Development Center
Kawasaki, Japan

INTRODUCTION

Extensibility is one of many claims of improved performance being made for distributed processing systems. Extensibility means system properties, such as "incremental growth and configuration flexibility," "highly adaptable to changes in workload," "incremental replacement and/or upgrading of components (both hardware and software)" and "easily expanded in both capacity and function."[2] Although the need for extensibility is strongly felt, research results for it appear to be still far from satisfactory.[3,4]

A distributed data base system is one example of distributed processing. Although its usefulness is well recognized, the research in this area is also still very much in its infancy. MINIMET, a transaction-oriented homogeneous distributed data base system, has contributed towards the understanding of the distributed data base system.[6,9] The MINIMET research put more emphasis on the lower level of system control so that any data model can be built on it.

The data base system described in this paper is a relational data base, one of whose characteristics, among others, is capacity extensibility.

Extensibility, in this paper, means the following three things:

(a) Physical extensibility
(b) Logical extensibility and data independency
(c) Minimal performance degradation in data base growth.

Physical extensibility means that the system can physically be extended to meet a workload increase. Logical extensibility and data independency mean that the system can logically be extended and that application programs are not affected by system extension. The third characteristic, minimal performance degradation, means that degradation in performance, response times in particular, in the growth of data base is kept minimal. Because of these characteristics, the system will be called an Extensible Distributed Data base System (EDDS).

For physical extensibility, it is apparent that the less hardware for interconnections is provided the more extensible the system is. Obviously, a system consisting of independent subsystems is then most extensible. However, this architecture provides no advantages in coordinating various kinds of information. Distributed systems must consist of autonomous, but not totally independent, cooperating subsystems. The next most extensible architecture would be a common bus system, as shown in Figure 1, in that a number of subsystems are connected by an intersubsystem bus. Any more complex architecture would impose a greater difficulty in expanding the system. Particularly, a shared memory causes a great difficulty.

In the above common bus architecture, the bus capacity is most important in determining system performance. As the workload of the system and the number of subsystems increase, the bus capacity must also be increased. One method to increase bus capacity is to add additional buses. Another is to replace the bus with a faster one. The first method is architecturally more complex than the second, but it has the advantage that no replacements are necessary to increase the capacity. The second method requires bus replacement, but it is architecturally simpler. Both approaches are possible. Further details will not be gone into, it will simply be assumed that a common bus architecture is the basis of the present system.

Another important aspect of extensibility is performance degradation in data base growth. There are two major areas which cause performance degradation; input/output channels and the system itself. In order to avoid performance degradation due to the limitation in input/output channel capacity, it is assumed that the system is connected by n input/output channels to the user systems as shown in Figure 2. This is one of the reasons that a centralized control should be avoided. If there is a centralized control, then any and all data and control information must go through it and the central control may become a major bottleneck.

Like the intersubsystem bus, it is also necessary to try to minimize input/output channel replacement cost. For this purpose, additions rather than replacements are desirable

* This work has been supported by the Agency of Industrial Science and Technology, Ministry of International Trade and Industry, Japan, under the project Pattern Information Processing System.

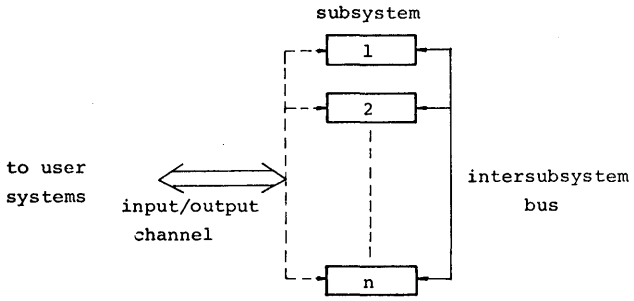

Figure 1—Common bus architecture

when more capacity is needed. Both approaches are feasible and the architecture shown in Figure 2 is assumed to be the basis of discussions.

Performance degradation in the system itself is mainly caused by speed limitation of the intersubsystem bus, which is necessary to transfer data and control information between subsystems to assure proper system operation. The bus capacity is thus an important system parameter. Performance degradation is analyzed in a later section.

As indicated earlier, the system described in this paper is a relational data base. The query language for the system is relational-calculus oriented and has the following three basic statements.

Retrieval
  Get R | condition
  Those tuples that meet the "condition" are retrieved and placed into relation or view "R". The condition is any relational calculus involving relations and views, which are specified only by name.
Relation creation
  Create R | condition
  Relation "R" is created under the "condition".
Relation deletion
  Purge R
  Relation "R" is deleted.

Logical extensibility and data independency are now described in more detail.

LOGICAL EXTENSIBILITY AND DATA INDEPENDENCY

Logical extensibility and data independency mean that neither internal nor external logic is affected by system extension. The approach described in this paper, whereby to obtain this property, is one of the extremes of modular approach. In a general modular approach, a number of modules are prepared and put together to form a particular system. Extensibility is obtained simply by adding more modules. Depending on the size of the modules, the cost of interconnecting them and flexibility of resulting systems vary. The present system requires the following:

(1) The system must be able to work even when it consists of only one subsystem. This implies that the subsystem must be able to perform all the functions required for the data base processing.
(2) No additional programming work, either internal or external, should be required in order to add additional subsystems. This implies that every subsystem must be logically identical.

The EDDS tries to obtain internal logical extensibility in the following way.

(a) Any internal logic is exactly copied and placed in each subsystem. Therefore, no program moves are required. Note that although user programs are allowed to be cataloged and executed at a user request, they are here considered to be data.
(b) Data are separated into two categories: relations and internal data. Relations are made up of information directly created and accessed by users. Internal data are the information necessary for assuring proper system operation. These data are created and maintained by the system. Relations keep spreading over the subsystems and only one copy of each is maintained at any time. A single relation can be spread over several subsystems. On the other hand internal data are duplicated and placed in each subsystem. Some examples of internal data are relation sizes, locations and structural characteristics. This information is distributed among subsystems under a loose control. Here, loose control means that the control of mutual exclusions is neglected and, thus, there might be some discrepancy at some time between multiple copies of internal data distributed among subsystems. The correctness of any decisions based on this information is, as a result, probabilistic.

The above discussions focus on the internal logic of the data base system. The external logic's logical extensibility is also very important, which is commonly known as "data independency." Particularly, we are here concerned with the number of subsystems. Data independency requires that accesses to data base be made independently of the internal structure, including the number of subsystems. In order to obtain this data independency, the following basic approach is used.

(a) Each request from a user system is broadcast to every

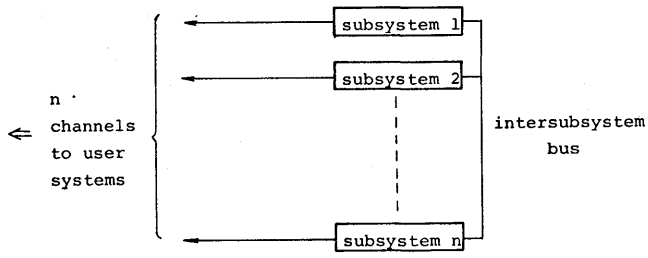

Figure 2—System architecture

subsystem. Note that, at this point, it is not yet known where the necessary relations reside and which subsystem is going to take care of the request. The request itself does not contain any such information. The request is written in the query language mentioned before.

(b) Let every subsystem start to try the processing of the request, but make all the subsystems except the optimal one drop out during the course of processing. Eventually, the request is taken care of by the optimal subsystem. The results are returned to the user system directly from it.

A key characteristic of this approach is expressed by the term "eventually" in the above sentence. No central control exists and no one tells any subsystem when to quit. Each subsystem is autonomous. This approach can be realized by the following algorithm.

Algorithm

1. A user system issues a request. The request is accompanied with the time when it was created. This created time, together with the user system identification, will be used as a unique identification of the request.
2. The request is broadcast to every subsystem in the data base system.
3. The request is placed in the waiting queue of each subsystem.
4. When the turn of the request comes, its subsystem tests whether the processing of the request has already been started by another subsystem. If so, the subsystem simply discards the request; otherwise it analyzes the request and, using some criterion, it determines whether it should accept the request. If it has decided not to do so, then the request is simply discarded. Otherwise, the processing is started. The above criterion will be discussed later.
5. A subsystem now starts processing the request and sends a signal to other subsystems to notify it. If the request involves a creation of a relation, an OPEN to a dummy relation is made prior to any operations necessary for the request.
6. It is assumed that any relation must be OPENed before any accesses are allowed. When an access to a relation is made with an OPEN procedure, a check is made to determine whether an access to it has been made for the same request from another subsystem. If so, the subsystem terminates the processing of this request and simply discards it. Otherwise, it continues the processing. This checking mechanism will also be discussed later.
7. When the results are produced, they are simply returned directly from the subsystem which accepted the request to the user system that issued the request and no other subsystems and/or user systems will be involved.

Next, the acceptance criterion mentioned in (4), notifying mechanism in (5), checking mechanism in (6) and an OPEN to a dummy relation in (4) are discussed.

Acceptance criterion

Each subsystem determines whether it accepts a request or not according to some acceptance criterion.

This acceptance criterion should be aimed at obtaining a balanced load assignment with a minimal overhead. It must assure that at least one subsystem accepts a request. A simplest algorithm is to let each subsystem accept every request and attempt to try its processing. This algorithm is simple and uses no information about the request. We call this algorithm "all selection algorithm" for later references and assume that the queue discipline is first-come, first-served.

The algorithm can be improved by utilizing information about the request. The following information is useful:

(a) Which relations are to be referenced.
(b) How often they are to be referenced.
(c) Which of them are in the subsystem concerned.

Suppose that request R_i references relations $D_{i1}, D_{i2}, \ldots, D_{im}$ with frequency $F_{i1}, F_{i2}, \ldots, F_{im}$, each. Then, the total number of references is

$$\sum_{j=1}^{m} F_{ij}.$$

Assume that a fraction W_{ij} of relation D_{ij} resides in the subsystem concerned. Then, the probability that an access falls into the subsystem concerned is

$$W = \frac{\sum_{j=1}^{m} W_{ij} F_{ij}}{\sum_{j=1}^{m} F_{ij}}$$

A natural acceptance criterion is then:

$$\text{accept if} \quad W \geqq \alpha$$

for some threshold value α. If we take $\alpha=0$, it becomes the all selection algorithm. If we take $\alpha=1$, many requests would be missed and there would be a very high probability that a request would not be served by any subsystem at all. The maximum value that insures the acceptance of a request by at least one subsystem is

$$\frac{1}{n}$$

where n is the number of subsystems. We call the above improved criterion "sufficient selection algorithm" for later references.

Notifying mechanism

The request acceptance notification by a subsystem is not essential for proper system operation, but is employed to reduce overhead. The mechanism is a very simple one. Each

request is labeled with a unique identification, as mentioned before. Whenever a subsystem starts processing, it broadcasts a signal to notify every other subsystem of this. No control is placed on the work of this mechanism. Assurance of the proper operation of this mechanism requires a system-wide or intersubsystem mutual exclusion of signal setting, resetting and checking. Without a shared memory, this implementation of intersubsystem mutual exclusions is a rather time consuming process. Rather than trying to make the mechanism complete, instead it is made probabilistic. In other words, no intersubsystem mutual exclusions are employed, although intrasubsystem mutual exclusions are guaranteed. This simplification causes cases where, due to the delay in signal transferring, a subsystem checks the signal before it arrives. Therefore, a subsystem may proceed in spite of the fact that another subsystem is already processing. This causes some loss in processing power due to duplicated work, but the mechanism itself does not need a difficult control and the architecture can remain simple. Note that a logic can be built so that there are no opposite cases; namely the case that the signal is set while no subsystems actually have started. This guarantees a necessary request acceptance condition wherein a request is always accepted by at least one subsystem.

Checking algorithm

The checking algorithm is the last gate that a request must go through. If a request is passed through this check, then it will be processed through the completion. The checking algorithm is implemented in the OPEN procedure for a relation. Each OPEN procedure has a list of processed requests augmented with their subsystem's names. Whenever an OPEN is requested, it checks whether or not another OPEN for the same request from a different subsystem has already been made. If so, the OPEN procedure returns control indicating this and the subsystem then simply discards the whole request. It is assumed that any relation is always OPENed by its owner subsystem. This assures the mutual exclusion of OPEN procedure and makes the checking mechanism much easier. Note that it is assumed a relation is owned by a single subsystem although it may be spread over several subsystems.

OPEN to a dummy relation

An OPEN to a dummy relation is issued to assure proper relation creation. For relation creations, the following problems must be considered:

(a) How to control a relation creation so that one and only one is properly created.
(b) How to distribute relations in a balanced way.

The first problem is specific to the EDDS, in which a number of subsystems essentially try to do the same operation in regard to the same relation, including a relation creation, at the same time. Thus, when several subsystems try to create a relation, operations must be controlled so that one and only one subsystem will do the job. For this control, an access is defined and attached to a dummy relation to each request that involves a relation creation. It is assumed that this access to the dummy relation is made at the top of processing the request. In this way, through using the above checking algorithm, it will be assured that one and only one subsystem completes the operation and that no extra operations are made. A small problem is how to determine the name of the dummy relation. The naming mechanism should have the characteristics:

(a) Dummy relations are distributed to each subsystem so that the system can operate irrespective of the number of subsystems.
(b) Accesses to the dummy relations are evenly distributed among subsystems.

In order to accomplish these characteristics, the following method is adopted.

(a) A dummy relation is assigned to each subsystem, whose names are subsystem numbers 1 through n.
(b) Each request is accompanied with its created time, t. The name of the dummy relation for this request is computed as (modulo n of t)+1.

In this way, it should be obvious that the required characteristics are achieved, although the total number of subsystems, n, must be known to each subsystem.

The second problem, how to distribute relations in a balanced way, is another important problem. A simple and perhaps natural way to obtain this is to let the first available subsystem accept the request and create the required relation. This method sets up a relation to be assigned to a most likely lightest-loaded subsystem. Another simple and natural way is to assign the relation to the subsystem that has the largest amount of empty space. Control of this method is also easy. However, the former load-oriented approach is taken, since it is easier when it is combined with data search operations.

CORRECTNESS AND OPTIMALITY

This section proves the correctness of the algorithm presented in the previous section and shows that the algorithm is statistically optimal for system balancing or load sharing.

Correctness

Algorithm correctness will be proved by showing:

(a) At least one subsystem accepts a request,
(b) No more than one subsystem accepts a request,
(c) No deadlocks occur
(d) System is alive

Methodology

The methodology used here is a slight extension of Bochmann and Gecsei's method.[1] It is extended by adding remote read and write operations, denoted by READ (a:=v) and WRITE (v:=a). A READ (a:=v) specifies an access to a remote variable v and assigns the value of v to local variable a. Some arbitrary time delay exists between the initiation of the action and an actual reference to variable v. Control, however, stays at the READ command until the action is completed. A WRITE (v:=a) causes a remote variable v to be changed to the value of local variable a. A WRITE action does not wait for the completion of the action and some arbitrary delay exists between initiation and an actual change in v.

Model

For simplicity, it is assumed that the acceptance criterion is the all selection policy and limits the number of subsystems to two. Also, the number of relations used by a request is limited to two. As will be seen, an extension to a general case is very straight forward. A description of each subsystem can be given, referring to the algorithm described in the previous section.

(a) State transition diagram for subsystem k. (see Figure 3)

(b) Variables

Variable

$C_i[1:n]$: integer for each relation i

$$C_i[j]=\begin{cases}\text{Meaning}\\ h & \text{if the } i\text{th relation for the } j\text{th request is OPENed by the } h\text{th subsystem.}\\ \text{null} & \text{otherwise}\end{cases}$$

$S_k[1:n]$: (0,1) for each subsystem k

$$S_k[j]=\begin{cases}1 & \text{if the } j\text{th request is already being processed by some subsystem}\\ 0 & \text{otherwise}\end{cases}$$

(c) Actions

Transition	Enabling predicate	Action	Meaning
Arrival	at least one request is waiting	;	take the next request, say jth, from the waiting queue
Notify	$S_k[j]=0$	$S_k[j]:=1$; WRITE $(S_i[j]:=1)$ for $i=1,2,\ldots,n,\ i\neq k$;	notify the start of processing
Processed	$S_k[j]=1$	;	discard the request
OPEN OK	$C_h[j]=$null $\wedge C_h[m]=$null for any $m\neq j$	$C_h[j]:=k$;	the first OPEN of the jth request is for the hth relation
OPEN Unsuccessful	$C_h[j]\neq$null	;	another subsystem has already OPENed relation h
OPEN Good	$C_i[j]=$null $\wedge C_i[m]=$null for any $m\neq j$	$C_i[j]:=k$;	the first OPEN for the ith relation
OPEN Failure	$C_i[j]\neq$null	;	another subsystem has already OPENed relation i
Return	true	$C_h[j]:=$null; $C_i[j]:=$null;	after the completion restart a new cycle

Verification

The enabling predicates for OPEN OK and OPEN Good involve more than a single request. Because of this, deadlocks can occur between conflicting requests. Since these deadlocks can be avoided by a usual technique, it is assumed they will not be a problem. Then, it is only necessary to analyze the case for the single same request.

Let us denote by (t_1,t_2) the global system state, where t_1 and t_2 are two subsystem states. Possible transitions of the global system can be drawn as shown in Figure 4. Note that, since the subsystems are logically identical, the order of executions of OPEN's for the relations for the same request is the same in each subsystem. From Figure 4, we can prove the four properties of the system.

(a) At least one subsystem accepts a request.
This is verified because once the system makes a transition "Arrival," it always comes to a state involving a subsystem state (5).

(b) No more than one subsystem accepts a request.
This is verified because no (5,5) states are allowed and because once a state $(5,x)$ is reached, then state

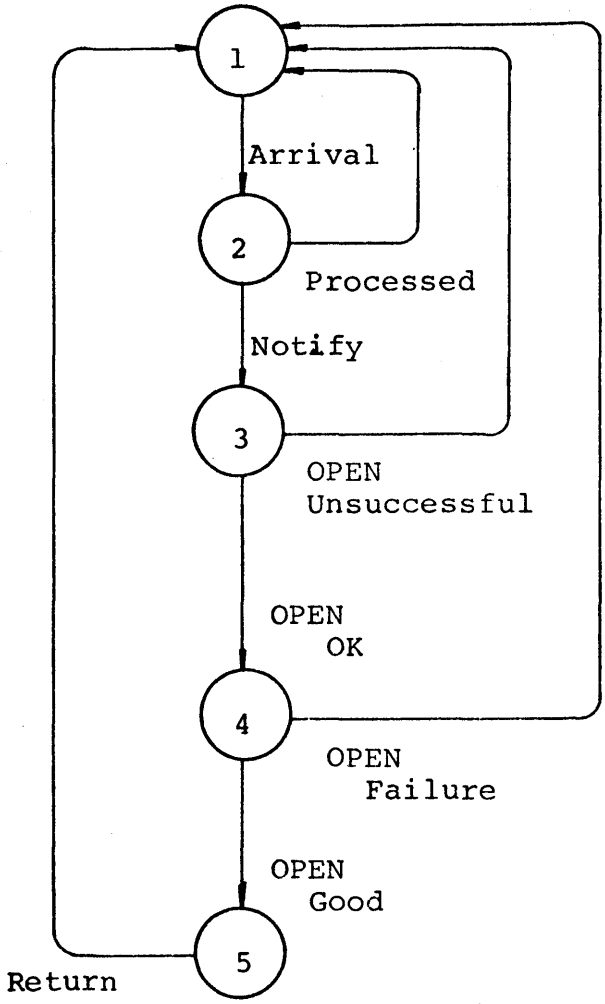

Figure 3—State transition diagram

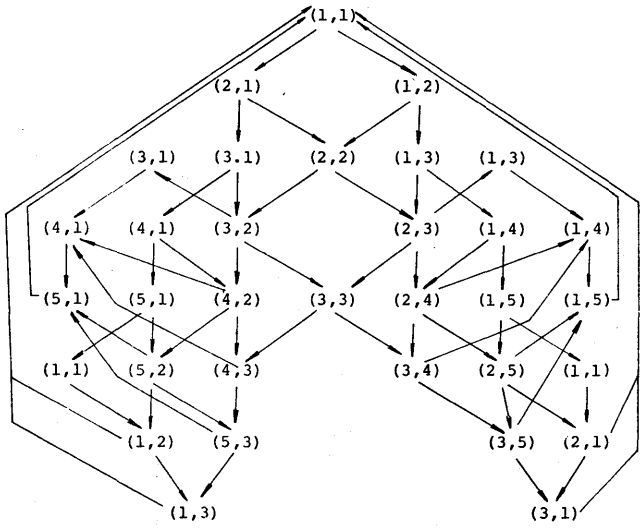

Figure 4—Possible transitions

(y,5) can never be reached for the same request, and vice versa.

(c) No deadlocks occur
Since no states are blocked, no deadlocks occur.

(d) System is alive
This can be shown because, after the system reaches state (5,x) or (y,5) it always returns to the original state (1,1).

The above verification is limited to a special case, but an extension to a general case should be obvious and straightforward.

Optimality

It can be seen that the algorithm described in the previous section contains so called automatic load sharing. Several methods for automatic load sharing have been proposed. LeLann's two methods,[7] for instance, are:

(a) Diffusion technique
(b) Circulating vector technique.

The above two methods and many others exchange information about the load of each subsystem. Based on this information, each subsystem determines whether it accepts a new request. The present method, under the all selection discipline, does not need any information exchange and can be proved to be optimal for load sharing in a statistical sense. The present scheme is free from any consistency problems caused by communication delays, because no information exchanges are required. Note that any scheme that exchanges information may have consistency problems, due to communication delays.

Model and proof

The present method, under the all selection discipline, is statistically equivalent to a single queue with multiple servers, because each request is placed in every queue. Any scheme that exchanges information corresponds to a system of separate-queues with some jockeying. Whatever jockeying is used, they cannot be better than a single queue as far as load sharing is concerned. This can be proved very easily. Some simple analysis for jockeying for a variety of strategies is made by Koenigsburg[5] and a detailed analysis of two queues is made by Maekawa.[8]

PERFORMANCE ANALYSIS

For performance analysis, the data base is simply considered to be a collection of pairs (attribute, value). They are put together to form records, domains and relations. In this section, the only concern is with their statistical characteristics. There is no concern over whether they are actually relations, domains or records.

The present data base system consists of a number of subsystems, as shown in Figure 2. Each subsystem has a

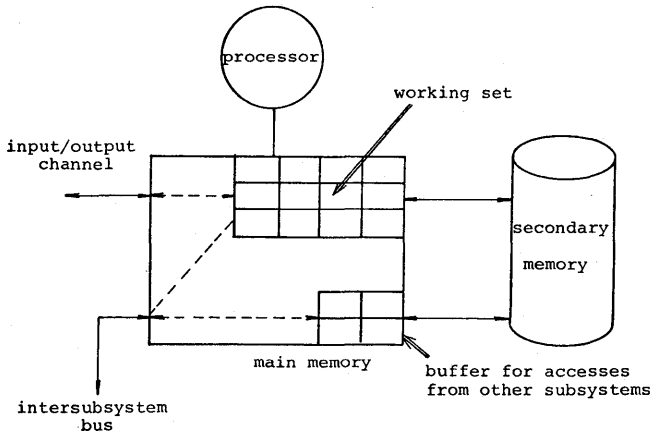

Figure 5—Subsystem

processor, main memory and secondary memory, as shown in Figure 5. In the main memory, there are two kinds of buffers; one is for data handled directly by its own processor and the other for accesses from other subsystems. The former buffer contains a working set of data. It is assumed that both main memory and secondary memory are divided into pages of equal size and that a paging scheme is employed. A model of the whole system is shown in Figure 6.

(1) There are m users and n subsystems connected by n input/output channels
(2) Each user issues a request with rate λ.
(3) A request is first examined by its subsystem. It is discarded unless the subsystem decides to accept it. It is assumed that the initial examination time is governed by random variable A and the probability of acceptance is denoted by a. Probability a is dependent on the system state.

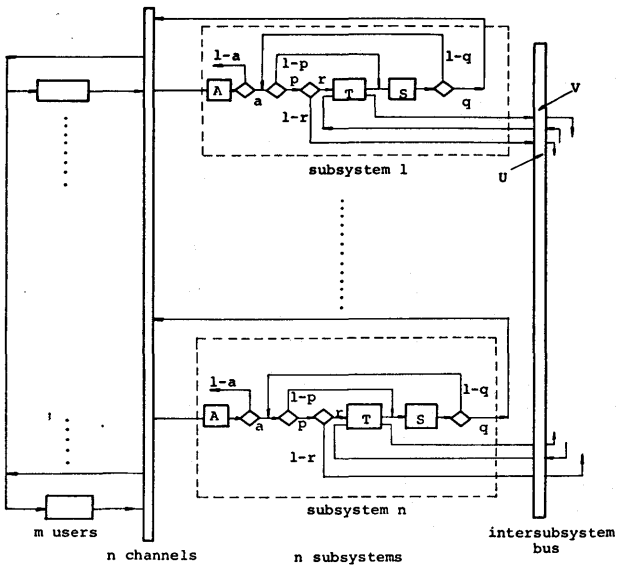

Figure 6—Mathematical model

(4) The processing of a request is a cycle of an access to data, usually a tuple of a relation, and its processing. When data are not in the main memory, they are brought into the main memory from a secondary memory. Time to access data in the secondary memory is assumed governed by random variable T. When data are obtained in the main memory, processing the data is started. Its service time is assumed governed by random variable S. On the completion of the service, request processing completes with probability q and repeats with probability $(1-q)$. Thus, the number of cycles per request is geometrically distributed with mean $1/q$.
(5) The missing page rate is denoted by p. When a page is not already in a main memory, the required page is brought in from its own subsystem's secondary memory or from another subsystem. It is assumed that the probability that a page is brought in from another subsystem is $(1-r)$. If a page is in its own subsystem's secondary memory, it takes only time T to bring the page in. If it is not, however, a request for data acquisition and the obtained data must go through the intersubsystem bus, whose times are governed by random variables U and V, respectively.

The major performance problems in this system are

(a) How much performance degradation is imposed in each subsystem due to this architecture.
(b) How good is load balancing.
(c) How much overhead due to this architecture is imposed.

The performance degradation is, to some extent, controlled by the acceptance criterion. The performance degradation of the system, excluding I/O channels, is mainly due to the following overhead.

(a) An unsuccessful attempt for access to a relation per subsystem for each request may be necessary.
(b) When a page is in another subsystem's secondary memory, it must be brought in through the intersubsystem bus.

Overhead (a) is negligibly small, compared to the total processing necessary for a request. Thus, overhead (b) is the major cause for performance degradation. Instead of analyzing the whole system shown in Figure 6, the performance of each subsystem may be approximated by the model shown in Figure 7. The rationale behind this approximation is obvious. The number of subsystems affects probability r

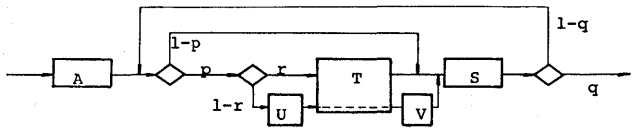

Figure 7—Approximation model

as well as transfer times U and V. As a simple comparison, make a mean-value analysis.

(A) Single-subsystem case
In this case, $r=1$. Then, the mean service time for a request is

$$E[\text{service time}]_1 = E[\text{cycle time}]E[\text{number of cycles}]+E[A] = (pE[T]+E[S])/q+E[A] \quad (2)$$

(B) Multi-subsystem case

$$E[\text{service time}]_m = E[\text{cycle time}]E[\text{number of cycles}]+E[A] = \{pE[T]+p(1-r)(E[U]+E[V]) + E[S]\}/q+E[A] \quad (3)$$

Since $E[A]$ is small, compared to the total processing time, ignore $E[A]$ and then take the ratio of the two for comparison purposes.

$$d=\frac{E[\text{service time}]_m}{E[\text{service time}]_1} = \frac{p+E[S]/E[T]}{p+p(1-r)(E[U]+E[U]+E[V])/E[T]+E[S]/E[T]}$$

Table I shows the values of d for various values of

$$h=(1-r)(E[U]+E[V])/E[T]. \quad (4)$$

It is assumed that $E[U]$, is one-tenth of $E[V]$, page size is 2 kilo-byte, $E[T]$ is 30 ms and (1−r) is 0.3. Then h and c are related by

$$h=(1-r)(E[U]+E[V])/E[T] = 0.022/c.$$

Under normal operation conditions, the missing page rate, p, should be less than 1/100. If it is assumed that $h=0.1$, then performance degradation is 2 to 6 percent. For $h=0.1$, 0.22 mega-byte/second per subsystem is needed. Thus, if a 1 mega-byte/sec bus is provided, then a system, made up of 4 subsystems, should be able to work with 2 to 6 percent performance degradation. When there is a fairly fast secondary memory and $E[S]/E[T]=1/20$ is justified, then, for $h=0.7$, or $c=1$ mega-byte/sec, performance degradation is only 10 percent with 30 subsystems. At any rate, it is observed that the smaller the missing page rate, and the faster the secondary memory, the less performance degradation is incurred and the larger a system can be constructed. Thus, a faster buffer memory between main and secondary memories would greatly improve system performance. A magnetic bubble or CCD memory would be a great help here.

Next, the acceptance criterion effect is analyzed. The two policies discussed before are compared.

(a) All selection policy
(b) Sufficient selection policy

Again, only a mean-value analysis is made. The assumptions are as follows:

(1) The subsystem reference frequency is described by a truncated geometric distribution with parameter $(1-w)$. Namely, a request R_i refers a subsystem S_{ij} with probability

$$f(j)=\frac{w(1-w)^{j-1}}{1-(1-w)^j}, \qquad 0<w\leqq 1. \quad (5)$$

(2) Each subsystem is identified with the number k, $1\leqq k\leqq n$. The kth subsystem is denoted by S_k. The correspondence of S_{ij} to S_k is assumed to be random. Namely, S_k corresponds to S_{ij} with equal probability $1/n$.

(3) The request R_i's processing time by subsystem S_{ij} is denoted by

$$P_{w,j}.$$

Since the system is symmetric and, if a page transfer time between subsystems is assumed independent of

TABLE I.—Performance Degradation

h	c (mega-byte/sec)	$p=1/3$ $E[S]/E[T]=1/20$	$p=1/3$ $E[S]/E[T]=1/200$	$p=1/10$ 1/20	$p=1/10$ 1/200	p=1/100 1/20	p=1/100 1/200	p=1/1000 1/20	p=1/1000 1/200

TABLE II.—Overhead

w	j=1	j=2	j=4	j=6
0.9	0.1	0.505	0.750	0.833
0.7	0.3	0.545	0.752	0.833

the subsystems chosen, Eq. (3) can be used as $P_{w,j}$ where r is to be replaced with $f(j)$ of Eq. (3).

$$P_{w,j}=\{pE[T]+p(1-f(j))(E[U]+E[V])+E[S]\}/q+E[A]$$

The following observations are made.

(1) Under the all selection policy, each request is equally selected by a subsystem. Thus, the average service time would be

$$\frac{\sum_{j=1}^{n} P_{w,j}}{n}.$$

For a system made up of a single subsystem, service time is $P_{1,j}$, which is described by Eq. (2). The system load would be very well balanced, because each request is assigned to the first subsystem that becomes empty. The assignment is a reversed FIFO.

(2) Under the sufficient selection policy, only k subsystems become candidates for selections, where $1 \leqq j \leqq k$ and k is determined by the policy. Variable k itself is a random variable. The average service time would be

$$\frac{\sum_{j=1}^{k} P_{w,j}}{k}.$$

Under this policy, the load would also be well balanced but there may be some processing time loss, because there are some chances that empty subsystems cannot take unprocessed requests because they are assigned to some other busy subsystems. However this loss is ignored for simplicity and the necessary intersubsystem bus capacity is calculated for k=1, 2, 4 and 6, whose results are shown in Table III. It is assumed that the system consists of six subsystems. In Table II, the ratio

$$e=\frac{\sum_{j=1}^{k}(1-f(j))}{k}$$

is shown. The above ratio e is related to variable h defined by Eq. (4) as

$$h=e(E[U]+E[V])/E[T].$$

From Table III it can be observed that, for p=0.01 and $E[S]/E[T]$=1/200, the system can work with 10 percent degradation with h=0.15 or c=0.247 for j=2 and w=0.9. Thus with an intersubsystem bus whose capacity is 1 mega-byte/sec, the system of four can be constructed. With a bus of 4 mega-byte/sec, a system of 16 can be built. If $E[S]/E[T]$=1/20 can be assumed, h=0.900 or C=0.0529 is sufficient. This allows 19 subsystems for a 2 mega-byte/sec bus.

It should be noted that the above analysis is very simple. A more elaborate and precise analysis is clearly necessary and is now under way. Its results will be reported elsewhere. Relating to this, there are better subsystem selection policies. One of them is, for instance, to use the following criterion:

(a) Compute w, using Eq. (1)
(b) If w is fairly high for a subsystem, say w>0.7, then any subsystem whose value of w is not greater than 0.7 drops out.
(c) The smaller the value of w is, the more subsystems can be assigned.
(d) When w=1/n, assign all the subsystems. Analysis of this policy would require a more elaborate analysis and is not included in this paper.

CONCLUDING REMARKS

Extensibility is one of the important system properties of future systems. Among many extensibility aspects, the present work is concerned with extensibility in capacity. Extensibility, in this sense, is first defined and then a scheme to obtain it is proposed and described. The scheme is shown as an algorithm and then its correctness is verified. Extensibility contains automatic load sharing. Scheme optimality is also shown. Performance analysis shows that this scheme can be used to build a fairly large size extensible data base system without much performance degradation.

Extensibility in capacity means three things; physical extensibility, logical extensibility and minimal performance degradation. The key property of the scheme for logical extensibility is that each request is broadcast to each subsystem and is then tried by every subsystem. Eventually, however, one and only one subsystem completes the request. Each subsystem is autonomous and it itself determines when to drop out. In doing this, no exchanges of information about the load of each system are required. For this reason, no consistency problems occur. No system wide mutual exclusions are necessary in this respect, which makes the logic considerably simpler.

The system performance is analyzed using a simple mean-value analysis. It is observed, from this analysis, that a fairly large size data base system can be built, based on the proposed scheme. Necessary capacity of the intersubsystem bus can remain realistic. Any means of reducing missing page ratio would greatly help improve the performance of the system. Here, magnetic bubble or CCD memory can be a great help.

ACKNOWLEDGMENTS

The authors would like to acknowledge Prof. Eric Manning of the University of Waterloo for his helpful comments and our colleagues, particularly Mr. Shigeru Oyanagi at Toshiba Research and Development Center, for their valuable discussions and various supports.

Practical problems in a distributed application

by ERIC D. CARLSON and MARY C. SMYLY
IBM Research Laboratory
San Jose, California

INTRODUCTION

In this report the term "distributed application" is used to refer to application programs with modules which operate on two or more computers, and which communicate with each other in real time. In particular, this report describes experience with an IBM Program Product, Trend Analysis/370 (TA/370). TA/370 is a distributed application employing two computers, a host and a satellite. The satellite computer is used for a color graphics feature, which can produce line graphs or bar charts in multiple colors. The host computer is used for data base management and non-graphical data transformations (such as computing ratios). Figure 1 shows the TA/370 system configuration, and details on the system can be found in the reference manuals.[5,6] In TA/370, user queries are processed in the host computer. If the query contains a request for a graph or bar chart, the appropriate parameters (data and formatting) are transmitted from the host to the satellite. The satellite acts as a formatter and controller for the graphics terminal on which the graphs and bar charts are displayed. Thus, only the graphics formatting and control functions in TA/370 are distributed, and communication is from the host to the satellite.

Of the many possible reasons for a distributed application, the reason for distributing the graphics functions in TA/370 appears to be performance. Specialized graphics formatting functions, such as labelling and scaling, can be performed in the satellite based on encoded commands from the host. Thus, not all the formatting data for a graph need be transmitted from the host to the satellite (reducing transmission time) and the formatting commands can be executed in the satellite. Reduced transmission times and a special-purpose graphics formatter are intended to improve response time and reduce costs for creating graphical outputs in TA/370. To achieve these benefits, a special-purpose protocol for data communications was developed, and the satellite programs for graphics formatting were application-specific and coded in assembler language.

Our experience with TA/370 began with an attempt to modify the code for the satellite in order to be able to use different i/o hardware than supported by TA/370. These were differences in implementation and not in functional capability. Because of the special-purpose nature of the satellite code and data communications protocol, we found modification difficult. Attempting to add new graphical functions to TA/370 appeared even more complicated. The difficulty in modifying and extending the graphical capabilities of TA/370 led us to investigate the possibility of using a general-purpose graphical subroutine package, developed by IBM Research for other applications,[2] in TA/370. Because this subroutine package was developed to operate on the host computer, we expected that we would lose the performance advantages of the distributed processing for graphics in TA/370.

We implemented a prototype revision of TA/370 using the host-based graphics subroutine package. In comparing the prototype with the original TA/370, there was no noticeable change in response times. Further investigation of the two versions was made to find out why the theoretical performance advantage for distributed processing was not realized in practice. The results of this investigation indicated that the overhead in the host-satellite protocol was so large that advantages from reduced data transmission or parallel processing did not affect response time significantly. In addition, advantages from distributed processing appeared to be offset by need for data encoding and decoding to communicate between the host and the satellite. Use of a general-purpose software package operating on the host computer seemed to offer greater flexibility, easier maintenance and extensions, and reduced hardware and programming costs without any performance penalty compared to the original version of TA/370.

In the next section of the report we describe in more detail why we wanted to modify TA/370 and the problems we encountered in doing so. The third section describes the implementation of the "non-distributed" prototype and the benchmark comparison with the distributed TA/370. In the fourth section we analyze the results of the comparison, and in the fifth section we discuss some alternatives for distributed processing in applications such as TA/370.

THE PROBLEMS WITH THE DISTRIBUTED VERSION

We were interested in modifying TA/370 for two reasons: (1) to make it operational on a satellite computer with a different graphics terminal and host-satellite communications interface, and (2) to add new graphical functions (such

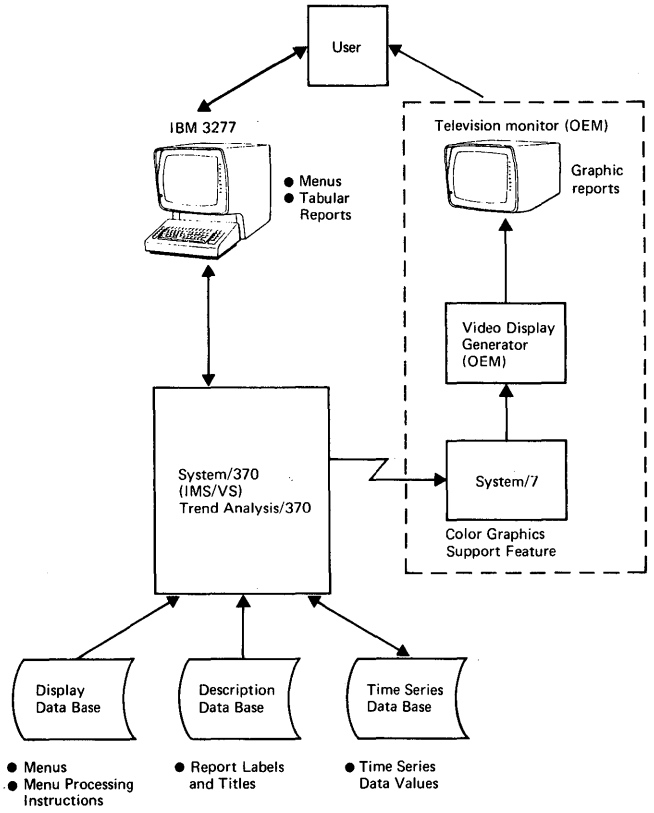

Figure 1—Trend analysis/370 configuration

as drawing maps). The modification to support different I/O hardware involved adding a few hundred lines of code to the TA/370 modules in the satellite. The addition of new function would require adding modules in both the satellite and the host. Because of time constraints and the difficulty of modifications, only the modifications needed to support the I/O hardware were completed.

In making the modifications we encountered several problems:

1. The satellite code was special-purpose, designed for this application and satellite computer, and was written in assembler language. Even after six months of work, we never totally understood the satellite code, and the programmer who wrote the original code had to make the modifications. Even if we had been experts in the assembler language for the satellite, modifying the code would have been difficult because it required detailed knowledge of the hardware and of the data communications protocols.
2. Communication between the host and the satellite used a special-purpose set of records, with five basic record types, each of which was encoded at the bit level. That is, instead of using an extension of a standard communications format, such as the ASCII character set, TA/370 essentially used five special-purpose bit strings for which we had to learn the encoding and decoding.
3. The distribution of graphics function had resulted in duplication of functions in the host and the satellite computers. Specifically, the host modules scaled the data to be displayed into value ranges compatible with the range of values which could be represented in one word on the satellite, and the satellite rescaled the data into ranges compatible with the address space of the graphics display. In addition, the host modules encoded the graphics commands and data into the five special purpose records for transmission to the satellite, and the satellite modules decoded these records and then recoded the data for transmission to the graphics terminal. Thus to make any modifications to the graphics modules, one had to understand the details of both the host and the satellite coding schemes.

In looking at more complicated modifications of TA/370, such as adding new graphics functions or supporting a different type of graphics terminal, it was apparent to us that problems, such as those listed above, would become more severe. We would have to add and modify code in both the host and the satellite and we would have to modify or extend the data communications records.

EXPERIENCE WITH A NONDISTRIBUTED VERSION

Graphics functions in the nondistributed version

We had several years experience with an application similar to TA/370 in which the graphics functions were not distributed.[2] This system used a general-purpose graphics subroutine package, called DISPLIB, which was developed to support a variety of graphics functions and graphics terminals. This package, written in FORTRAN, provides basic commands for displaying text, lines, and points, as well as for display transformation (e.g., scaling) and user input. The package is similar in style to the standard subroutine package currently being proposed by ACM SIGGRAPH.[1] The package also uses extensions of the ASCII or Correspondence character sets for graphics communication to the terminal; this convention is used by several terminal manufacturers. Because the package operated on the host computer, its use in TA/370 required that we not distribute the graphics functions. We expected that this change to a nondistributed application might degrade performance.

A prototype version of TA/370 using DISPLIB was implemented. The prototype supported only simple bar charts and therefore was not functionally equivalent to the original TA/370. In addition, the prototype simply translated the five records (that TA/370 created to send to the satellite) into DISPLIB calls. It would have been more efficient to replace the TA/370 code that creates the five records with code calling DISPLIB, but simply translating the records required fewer changes to TA/370 and was easier to program.

Comparison: distributed and nondistributed

Table I gives a comparison of the graphics functions in TA/370 and those in our prototype revision of TA/370. This comparison indicates the basic differences between the two versions.

The prototype was implemented and a benchmark bar chart containing data on six organizations for five years

TABLE I.—Comparison of Graphics in TA/370 and TA/370 Prototype

Feature	TA/370	TA/370 Prototype
graphics package language	assembler	FORTRAN
style	special-purpose	general-purpose
graphics function implemented on	satellite	host
graphics functions invoked by	building graphics records	subroutine calls
host code language	PL/1	PL/1
type of graphics	line graphs and bar charts	simple bar charts
communications	5 special record types	ASCII extension
what communicated	data + graphics format codes	data + graphics formats
terminals per satellite	4	1
terminal types supported	1 (raster)	3 (raster, vector, storage)
size of host code for graphics (approximate)	29K bytes	113K bytes
lines of host code written by applications programmer (approx.)	500	170
satellite code size (approximate)	47K bytes	24K bytes

(=30 bars) was used to compare performance. Amount of code and communication load also were compared, and flexibility and programming cost were compared subjectively.

1. *Response time:* For each version the time to draw the bar chart was about 15 seconds. (Note: in other installations of TA/370 which use a S/7 with hardware features to assist in host-satellite communications, response times for bar charts similar to the one used in our benchmark are about 10 seconds.)
2. *Communication load:* In the original TA/370 implementation about 800 bytes of bar chart values and formatting keys were transmitted from the host to the satellite. In the prototype version of TA/370 about 2500 bytes of bar chart values and formatting data had to be transmitted. Transmission was at 1200 Baud. TA/370 sends 268 byte blocks and the prototype used 256 byte blocks.
3. *Communications protocol:* Both versions use 1200 Baud asynchronous communication over voice grade lines. The original version uses a transmission code (Paper Tape Transmission Code) developed for IBM 2740-1 terminals. The prototype based on DISPLIB uses ASCII or Correspondence codes. The protocol in the original version uses five special-purpose data communications records with host-satellite "handshaking" after each block is transmitted. The prototype uses "standard" ASCII codes with "handshaking" only at the start of host-satellite communications.
4. *Amount of code:* Even though we implemented only a subset of the TA/370 graphics functions, the prototype version of TA/370 required much more code in the host because a general-purpose package was used. However, the applications programmer wrote less code in the prototype because this package was available. The code written by the applications programmer in the prototype is about 10 percent of the total amount of code, whereas in the original TA/370 it is 100 percent. We estimate that if we had chosen to implement only the TA/370 graphics functions (eliminating any DISPLIB code not required for these functions) and to rewrite the TA/370 host code for (creating graphics records rather than adding code to translate those records into DISPLIB calls), the amount of host code in both versions would have been approximately equal. Any implementation of the prototype would require less code in the satellite. Moreover, the satellite code used in the prototype would support all the TA/370 graphics functions and would not require modifications for most additional graphics functions.
5. *Size of satellite computer:* The original TA/370 required an IBM System/7 with disk storage, while the prototype could operate using an IBM 5100. The System/7 is about five times more expensive that the 5100 (about $50,000 more).
6. *Programming cost and skill level:* Because the prototype used a high-level language of graphics calls rather than having to create records at the bit level, we believe that the cost to program the prototype was less than the cost to program the equivalent function in the original TA/370. The prototype was developed in less than two person months for a programmer who was not familiar with the DISPLIB package. In addition, both the host and satellite code for graphics in the prototype would not need to be changed if new graphics functions were required. This type of general-purpose graphics

would greatly reduce the programming cost for modifications of TA/370.

7. *Flexibility:* Because the prototype used a high-level language for graphics functions, and a general-purpose graphics subroutine package which supported several types of terminals, we believe that the prototype version was more flexible and would be easier to modify or extend than the original version of TA/370.

In summary, the experience with the prototype indicated that a nondistributed version of TA/370, using a general-purpose graphics subroutine package would not degrade performance, even though the communication load was increased, and would offer significant advantages in terms of hardware costs, programming costs, and flexibility. The performance results of the benchmark were not as expected, so the prototype and original versions were further analyzed to try to better understand the performance implications of the distributed versus the nondistributed implementations.

ANALYSIS: DISTRIBUTED VERSUS NONDISTRIBUTED VERSIONS

One could argue that the prototype performed as well as the original version of TA/370 because we implemented only a subset of the graphics functions of TA/370 and because we had the advantage having the original version as a model for implementing the prototype. Both these arguments are partially true, but further analysis indicated that even with equal functions and equal skill in implementation one should not expect much difference in performance between the distributed and nondistributed versions. The analysis indicated that the predominate factor in performance was the time to transmit data from the host to the satellite over the 1200 Baud line. For the bar chart used in the benchmark comparison the original version of TA/370 transmitted less (about one-third as much) data than the prototype version. However, in the original version of TA/370 there is "handshaking" between the host and the satellite once for every transmitted block. This "handshaking" is implemented in software. The "handshaking" consumes enough time to eliminate any performance advantage for the original TA/370 due to reduced data transmission.

This informal analysis of the performance of each version is substantiated by an analysis using a simple model. This model is a simplification of a model of distributed (graphics) systems proposed by Foley.[3] The model consists of four factors which affect performance: data base access time in the host, execution time in the satellite, and data transmission time. Thus for any graphics function in either version, a model of performance is:

T=TD*ND+TH*IH+TS*IS+TT*TL

where:

T=total time (e.g., response time)

TD=average time for data access in host, ND=number of data base accesses

TH=execution speed of host, TS=execution speed of satellite

IH=instructions executed in host, IS=instructions executed in satellite

TT=transmission speed, TL=transmission load

For either the distributed or nondistributed versions of TA/370, the TT*TL term in the model is the predominate factor. Transmission speed is 1200 Baud and the transmission load is in thousands of bits, so that TT*TL results in times measured in seconds. The data base access times (TD*ND) in both versions are equal because the same data must be retrieved. These times are usually in hundredths of a second. The host and satellite execution speeds are approximately equal because the satellite is about one-third as fast as the host, but the host is time-shared and time-sharing, on the average, reduces the effective execution speed by about one-third. The execution plus data base access times (TD*ND+TH*IH+TS*IS) in both versions of the system are in tenths of seconds. Thus, the model indicates that any performance difference between the two versions is going to be due to differences in transmission times. Detailed expressions for computing the transmission loads in each version were worked out, but are omitted here. In general, for a simple graph or bar chart the transmission load in the original TA/370 is about half that in the prototype (approximately 600 bytes compared to 1200 bytes). For a complicated graph it may be only one-sixth as much (about 1000 bytes compared to 6000 bytes). Note that at 1200 Baud the transmission load in the prototype version could take up to 40 seconds to transmit. In practice, however, the performance advantage that this simple model predicts for the original version is not realized. As previously mentioned, the practical failure to realize this advantage seems to be due to the overhead of the transmission protocol used in the original version.

ALTERNATIVES FOR DISTRIBUTED FUNCTION

Models of distributed applications

To choose among alternative configurations for a distributed application such as TA/370, one could use the model proposed by Foley.[3] Given a set of alternatives for host, satellite, and data link hardware this model can be used to select the configuration which will produce the best response time for a given cost constraint. However, one needs to have predetermined the distribution of function and to have estimated the frequencies of graphic macro instructions, the probabilities of various user interactions, and the data base accesses required per interaction.

It would be very difficult to estimate the parameters of TA/370 and the parameters of hardware alternatives needed for the Foley model. More significantly, the hardware alternatives for TA/370 are restricted by the application's requirement for a color graphics terminal which could be attached to a host over voice grade lines. Therefore, the Foley

model does not provide much help in selecting among alternative distributions of function for TA/370. However, Foley used his model to analyze four "typical" graphics applications, one of which, two dimensional drawing, is similar to TA/370.[3] Foley's analysis considered over 12,000 possible hardware configurations. Based on this analysis, Foley recommended that, in general, the best system configuration for graphics applications consisted of the simplest possible satellite (which provided enough function) using a voice-grade (2400 Baud) data link. Foley's analysis indicated that the data link and bulk storage on the satellite are the two components which most influence response time. Foley's analysis of distributed applications thus is very similar to our study of TA/370: data transmission load is the key variable affecting cost/performance in a distributed application, and distribution of function (or data) is useful only to the extent that it helps reduce this load.

Foley's model gives us insight in selecting a hardware configuration, given a set of functional modules for a distributed application. For a given hardware configuration and function modularization, a graph partitioning model, such as that suggested by Hamlin,[4] can be used to decide which modules should be distributed. In a graph model of a program, the modules are nodes and among the nodes there are directed arcs which represent the calling and returning structure of the program. Associated with each arc is a cost, such as the amount of data passed or the overhead time for calling. Other costs, such as the amount of global data accessed from each module or the execution time for each module on the host and on the satellite, may be associated with each node. The graph partitioning algorithm attempts to minimize the cost associated with assigning the modules (nodes) to the host or the satellite. To do this, the model requires an estimate of the frequencies of data accesses and inter-module calls. For an example of such a model see Hamlin.[4] As indicated by Hamlin's example, unless there are constraints (such as limited memory space) which prevent all modules from being assigned to one computer, the cost function usually is minimized if there is no distribution of function.

Note that both the Foley and Hamlin models assume that the program modules are defined. Yet the definition of the modules is a primary factor affecting the cost functions in both models. This suggests the need for a model based on the costs of performing various graphics functions, independent of program modularization, which could be used to analyze alternative modularizations. In addition, both models require many parameters of the application, program, and hardware. Estimating these parameters is difficult, and likely to be error prone. To the extent that the models are sensitive to errors in the parameters one would expect the models to suggest suboptimal alternatives which, if used, would need performance tuning. For performance tuning, it would be useful to be able to move program modules between the host and satellite computers. To make this easier, one needs to be able to compile and execute the same language on both machines,[4] and to have a mechanism which supports calls and parameter passing among modules on different machines.

Possible alternatives for TA/370

The general guidelines of the Foley and Hamlin models for distributed applications suggest two alternatives for TA/370.

1. Reduce the size of the satellite computer and the modules assigned to it to as small as possible to contain the bar chart and graph formatting functions. Place all remaining modules in the host. This distribution will limit data transmission to data values only. The double encoding/decoding and data scaling currently in TA/370 will be eliminated. Our prototype is representative of this alternative.
2. Distribute the entire application program to the satellite, with batch transmission of a subset of the data base to each satellite on an as-needed basis. However, both the data base and the application program are too large for most satellites. A variation of this alternative would be to keep a working-set of the data base in the satellite (e.g., the data used in the previous "*n*" displays), and distribute all the graphics functions to the satellite, as done in the original TA/370. This alternative will reduce the data transmission because all the data for a graph or chart will not need to be transmitted if it is a variation on one of the charts stored in the working-set.

For either alternative it would be beneficial to use the highest speed communication link compatible with the applications' requirement for a voice-grade line. Currently 4800 Baud is possible, although to use 4800 Baud would require changes to the satellite hardware (System 7 or 5100) and to the communications protocol (bisynchronous instead of asynchronous).

CONCLUSIONS

The experience with TA/370 identified several practical problems in distributed applications:

1. The potential performance advantage of distributed function was reduced because of the overhead of host-satellite communication protocol.
2. Distributed function resulted in special-purpose programming and data encodings which made modifications and extensions difficult.
3. Distributed function greatly increased the cost of the satellite computer, without compensating savings in the cost of the host computer.
4. Distributed function probably increased the amount of code and the programming cost for this application.
5. Transmission time between the host and the satellite was the primary performance factor. The application's need for a 1200 Baud line limited the performance improvement that could be achieved by distributed function as long as the data base was stored on the host.

6. Deciding how to distribute function involves considering hardware configuration, alternative distribution of program modules and data, and alternative modularizations. Existing analytic models of distributed applications do not encompass all of these considerations.
7. In designing distributed applications such as TA/370 the constraints are: the available hardware, the hardware costs, and the software development and maintenance costs. As with most programs, the software development and maintenance costs are likely to be the most important constraint.

This study does not indicate that distributed processing is ineffective for applications such as TA/370. It does indicate that distributed processing is not simply a separation of function among computers, because the separation requires communication. Because communication is involved, design decisions can become more complicated (as indicated by Foley's model), and unexpected inefficiencies can result (such as the "handshaking" problem). Most importantly, when the design objectives change (e.g., added function or different hardware), a distributed implementation may be more difficult to modify than a non-distributed version. Our experience with TA/370 indicates that these "practical" problems can eliminate a theoretical advantage for a distributed application.

A panel session—Distributed systems—A challenge to management

SESSION CHAIRMAN—GEORGE M. CRANDELL, JR.
McKinsey & Company, Inc.

Panel Members

Lester Stubbs—Mattel Toys
Michael C. Dowling—Fireman's Fund Insurance Company
Mario Calderin—Aratex, Inc.

PANEL OVERVIEW—George M. Crandell, Jr.

This session addresses the management issues and decisions that concern MIS directors, project leaders, and users in the implementation of distributed systems. The panelists, who have been selected to provide a cross section of industries, will briefly describe their distributed systems and then focus on the most significant managerial/organizational challenges encountered during implementation. The pros and cons of alternative approaches will be evaluated, and mistakes as well as successes will be discussed.

Areas to be explored include:

1. Considerations and caveats in allocating responsibilities between headquarters and local MIS personnel, users, hardware vendors, and software houses/consultants
2. Approaches for carrying out system design, development, implementation, training, maintenance and trouble handling
3. Lessons learned by the panelists from their experiences, and their suggestions for avoiding potential pitfalls.

There will be considerable time for questions and general discussion following the presentation.

INSTALLING IBM 3790's IN A MANUFACTURING ENVIRONMENT—Lester Stubbs

During the last two years Mattel Toys has installed various phases of its new manufacturing system utilizing the IBM 3790 in a distributed processing environment. Each installation has been extremely smooth and relatively error-free. Besides having luck on its side, Mattel used a project management approach throughout the development and implementation process that contributed greatly to this success. This presentation is centered around the actual implementations and the planning that went into them.

There are two extremely important factors that must be continually evaluated for any new system being developed. The first is constant review to make sure that the system will meet the end-users' needs and that the end-users can effectively work with the system in a production environment. The second factor is selecting and tailoring the equipment so that it will perform properly when in production. A closer look at how Mattel approached these two factors will be presented.

As installation nears, there is system testing, user testing, acceptance testing, system documentation, equipment installation and conversion. How Mattel approached each of these tasks will be reviewed. The project management approach used will be emphasized and the critical factors will be evaluated.

Finally, there is the day of installation. If properly planned, this event can be very anti-climactic. The first few weeks of production will be reviewed with emphasis on Mattel's warranty period concept.

Everyone hopes to install a system that is a glowing success, and, through personal experiences and the experiences of others, system installations can result in rewarding experiences for all. Hopefully, this presentation, and others like it, will help.

DISTRIBUTED DATA PROCESSING IN A CLERICAL ENVIRONMENT—Michael C. Dowling

Fireman's Fund direction and plans in distributed data processing must be taken in the context of the nature of its business, its field organization, its current data network, its relationship to American Express Data Processing, and its view of the business process and its role in the marketplace over the next 10 years. Given our structure and business needs we sought a means of reducing our operating expenses while improving the quality and speed of services we provide, i.e., insurance policies, quotes, and loss payments. Data processing and improved manual procedures provided a basis for achieving this business objective.

In the data processing area, we looked at the technology

available and found that three fundamentally different approaches were available:

1. Batch store and forward
2. On-line processing
3. Local processing.

Our research into the business needs indicated that to reduce cost and improve service we should use all three approaches in an optimum mix. Thus we are aggressively pursuing the development of systems utilizing all three fundamental approaches. From a strategic point of view, we intend to place computing power in the hands of our local offices while retaining full control of programming and program version release at the central site.

In order to adequately address the new business and systems environment of remote computers and computer processing in essentially clerical offices, we established a Distributed Systems Department. This department is responsible for all local applications and the local portion of batch store and forward applications. The department reports to the Senior Systems Executive and is essentially a microcosm of the total systems organization.

Not only did the systems organization undergo substantial revision, but new user departments were created and an extremely active and important executive steering committee was established. The business executive was made responsible for priority setting, business definition, systems justification and establishment of a responsive Business Systems Plan.

As our systems become an integral part of our daily field operations, we are learning what manufacturing companies with computer assisted production have known for some time: that a new level of responsiveness to system problems is required. We have been deeply committed to this task for the last two years and we have learned lessons in every area from equipment selection to field implementation. Most importantly, however, we have developed from our experience seven postulates for effective distributed system development:

1. Demand user participation
2. Insure management commitment
3. Maintain high visibility
4. Fund development on a step by step basis
5. Define accountability
6. Balance technology with business needs
7. Integrate manual systems planning with EDP systems planning.

DISTRIBUTED SYSTEMS IN RETROSPECT: LESSONS WE LEARNED THE HARD WAY—Mario Calderin

Aratex, Inc., an Encino, California based textile rental company, installed one of the first 3790 distributed processing networks in the country. Running under the Systems Network Architecture (SNA), the 3790 has brought new data processing capabilities to the company's remote locations.

At each of Aratex's 35 locations across the country, plant personnel using 3271 display terminals linked to a 3791 controller, which acts like a small computer with its own locally stored data, constantly update and interrogate data regarding Customer Billing, Accounts Receivable, Payroll, Sales Analysis, and Inventory Control. All data is checked for validity using extensive edit programs. Since the system is installed at locations where there is no EDP expertise, all transactions are checkpointed to provide automatic restart capability.

At the end of the day, all pertinent data is transmitted unattended to a 370/148 at the Encino National Data Center. After the necessary processing is performed, approximately 500,000 lines of output is transmitted back to the remote locations daily, where it is printed on the 3790 printer. A 3790 system is also installed as part of the network at the company's Central Warehouse facility in Fresno, California. The system accepts on-line order entry transactions from 3790's at any plant in the network and produces order status, packing slips, shipping confirmation, and invoices at the warehouse, as well as assigning goods for replenishing random locations, and regulating the warehouse work schedule based on order arrival frequency.

The entire system is comprised of over 400 programs developed over the last two years. As one of the first companies in the United States to deal extensively with distributed processing, we have developed expertise in the control aspects. Our experience indicates that the most important areas to consider are:

1. Control of programs at remote sites
2. Data synchronization between remote sites and central data bases
3. Communication programs to allow simultaneous transmissions to and from the host system by multiple users
4. User backup and recovery in case of down-time
5. Response to user questions while operating the system
6. Centralized problem determination for both hardware and software
7. User training
8. System installation guidelines.

Database management systems

Database management as a technology has made tremendous strides in recent years. Database management systems are offered by every major hardware vendor and many software houses. Installations which operate database management systems in support of their management's objects now number in the thousands. Two database management specialized conferences are held each year with hundreds of attendees present. The first of these is held by the ACM Special Interest Group on the Management of Data (SIGMOD). The second is the Very Large Database Conference (VLDB) which has moved around the world with Germany as the host for 1978. These newer conferences have collected most of the leading edge database technology papers because it is possible to concentrate more of the research-oriented people, their papers and discussions into smaller towns and smaller hotels.

Therefore, the Database Management sessions for NCC '78 have focussed upon the problems and solutions associated with use of the currently available database management systems. Four panel discussions and four technical sessions have been planned for your attendance at NCC '78. Three of these panel sessions are focussed upon users' experiences relating to their database systems. One panel session focusses on "end user facilities," one of the leading edge areas of database management. The four technical sessions bring papers which are oriented toward improving performance of database systems, distributed database systems, conversion and language aspects of database systems.

For the many thousands who may not be familiar with the concepts of database management systems, a short primer may be appropriate so that the panel discussions and technical sessions will make some sense.

What is database management? Roughly, this means the establishment, and maintenance of computerized collections of information about an enterprise (manufacturing company, bank, hospital, school or other organizations). This infor-

mation, stored in permanent files, contains historical, current and future planning information about the enterprise. All this information is collected and preserved at considerable expense so that it will be available when needed; to answer a question, to assist in making a decision, or to guide someone as to the next task to execute. This collection of information has been called the database, as it forms the basis or foundation upon which the operations of an enterprise is built.

Database data represents one of the two kinds of data found in a computerized information system. The other kind is message data. The easiest way to understand the difference between the two kinds of data is to ask the question "what happens after the data has been processed?" Database data is characterized as being put away and remaining static until some process subsequently requests its retrieval. Message data, on the other hand, is active. It is being transferred by one process because it is relevant to the actions of another process which is anticipating its receipt. One or both of these processes may be manual and outside of the computer. Thus, the message data and database data complement each other and represent the "hurry up" and "wait" of the computerized information systems. Database Management is the title given to the art of storing and retrieving data. Message Management and Communications Management are the titles given to logical and physical aspects of moving data between processes. The reader is urged to look at the sessions with titles using the term "communications" or "networks" or "distributed systems" to find additional material on the current state of the data movement technologies.

Network database evaluation using analytical modeling*

by TOBY J. TEOREY and LEWIS B. OBERLANDER
The University of Michigan
Ann Arbor, Michigan

INTRODUCTION

The proliferation of computerized databases and the widespread demand for timely access to data has resulted in the need to develop automated techniques for database design. In the past, database design was accomplished manually by data processing personnel through past experience and trial and error. However, the implementation of large integrated databases in organizations made it increasingly difficult for individual users to do the necessary design. A new approach was required to consider the many tradeoffs among user objectives and within the complex logical structures required to integrate the various types of data.

The stages of database design have only recently been well-defined,[5] and much of that work is still done manually with some assorted design aids available at some of the stages. One of the more quantifiable stages in the database design process is the implementation of a physical database from a logical database design. Logical database design results in the definition of record types and their relationships under the constraints of a particular data model, but independent of physical structure. The design of the physical database must take into account the variations in access methods, i.e., the access paths and search mechanisms available, as well as physical clustering of records near each other within blocks or in a contiguously defined set of blocks. Considerably more insight is required in physical database design before determining whether or not it can be accomplished independently of logical database design.

Currently there exist some very general physical database designers[10,13] which address tradeoffs among major classes of storage structure. On the other hand, several evaluators of physical databases have also been proposed. Some are simulation models and are quite expensive to run.[2,7,9] Others are probabilistic and are limited by expected value assumptions.[3,11]

This paper described the concepts leading to the development of an operational Database Design Evaluator (DBDE), which accounts for the more significant parameters affecting physical database design performance and yet is computationally fast enough for consideration as the central module of a physical designer. The DBDE is a software package which evaluates Honeywell's Integrated Data Store or IDS.[6] While the model produces "expected value" results, it goes beyond the usual expected value assumptions and considers the effects of the distribution of logical record sizes and placement. The DBDE is directly applicable to CODASYL database systems.

The most easily identifiable forerunner to the DBDE was the general analytical method of evaluating physical database designs for single record type files proposed by Yao.[13,14] The general method decomposed all candidate organizations and access methods into several basic parameters: the number of index levels, the expected search length at each index level and the level of usable data, and the fraction of sequential accesses versus pointer (random) accesses at each level. All applications were assumed to consist of randomly addressed operations such as queries and updates.

The File Design Analyzer[11] extended the basic method to consider both sequential and batched processing in addition to random processing, and it extended the concept of the pointer (random) access parameter to specify the degree of randomness required by each configuration. An example of this is the implementation of overflow in an indexed sequential organization. The pointer to an overflow record could refer to another point on the same track, another track with the same cylinder, a different cylinder or even a different device. Each specification would imply a different expected access time to the overflow area. This extension enabled the File Design Analyzer to determine a range of performance between "single access" (i.e., a dedicated device with no seek time, but including an average rotational delay between consecutive sequential accesses) and "multi-access" (i.e., a shared device with the worst case conditions of all consecutive sequential accesses becoming random accesses in reality). The purpose of this dichotomy was to place bounds on I/O service time for the extremes of one user and many users. No attempt was made to determine the effect on queuing delays with this model or with the DBDE.

The DBDE does, however, represent significant improvements over the previous models in the following areas:

1. Computation of database overflow probabilities on the basis of database growth and distribution of record size, and determination of the effect of increasing

* Supported by the Defense Communications Agency, Contract Number DCA 100-75-C-0064 for the WWMCCS ADP Directorate, Reston, Virginia

overflow on the I/O service time required to execute various data manipulation operations.
2. The effect of buffering on I/O service time.
3. The modeling of "currency" and dependent sequences of operations performed on network databases.

Other analytical models have been confined to storage structures for flat files or hierarchical systems, but have not considered network databases. The proliferation of CODASYL DBTG or similar implementations for network databases have increased the need for network evaluation models.

INTEGRATED DATA STORE (IDS)

The Integrated Data Store (IDS) is a host language Database Management System which interfaces extensively with COBOL. It was developed in 1963 by General Electric and is now being used on the Honeywell 6000 series and other configurations. It is widely regarded as a forerunner of the CODASYL DBTG concepts, and is very close to the specifications of the 1971 DBTG report.[4] It was developed to organize information so as to minimize redundancy and duplication of records or data, provide a single database for many applications, store and retrieve logically related data in cohesive manner, and provide an efficient query capability.[6]

The structure of IDS may best be summarized in terms of the interrelationships between records and access mechanisms, and chain classification.

Record classification

A record may either be a master record or a detail record. Masters and details are related to each other by means of chains. A chain may contain only one master record. However, a record may be the master or detail of more than one chain, and a record may be a master in one chain and a detail in another chain simultaneously. All IDS records of a specific record type are fixed length and fixed format. Different record types may have different lengths and formats.

Another form of record classification is by the retrieval access mechanism. Three methods are allowed in IDS:

1. Primary records—retrieved by reference codes which point directly to the physical page and line number on which the record resides. The page is the basic unit of transfer between secondary storage and main storage. It is a physical block (with fixed size in subfiles, somewhat analogous to DBTG areas) that may contain many record types simultaneously. PAGE RANGE is a feature of IDS that specifies a set of physically contiguous blocks (pages) to contain records of a given type or types.
2. Calculated records—retrieved by calculating a page address (via hash code) from a particular key value. A sequential search in the page and possibly an overflow page yields the desired record.
3. Secondary records—These are records that can only be retrieved by accessing the master records and then traversing the chain to which they belong. Often it is possible that the immediate master cannot be accessed directly. In this event, master records that are on a higher level than that of the required immediate master need to be accessed. The search is then performed from these higher level records down to the immediate master in question and then finally to the desired secondary record. Such higher level masters are known as entry points and are accessed via primary record operation, calculated (CALC) record operation or by a RETRIEVE master record operation.

Chain classification

In IDS a record may belong to any number of chains. If retrieval of a record is specified by a particular chain, it is retrieved via that chain. If the chain through which the record is to be retrieved is not specifically stated, the record is retrieved via its prime chain which is declared a priori (in the RETRIEVAL VIA CLAUSE). This manner of retrieval by means of a chain applies only to the secondary records.

Finally, a chain may be implemented as any combination of the options chain PRIOR (backward pointer) and chain MASTER (pointer to the master record). Every chain has a NEXT (forward) pointer.

MODEL PARAMETERS

DBDE inputs

Categories of inputs and outputs are summarized in Figure 1.

a. Database Description

The IDS model requires the definition of master records and detail records of chains, the page size and page range of subfiles, and the record lengths and page ranges of all record types (see Table I for an example).

b. Workload Specification

The model identifies applications in terms of specific IDS operations called: RETRIEVE, HEAD (i.e., find master record), STORE, DELETE, MODIFY, and QUERY. An application can be defined by a sequence of related retrieval operations, which traverse the network in various ways, ending with a specified operation on the desired record(s). It is also possible to specify location mode in terms of database entry points and type of access method, and the PLACE NEAR option. PLACE NEAR allows the clustering of detail records near master records they are most frequently processed with.

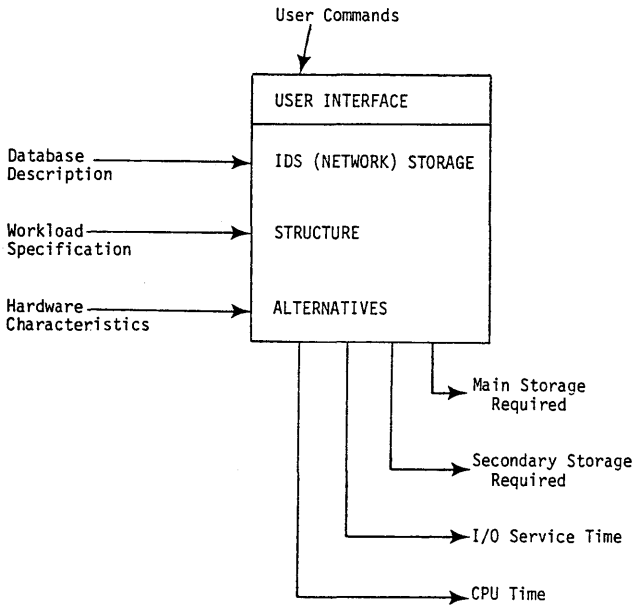

Figure 1—The data base design evaluator (DBDE)

c. Hardware Characteristics

Hardware specifications are, for the most part, limited to the timing characteristics and capacity levels of the secondary storage subsystem. It is assumed that only one type of secondary storage device is used, although the alternative types of devices could be evaluated by reinitializing these parameters. In IDS, allocation across several devices is possible.

Other input parameters which fall loosely under the category of hardware are the estimated CPU time required to initiate I/O starts and completions, the CPU time for moving data within main storage, and the main storage required for support software plus user applications.

One parameter that falls in none of the above categories is the specification that the effect of overflow on performance is desired. The analyst may specify any number of time periods that overflow performance data is to be computed, with the database growth rate implicitly specified by the current database size and the number of record additions per time period. All computations in the DBDE are based on a unit time period. The analyst may choose the most meaningful time unit for his analysis, and merely needs to be consistent with that time unit when specifying workload parameters and overflow time periods.

DBDE outputs

The DBDE outputs reflect an attempt to present a fairly complete picture of resource usage and the components of response time. Enough performance data is given so the analyst can estimate the real cost of the applications evaluated.

a. Main Storage Requirement

This is a straightforward computation, adding the user estimate for object program storage space to the space required for buffers for each application.

b. Secondary Storage Requirement

In IDS this is input explicitly by the user (analyst) in terms of subfile specifications for first and last page numbers.

c. I/O Service Time

I/O time implies elapsed I/O service time, which affects either response time or turnaround time. It differs from channel time in that it always includes all the major components of I/O service: seek time, rotational delay, and data transfer. Bounds on I/O time are provided for the extremes of "single access", and "multi-access" configurations described above.

d. CPU Time

The DBDE estimates the CPU time required for the database functions: overhead to start and complete I/O commands (for physical reads and writes), time for data movement between buffers and user work areas where applicable, database search time, and software write verification. The user CPU time to process logical records is merely echoed from the input data, and is an optional feature.

MAJOR COMPONENTS

An algorithm for database sizing and overflow computation

Given a database with N records of varying size, an algorithm to determine its size needs to answer the following questions:

1. How many physical blocks (pages) will be required if the database is organized sequentially and the ordering results in random placement of records of a given size?
2. How many record occurrences will typically fit into a block?

The first question is of interest in modeling the record distribution or population of sequential and indexed sequential database organizations, which can be computed by the DBDE. The second question is of interest in modeling the placement of chains in IDS.

If all records were of the same size, R words, and the physical block size were B words, then the number of records that could fit into a block would be $\left[\frac{B}{R}\right]^-$ where [expr]$^-$ denotes the "floor function" or "greatest integer equal to or smaller than" the actual value of the

TABLE I—Input data for test network database

HARDWARE SECTION	
Secondary storage device	Honeywell 6060/DSS191
Average seek time	30 millisec
Adjacent cyl. seek time	10 millisec
Avg. rotational latency	8.35 millisec

expression. The resulting database size would be

$$\left\lceil \frac{N}{\left\lceil \frac{B}{R} \right\rceil^-} \right\rceil^+ \quad \text{blocks}$$

where [expr]+ denotes the "ceiling function" or "smallest integer equal to or greater than" the actual value of the expression.

The problem becomes significantly more difficult when there are a variety of record sizes and not much is known about their distribution in the database. The database size is extremely sensitive to record placement when there are very few record sizes, but a large difference in those sizes.

An example will help illustrate the possible extreme values. Suppose there were 1000 records of length 20 words and 1000 records of length 90 words and a constant block size of 100 words. If the ordering specified all the large records must come first and all the small records second, the total size of the database would be:

$$\text{DATABASE SIZE} = \left\lceil \frac{1000}{\left\lceil \frac{100}{90} \right\rceil^-} \right\rceil^+ + \left\lceil \frac{1000}{\left\lceil \frac{100}{20} \right\rceil^-} \right\rceil^+$$

$$= 1000 + 200$$

$$= 1200 \text{ blocks}$$

On the other hand, an ordering which alternated large and small records would require 2000 blocks. Any other ordering of records would produce a database size somewhere between these two extremes. For very large databases this nearly 2-to-1 difference in size will greatly affect the estimated performance for many applications, and consequently record distribution must be represented accurately in the model.

The algorithm assumes that the size of any record in the database is independent of the size of its neighbors. If this assumption is not true for sequential or indexed sequential organizations, then the database size must be computed manually. The IDS model allows dependent record placement to be specified in terms of page ranges. The algorithm then enumerates the possible combinations of record sizes that would overflow a physical block and require the populating of the next block, and it obtains a distribution of unused space in each block. The expected used space in a block, called E(used), is easily computed as the difference between block size B and the expected value for unused space. The total database size is therefore computed as

$$\text{DATABASE SIZE} = \left[\sum_{\substack{\text{ALL} \\ \text{RECORD} \\ \text{TYPES;}}} \text{Record\_size}_j * \text{Number\_of\_occurrences}_j / \text{E(used)} \right]^+$$

where a record type is defined by its length and number of occurrences.

The algorithm takes into account parameters such as percent fill and page overhead associated with specific storage structures in order to compute realistic values for E(used).[12]

As an example of the type of analysis required, let the database consist of 1000 records with an expected record size of 200 words and a block size of 320 words. The actual distribution of record size is:

Record Type	Record Size (Words)	Number of Occurrences
A	100	300
B	200	400
C	300	300

For this simple configuration, a random distribution of record types across the database results in the seven possible arrangements of records in a block shown in Figure 2 occurring with the probability P_1, i = 1, 2, . . . , 7. From the

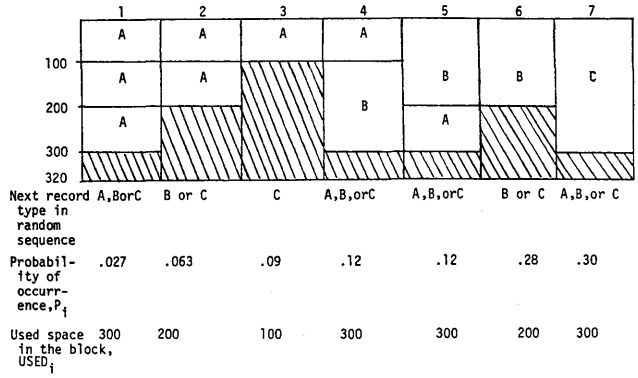

Figure 2—Random sequence distribution of record types in blocks

data in Figure 2 we can compute the expected value of used space in each block and then the database size.

$$\text{E[used]} = \sum_{i=1}^{7} P_i * \text{USED}_i = 247.7 \text{ words}$$

$$\text{Total data volume} = \sum_{j=1}^{3} \text{Record\_size}_j * \text{Number\_of\_occurrences}$$

where j is the number of record types

$$= 100 * 300 + 200 * 400 + 300 * 300$$

$$= 200{,}000 \text{ words}$$

Expected number of blocks required

$$= \left\lceil \frac{200{,}000 \text{ words}}{247.7 \text{ words/block}} \right\rceil^+ = 808 \text{ blocks}$$

The same number of fixed size records of 200 words each would require 1000 blocks. Therefore a significant reduction

is possible in this simple case when the record sizes are distributed over a larger range.

The above computation becomes extremely difficult as the number of record types becomes large (i.e., 500 or more), and even the computer time to exhaustively enumerate all cases is prohibitive. The DBDE uses an algorithm to compute E(used) that reduces the computational complexity to a feasible range for 50-100 record types, which is adequate for most IDS databases. The complete derivation of this algorithm is given in Reference 12.

A natural extension of the database sizing algorithm is to consider new records being added to the database and the probability that they will overflow the page where they would be naturally placed. From this value one can determine the expected number of overflow records generated by a given number of record additions over a particular time period. Overflow in IDS significantly increases the expected retrieval time for records.

Buffering

The original purpose for buffering on second generation (uniprogramming) computer systems was to provide a mechanism for overlapping CPU and I/O time and improve overall performance of each application. Buffering for multiprogramming systems still produces an overlap of resources, but not necessarily for the same application (job). While job A is executing, job B may be inputting into its buffer while job C is done with I/O and waiting for the CPU. The existence of a large number of jobs in the system causes other delays which usually subsume the synchronous CPU-I/O sequences of a sequential data processing operation. Consequently, the benefits of such buffering received by sequential or random database applications in multiprogramming environments are not easily measurable with probability models, such as DBDE, but they can be better approximated by a queuing model for the whole system.

The more directly measurable function of buffering in multiprogramming systems is that of keeping active data in main storage in order to reduce physical I/O operations when data is continually referenced. The DBDE considers this form of buffering, and it allows the analyst to specify up to 256 buffers for IDS applications. Naturally, increasing the number of buffers increases the probability that the next record you need is already in main storage and consequently decreases the expected I/O service time. However, increasing the buffer size too much may result in wasted storage, increased cost for storage used, and main storage allocation delays that may degrade overall performance. Therefore the choice of proper buffer size is critical to an effective IDS application. The DBDE implements the buffer concept by maintaining buffer currency data based on the most recently executed IDS operations and the database definition of chains and record types. It also simulates the basic IDS buffer replacement algorithm, least-recently-used (LRU). Thus, for this part of the IDS model, the DBDE uses a hybrid analytical and deterministic simulation technique.

Currency in a network database

IDS (as well as DBTG databases) has currency indicators which specify the most recently accessed record of a particular record type or master and detail records for a chain type, for example. The DBDE maintains similar information to represent the current status of access to the database. Consequently the next operation is evaluated according to current position and next position desired. The logical structure diagram of the database is implicitly known from the form of the input parameters, and the algorithm consults this information to compute I/O time and CPU overhead to access the next record.

EXAMPLE NETWORK DATABASE EVALUATIONS

The objectives of the test network database evaluations were to validate the IDS model with live test data from an existing database, to provide insight regarding the sensitivity of database performance to the values of storage structure and user workload parameters, and to compare the performance of alternative database designs.

The conclusions from preliminary validation tests ai • that the DBDE is able to describe the major database design parameters and their relationships accurately, that the input data can be created easily and quickly, and that many meaningful experiments can be conducted at a single interactive session with the program. The validation IDS database which represented a large equipment inventory system, was supplied by a client U.S. government agency. The database consisted of 155,000 records of varying length across three major record types, and live test data was collected on an IDS system interfaced with a Honeywell 6060 GCOS operating system for an extensive series of retrieval operations. The test was conducted during peak hours in a large batch multiprogramming environment. Estimates for elapsed time for the live test data ($54*10^3$ seconds) and the DBDE ($42.7*10^3$ seconds) differed by 21 percent. The ability of the DBDE to estimate total elapsed time was due to the availability of an extension which implements a central server queuing model of the test system and estimates total elapsed time based on CPU and I/O requirements derived by the IDS model for the test database. Although these preliminary results have been encouraging, we believe that the validation process should be a continually on-going one as more detailed monitor data is made available. Validation at the individual IDS operation level is currently not possible in the existing environment.

Example 1

The first test database chosen for experimentation was the support database for DBDE,[1] which provided the opportunity to evaluate our own design for DBDE before applying the technology to client systems. The test database schema is illustrated in Figure 3. The database contains eight record types and ten chain types. The database is quite small

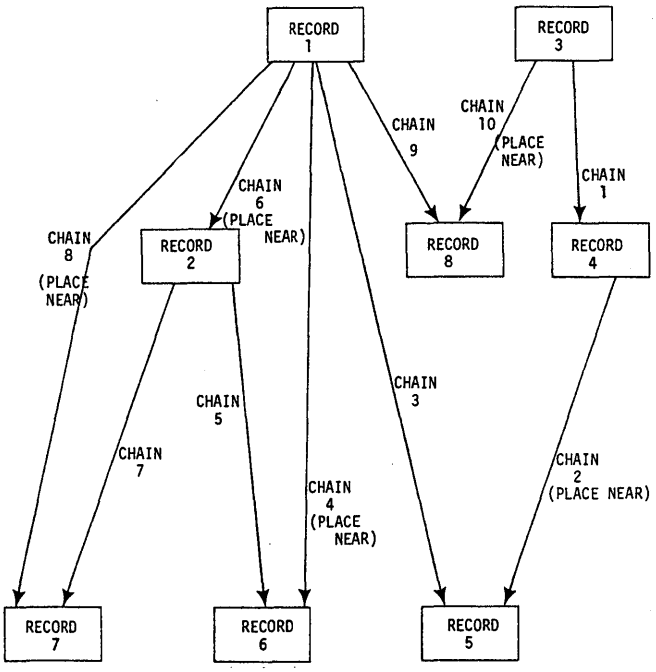

Figure 3—DBDE database schema

(755 records), but this kept the cost down while allowing a great deal of analysis of the model. Other input parameters are summarized in Table 1.

The basic output produced by the program is illustrated in Table II. Each operation is considered separately and totals are produced for given frequencies of occurrence of each operation. Table II illustrates a two-operation application that retrieves a record and modifies it. To accomplish this task, 2 sub-operations are required for each retrieval and 5 sub-operations are necessary for the modify operation. This feature of providing detailed output for each operation enables the analyst to obtain a better picture of cause and effect relationships for overall system performance, and thus make better decisions on parameter values to choose.

Example 2

The estimates of database I/O requirements for several configurations are summarized in Figure 4. The purpose of this experiment was to investigate the tradeoff between I/O time and secondary storage space for this experiment. It consisted of a single master record type (100 occurrences) and five detail record type (5000 occurrences each) with each contained in a separate chain type. The secondary

TABLE II—IDS retrieval and update application. Sample output

APPLICATION: Retrieve and Modify Record 7					
ACTION	Record Type	Chain Type	I/O Service Time (MLSEC)		System CPU Time Estimate (MLSEC)
			Single Access	Multi-Access	
Retrieve as CALC record	1	-	10.20	40.40	2.77
Retrieve as chain detail record	7	8	.07	.26	.02
Modify and delink	7	-	50.69	200.70	8.50
Retrieve master w/o currency table	2	7	10.14	40.14	2.75
Link to chain 7	7	7	20.28	80.28	2.00
Retrieve record 1 as CALC	1	-	10.20	40.40	2.77
Link to chain 8	7	8	20.28	80.28	2.00
TOTAL	-	-	121.86	482.46	20.81

storage space for this configuration was:

	CHAIN NEXT	CHAIN NEXT, PRIOR, MASTER
Master Records	100*(144 bytes)	100*(164 bytes)
Detail Records	25000*(128 bytes)	25000*(136 bytes)
Total	3214K bytes	3416K bytes

The implementation of pointers for PRIOR and MASTER in each record represents an overall increase of slightly over 6 percent in total storage space. The results illustrated in Figure 4 show that the I/O time for most operations is independent of chain pointer implementations. However, there is a slight increase in the STORE and a very significant decrease in HEAD (i.e., retrieve master) operations. The results for "multi-access" were relatively the same as those in Figure 4 but all values were approximately 30 percent larger on a point-by-point basis. The increase for STORE is due to a greater number of pointers to reset, while the decrease for HEAD is due to direct access to the master record with a MASTER pointer. Overall, this experiment shows that choice of pointer implementation depends on the types of applications to be run. Normally, a 6 percent increase in storage space is not significant, therefore, the increase in storage space appears to be less important than the effect on I/O time, which in turn affects total response time.

Example 3

We now return to the data structure for Example 1 to illustrate the capability of the DBDE to predict degradation

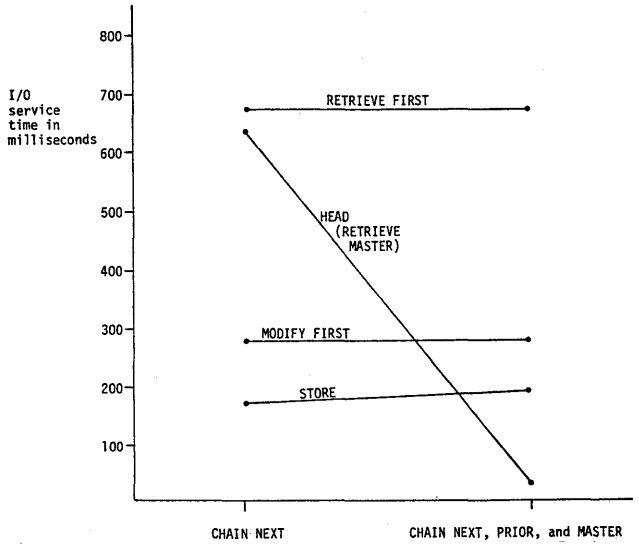

Figure 4—I/O service time for IDS operations with two pointer implementations ("single access" with dedicated disk)

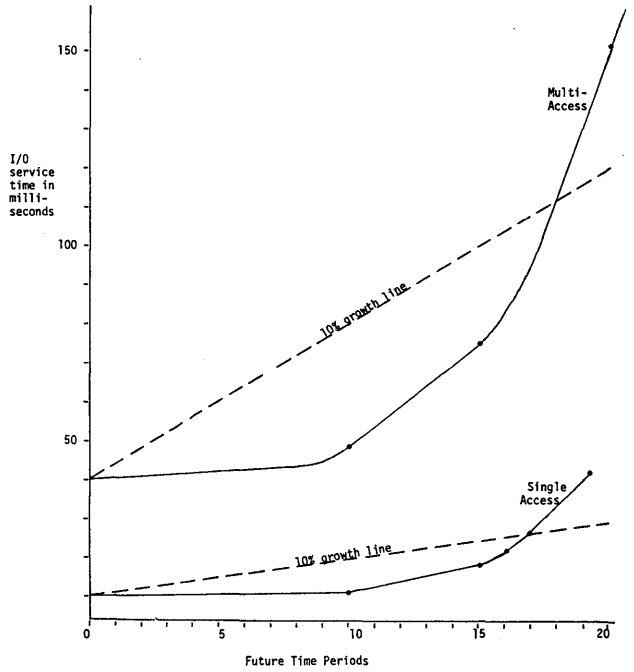

Figure 5—I/O service time for the retrieve record 7 operation as a function of increasing IDS database size

in I/O service time as the probability of overflow increases. Using the database configuration in Table 1, we assume a database growth rate (number of record occurrences of each type) of 10 percent per time period for an arbitrary time period length. The IDS model derives the overflow probability at discrete time period intervals for as many intervals as the analyst wishes to specify. The assignment of a value such as "3 days" for a time period has no effect on the model; real time units for time periods are independent of the overflow algorithm.

I/O service time to retrieve a record (type 7) is shown to degrade at a nonlinear rate over 20 time periods in Figure 5. The linear 10 percent database growth rate is included for comparison. The purpose of conducting this type of experiment is to compare storage structures, not just for the current configuration, but also for future configurations that involve more record occurrences and possibly a different level of workload. Observation of the results in Figure 5 could also help determine when and how often the database should be reorganized to clear the overflow areas.

FUTURE DIRECTIONS

Experience in the development of the DBDE has led to the conclusion that considerable insight can be gained into the causes and effects of physical database performance. Based on this experience it is felt that reasonable extensions can be made in three major directions. The first potential extension needed is to model the interface between the DBMS and the operating system in its many facets: mutual exclusion of processes attempting to read and update the

same data, queuing delays from mutual exlusion or other resource contention, and details of operating system overhead to facilitate DBMS commands to access data. The simulation model of Hulten and Soderlund[7] has achieved considerable success in this area.

Secondly, the evaluation can be extended to databases based on hierarchical or other logical models of data because they exhibit the same properties as network models: access can be described in terms of some combination of direct (hashing) or indexing plus a series of sequential or pointer steps within a particular level of indexing or at the final level of data. The generalization applies to existing search methods, indexing methods, and overflow techniques, although the resulting implementation in the analytical model is more arduous in some cases. At the level of detail exemplified by the DBDE, each technique must be modeled individually, and although models designed by Yao[14] and Severance[10] are more general, they lack important detail available in the DBDE.

The third major extension would be to incorporate the DBDE into a physical database designer that optimizes user specified performance measures as a function of user specified control parameters. Typically, the control parameters would be defined as a subset of the database characteristics currently input to the DBDE. Several of these characteristics are fixed (i.e., bound) at the logical database design phase, and so the range of physical design control parameters is further narrowed. In IDS one could control subfile page size, page range for subfiles and record types, PLACE NEAR specifications, RETRIEVAL VIA clauses, and pointer options.

Selection of an efficient combination of data files for a multiuser database

by R. A. DUHNE
Sistemas Computacionales Avanzados, S.H.
Monterey, Mexico

D. G. SEVERANCE
University of Minnesota
Minneapolis, Minnesota

INTRODUCTION

A database is a physical representation of information describing logical entities and relationships of interest to users. A database system functions both to *maintain* the accuracy and integrity of the representation as information changes over time, and to provide *access* to subsets of data as required by users. When choosing storage structures for a database, a designer is continually faced with tradeoffs between data maintainability and data accessibility.

The design problem is a difficult one. Typically, the number of design variations is enormous, and the choice of an efficient organization is dependent upon numerous problem characteristics:

1. the data to be stored—its sizes, volumes, and volatility;
2. the data storage environment—its operating costs and access characteristics;
3. the data retrieval applications—their frequencies, priorities, response requirements, and data selection criteria; and
4. the system's design objective—criteria for measuring performance, and an associated set of operational design constraints.

Precise mathematical formulations of realistic design problems generally reveal the presence of integer decision variables, nonlinear constraints and discontinuous objective functions. As a result, traditional mathematical optimization techniques cannot be applied to database design problems in a straightforward way.

Research aimed at systematizing the database design process is supported at a number of American universities[1,3,12,21-23] and research laboratories.[14-16] Our investigation at the University of Minnesota has evolved from research carried on first at the University of Michigan[17,18] and then at Cornell University.[7,9,11] Our approach to database design uses a model composed of (1) parametric descriptions of modular components of a generalized database organization, (2) analytic cost equations which evaluate proposed modular database designs, (3) an analyst interface which accepts and evaluates arbitrarily selected designs, and (4) search procedures which automatically generate and compare thousands of alternative organizations.

The purpose of this paper is to describe a methodology devised to permit our automatic design procedures to search a large set of alternative record access paths efficiently, while selecting the best combination for a given design problem.

THE MODELING CONTEXT

Figure 1 provides an overview of the modular, generalized database organization assumed in our research. While three major modules are distinguished, our concern here is with the design of Module A—the file structures which define access paths to subsets of database records. Results of projects to design search techniques (Module B)[4,19,20] and record structures (Module C)[2,7,10] are reported elsewhere.

We assume each retrieval request, input in Figure 1, is known and given by:

a. a relative *frequency* or priority of retrieval,
b. record *selection* criteria, based upon field values stored within data records,
c. attribute *projection* criteria defining fields to be retrieved from selected records, and
d. *ordering* criteria for the presentation of retrieved data.

To appreciate the combinatorially explosive nature of the access path selection problem, consider an employee database and the three retrieval requests described by Table I.* Any one of these requests can be satisfied by scanning all employee records in a database which is arbitrarily organized. Records of interest would be selected on the basis of DEPARTMENT and SKILL values and sorted as necessary

* Projection criteria are essential for the design of efficient record structures (Figure 1, Module C), but are ignored here.

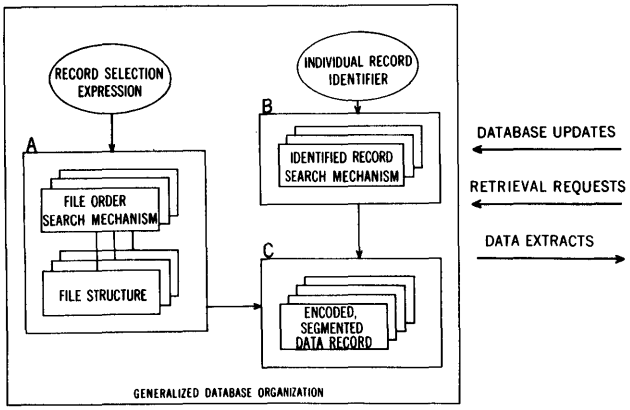

Figure 1—A component-level overview of the database design model

for presentation to the user. Since each subset is likely to be small, a number of alternative file structures might be used to organize these record collections for faster retrieval.[20] For example, one might connect the records of all engineers together in a list file in order by DEPARTMENT (Request 1), or construct an inverted list which points directly to all members of department A in order by NAME (Request 2). The "engineers in department A" (Request 3) could be retrieved via a scan and sort from either of these files, or a separate access path could be established for this request as well.

Each of the alternatives has a number of structural variations which trade record accessibility for database maintainability. Depending upon its expected rate of growth, a file may vary in its initial loading density or in its use of chained overflow areas to accommondate new records. List structures may or may not use back-pointers to facilitate record deletions. The type of pointers used within inverted files may vary depending upon the expected database volatility. Every ordered structure may use any of a number of order-value search techniques to speed insertion and deletion operations.

In general, consider a design problem with N retrieval requests, each of which on the average could be retrieved from any of K_1 distinct implementations of K_2 different file types. The problem of access path selection, then, is equivalent to choosing from among $(K_1 K_2)^N$ alternative database designs. Typical values for $K_1 K_2$ and N, in the range 20 to 50, make an exhaustive search of the solution space computationally infeasible.

TABLE I.— A Simplified Description of Three Data Extracts

Request Number	Frequency (per month)	Selection Criteria	Order Required
1	20	SKILL='ENGINEER'	DEPARTMENT
2	5	DEPARTMENT='A'	NAME
3	10	DEPARTMENT='A' and SKILL='ENGINEER'	PASS NUMBER

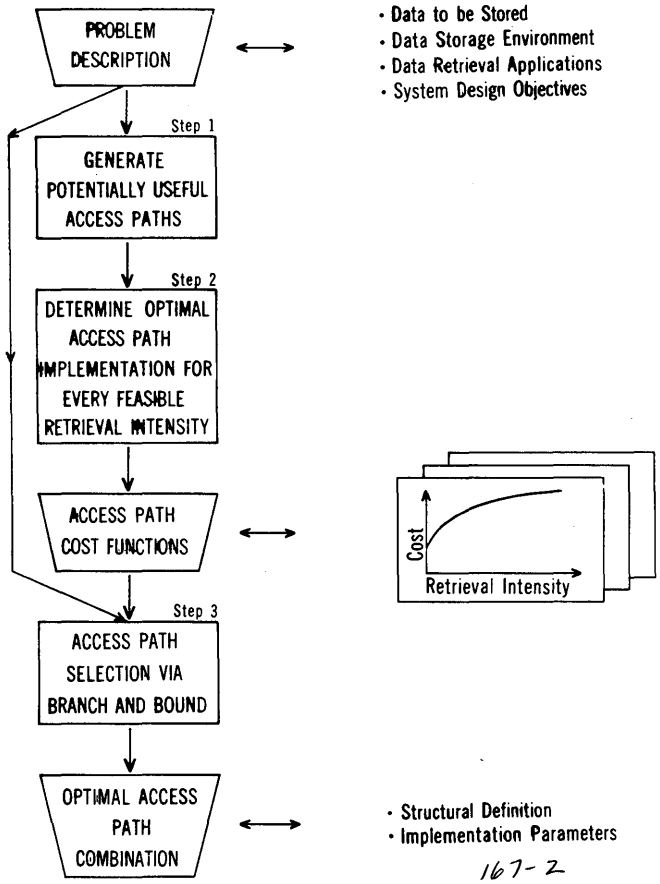

Figure 2—Overview of the access-path design procedure

THE PROCEDURE FOR DESIGNING ACCESS PATHS

A three-stage design process has been devised to select an efficient combination of access paths on the basis of the system's total cost. The procedure takes as input a quantitative description of the data to be stored, the data storage environment, and the data retrieval applications. Total cost is measured as the sum of storage, retrieval and maintenance costs. A detailed description of the analytic models used to calculate the total cost of a proposed design is well beyond the scope of this paper (Duhne[5] provides a thorough discussion). An understanding of the optimization procedure is, nevertheless, easily conveyed without substantial detail. Consider the basic design procedure as illustrated by Figure 2.

The first step in the procedure generates a large set of potentially useful access paths. Only a few will actually be selected in the final design. To insure the computational tractability of the optimization procedure, it is desirable to restrict the number of access paths considered. On the other hand, to insure the optimality of the selected design, no reasonable access path should be excluded. The set of paths is generated from the analysis of retrieval requests.[5] Each access path in the set is described generically in terms of its

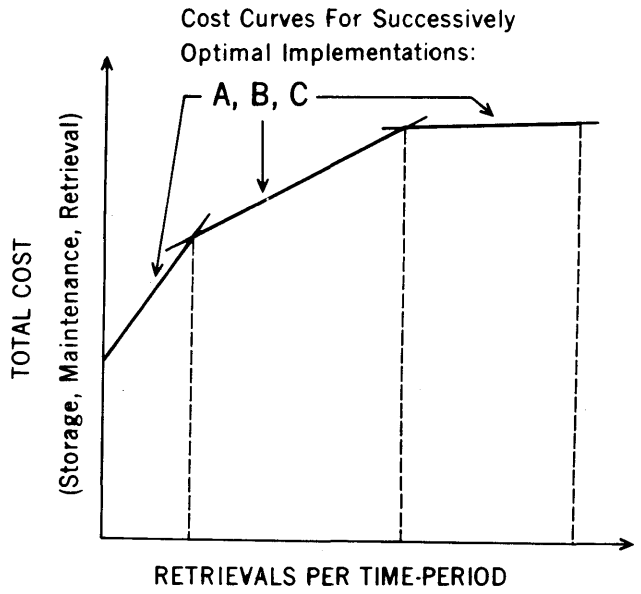

Figure 3—Typical access-path cost function

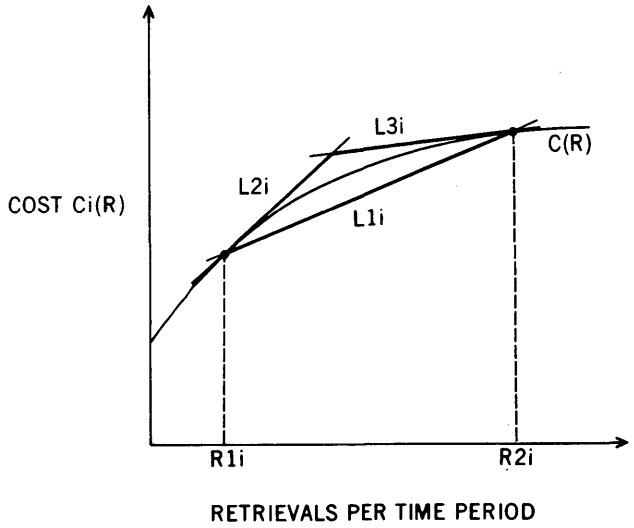

Figure 4—Cost function bounds in the interval (R1,R2)

record membership criterion, its record ordering, and its basic file type (e.g., sequential file, inverted file, etc.).

The second step shown in Figure 2 determines an optimal implementation for each potential access path at every feasible* level of retrieval activity. As was mentioned earlier, a variety of implementations trade record accessibility for data maintainability. For each level of retrieval intensity, a search procedure developed by Severance[17] and refined by Duhne[5] is used to locate an optimal implementation. Intuition correctly tells us that, as the frequency of file access increases, selected implementations will successively reduce the marginal cost for retrieving the file.

For each potentially useful access path, a cost function is output from Step 2. As illustrated by Figure 3, the function defines the minimal total cost (for storage, maintenance, and retrieval) at every level of retrieval intensity. The implementations which yield these minimal costs are stored for later recall. Duhne[5] shows that total cost is a continuous, non-decreasing, concave function of retrieval intensity. This is an intuitively reasonable property, and it is essential in the final setp of the design procedure.

The third step in Figure 2 assigns retrieval activities to access paths in a manner which minimizes total system cost. A branch-and-bound procedure is used—the reader is directed to Garfinkle and Nemhauser[8] for a thorough discussion of this optimization technique. Generally, branch-and-bound procedures implicitly enumerate all possible solutions to a problem by means of a search tree built from nodes and labeled branches. The root is associated with the complete solution space. Each other node corresponds to a restricted class of solutions derived by imposing solution restrictions which label branches on the path from the root to that node.

A search proceeds as follows: Starting with the root, a series of nodes in the tree are "visited." With each visit, upper and lower bounds on the cost of solutions reachable from the current node are computed; a least upper bound for the entire tree and its corresponding node are continually recorded. On the basis of the cost calculations at the current node, a branch is chosen for exploration. The search proceeds down the tree until a visited node is "fathomed" and no branches from that node are explored.

A node is fathomed either (1) when the upper and lower bounds for the node are sufficiently close that all solutions governed by the node are effectively equivalent, or (2) when the lower bound of the node is greater than the current least upper bound for the tree so that no solution governed by the node can be optimal.

The search algorithm "backtracks" from a fathomed node to its parent node and proceeds to search other unexplored branches in the tree. When none are left, the search is complete. The (any) solution defined by the node with the current least upper bound is selected as optimal.

This general procedure is applied to our specific problem by traversing a search tree in which each node is defined by a collection of retrieval activity intervals $\{[R1_i, R2_i]\}_{i=1}^{n}$, one for each of n potential access paths, i. Every solution governed by a node (i.e., reachable from it) must be composed of an optimal implementation for each access path given these activity intervals.* So that every possible solution is considered, the root of the search tree is defined by $\{[0, RMAX_i]\}_{i=1}^{n}$, where $RMAX_i$ is the sum of all retrieval activities which could potentially be satisfied via access path i.

An upper and lower bound on the total cost of *each* access path is computed at each node visited. Since the actual function $C_i(R)$ is known to be concave, a lower bound in the

* The maximum retrieval intensity for each access path is calculated as the cumulative frequency of all user retrieval requests which can use that path.

* If $R1_i = R2_i = 0$, then, optimally, the access path is not implemented.

interval $[R1_i, R2_i]$ (as illustrated by Figure 4) is given by the line $L1_i$ passing through $C_i(R1_i)$ and $C_i(R2_i)$. An upper bound is given by the intersecting lines $L2_i$ and $L3_i$ (passing through points $C_i(R1_i)$ and $C_i(R2_i)$ with slopes $dC_i(R1_i)/dR$ and $dC_i(R2_i)/dR$ respectively.)

Using the lower bound approximation, extracts are assigned to the access paths from which they can be retrieved at least cost. Cost is calculated as the sum† of:

(1) the cost of access path retrieval which is taken to be the slope of $L1_i$, and
(2) the cost of extract sorting, which is a function of the size and retrieval criteria of the extract, and calculated using statistics which describe the sort utility of the host system.[13]

Duhne[5] has shown that the total cost of any solution reachable from a node is bounded by the sums of upper and lower bounds for the individual access paths. If the current node is fathomed by these bounds, the search returns to its parent node. If the node is not fathomed, two new branches are generated by partitioning the retrieval interval of a selected access path into two parts. The interval to be divided is chosen so that the difference between the upper and lower bound (at the point of cumulative retrieval assignments) is greatest. The partition boundary is set at the point in this interval where the difference between its current bounds is greatest.* The search proceeds as described for the general algorithm and terminates when an optimal collection of access paths has been determined.

The design procedure has been encoded as a FORTRAN program and run on a CDC CYBER 74 at the University of Minnesota.[6] It has been applied successfully to a number of realistic design problems using less than a minute of CPU time. The cost estimates generated by our analytic models have been verified via comparisons with actual costs of design implementations. Model accuracy has ranged from one to six percent.[5]

SUMMARY

The application of mathematical optimization techniques to the difficult problem of database access path design has been described. The design process is divided into three steps. Generic descriptions of potentially useful access paths are first developed from user retrieval specifications. An optimal implementation for each access path at every feasible level of retrieval intensity is then determined. For each path a function describing minimum total cost for every retrieval intensity is constructed. Using the fact that these functions are continuous, non-decreasing, and concave, a branch-and-bound procedure is used to locate access path implementations which can be used at minimal cost for the retrieval of user extracts. The result is an efficient database design.

The design procedure has been applied to realistic problems and executes in a reasonable time. The accuracy of our analytic cost models has been verified through implementations of selected designs. Details of these models have been purposely suppressed in an effort to highlight the structure of the optimization procedure which we believe is generally applicable to the problem of access path selection. Since the procedure basically requires only that a cost function (with reasonable properties) be constructed for each access path to be considered, we feel that the algorithm can be readily adapted to the modeling work of others.

Programming languages for relational data base systems*

by CHARLES J. PRENNER and LAWRENCE A. ROWE
University of California at Berkeley
Berkeley, California

INTRODUCTION

There has been a remarkable growth in the use of data base management systems over the past decade. This has resulted from the recognition that many practical applications, previously implemented by special purpose programs, can be developed more easily through the use of a general data base facility. Here, we will only be concerned with relational data base systems. The advantages of such systems have been discussed at length in the literature.[7,9,10]

In modern data base management systems, users typically interact with data bases via a query language.[4,6,8,20,41] These languages, which are often interactive, allow creation and deletion of data bases as well as retrieval from, and updating of, existing data bases. Because query languages have not provided a complete programming environment, most of these languages have been coupled to existing programming languages. Application programs consist of statements in the programming language intermixed with statements in the query language to access the data base system when required.

Previously investigated approaches to providing such access include the definition of subroutines to execute data base functions and the embedding of data base constructs into an existing language, using a preprocessor to translate these constructs into run-time calls on a data base system (e.g., EQUEL,[2] and the embedding of SEQUEL in PL/1[6]). Because the primary focus of this work was to provide data base access from a programming language, little attention was paid to the programming environment resulting from the combination of the two languages.

While a given programming language and a given query language may each be satisfactory in isolation, their combination may be less than satisfactory because neither one was designed for this more general setting. In this paper we discuss techniques for improving the programming environment for data base applications. Our hypothesis is that a superior environment can be realized by incorporating the data base operations as part of the programming language itself. In the second section we outline some limitations associated with previously proposed environments. These stem primarily from the fact that the programming language is totally unaware of the data base. In the third section we illustrate some of the benefits provided by an integrated approach through the application of current techniques from programming language research.

* This research was supported in part by U.S. Army Research Office Grant DAAG-29-76-G-0245, and by the University of California under a Faculty Research Development Grant.

CURRENT APPROACHES

Most current approaches to providing data base access from a programming language are constrained by the fact that the language system has no knowledge about the data base. We divide our discussion of the impact of this constraint into five areas: data base interface, data base operations, type system, compilation, and abstraction.

Data base interface

As mentioned previously, the two primary approaches to providing data base access have been to provide subroutines for data base functions and to embed data base constructs through the use of a preprocessor.

The subroutine approach suffers from the limitations inherent in any use of subroutines to extend the semantic space of a language; programs become essentially a series of calls which are often unreadable because of the many (bookkeeping) arguments which must be passed to the subroutine. No syntactic aids are provided to make the use of these arguments understandable.

The preprocessor approach is somewhat better in that an actual query language is used. Program statements and query language statements can be freely intermixed. In most systems the preprocessor does not have to parse the entire language because query language statements are tagged with some distinguished symbol. The preprocessor removes the query language statements, replacing them with calls upon the data base subsystem, before the program is passed to the language translator. The programmer transacts with a readable version of the program and only the language translator need be concerned with the less readable version.

Unfortunately, the preprocessor approach is limited as well. Since the query language is not part of the programming language, communication between the programming language and the data base system can become awkward.

For example, it is often necessary to use implicitly defined global variables to communicate the status of queries. In some contexts, program variables which are to be made accessible to the data base system must be preceded by "special symbols" so that they may be recognized by the preprocessor. In some preprocessors arbitrary constraints are imposed as to which arguments to a data base operation can be variables and which must be constants. In other implementations, even though the language being extended is strongly typed, the same level of checking is not extended to the data base objects and their operations. Detailed examples illustrating these problems are given in a previous paper.[35]

Although preprocessing the entire language would remove some of these limitations, this approach is still constrained by the fact that (practically speaking) no amount of preprocessing can extend the language to incorporate relations with the same amount of symmetry, type checking and protection available for built-in objects.

Data base operations

In considering the query language as part of the programming language one finds that the notation and orientation of the two are quite different. Commonly used programming languages are procedural, with built-in facilities for iteration, manipulation of complex data structures, and procedural abstraction. On the other hand, most query languages are non-procedural. In the context of a procedurally oriented programming language these non-procedural operations seem out of place. To provide a consistent programming environment the objects manipulated by the data base system and their attendant operations and control structures should be related to the objects, operations and control structures of the language itself. For example, a join operation may be thought of as a nested iteration over relations yet the operation "join" usually appears in a form completely unrelated to the iteration operations in the programming language. We do not advocate that higher level operators such as joins be excluded from a language. Instead, we suggest that they be defined as extensions to the language in terms of existing primitives.

Type system

Because the programming language has no knowledge of the data base system, the type systems of the two are usually distinct. Data base objects cannot be manipulated in the programming language with the same ease and flexibility as language objects. For example, records, as used in a relational data base system, often are not treated as composite structures in the language environment (e.g., EQUEL or SEQUEL). This means that values must be copied individually from data base records into program variables before the values can be used. Thus, a record from a data base cannot be an argument to a procedure nor an operand to an otherwise meaningful operation (e.g., record selection or the right-hand-side of an assignment). The same situation holds for relations. For example, relations may not be passed as parameters to functions. In addition, it is impossible to operate on relation types, say, to obtain the count of the number of columns in the relation, or to obtain the domain of a column as a type. The existence of two type systems may require conversions to be performed on objects as they flow between the two systems. One type system controlling data access whether in main memory or secondary storage would be more efficient because it removes the need for such conversions.

Compilation

In programming languages, there is often a tradeoff between program flexibility and run-time efficiency. Most data base systems are committed to one extreme or the other depending upon whether data base operations are interpreted (less efficient but more flexible,* e.g., INGRES) or compiled (more efficient but less flexible, e.g., SEQUEL). When a language is committed to one extreme the resulting design decisions make the language awkward to use, or less efficient, when the application requirements are not matched to that commitment. For example, consider the treatment of relation names in SEQUEL. In order for a query to appear explicitly in the text, all relation names must be constant (to allow compilation to be performed). If dynamically varying names are desired, then a string for the query text must be constructed and the relation name inserted into it at run-time. On the other hand, INGRES allows dynamically varying relation names but cannot utilize the fact that a relation name is constant in a given instance. A better programming environment would allow for a continuous spectrum ranging from dynamically varying requests with less efficient execution to fixed requests with more efficient execution so that the system can provide the best possible solution for the requirements of the problem to be solved.

Abstraction

The concept of data abstraction has received much attention in the programming language community. Recently, there has been interest in the use of data abstraction with respect to data base systems.[18] Many data base systems support abstraction related facilities such as views, integrity constraints and triggers.[3,12,19,33] For example, a view provides a form of abstraction in that the user can construct queries for relations which do not actually exist but are materialized from a number of relations. If the organization of the relations is changed, the view can be maintained by redefining it in terms of this new organization. In addition, some authors have proposed mechanisms for specifying higher level operations on data bases (such as "hire" and "fire").[18] Although some systems offer these abstraction

* Requests can be changed at run-time (e.g., in EQUEL relation and domain names can change dynamically).

facilities, they have not yet integrated them with their counterparts in data abstraction from programming languages.*

AN INTEGRATED APPROACH

We will now consider the integration of data base objects and operations into a programming language. We will not attempt to give a complete language proposal here. Instead, we shall illustrate some of the benefits of this approach. Our discussion is divided into four areas: type system, data base operations, compilation, and abstraction.

Type system

An extremely important aspect of the language is the extension of the type system to provide access to data base relations residing on secondary storage. While a complete discussion of the type system is beyond the scope of this paper, we will discuss a few aspects of the type system to demonstrate the usefulness of an integrated approach. We have been strongly influenced in our thinking about types by the Mesa language.[15]

In introducing data types for relations in the programming language we will exploit the obvious correspondence between relations and collections of records in programming languages, namely, a relation may be viewed as an unordered collection of records (tuples in data base terminology), where the collection may not contain duplicate tuples. For example,

```
Employee: type=relation of
                    name: string(20),
                    dept: integer,
                    salary: integer,
                    manager: string(20),
                    jobtitle: string(15)
                  end
```

defines Employee as a relation type, where *"relation of"* means "unordered collection with no duplicates of . . .".

A relation type is itself an object upon which operations may be performed to obtain access to types contained within it. Thus,

```
declare e: record(Employee)
```

declares e as a variable whose type is identical to the underlying record type of the relation, and

```
declare deptno: Employee.dept
```

declares deptno to be a variable whose type is identical to the dept column of the relation, i.e. integer.

By allowing the types contained within the relation type to be extracted in this manner, duplication of these types in the program is avoided. Thus, a degree of modularity is achieved. In addition, data integrity is enhanced because the only operations that can be performed on the values in the data base are those allowed on the given type. Because there is only one representation for a value of a given type, whether in the data base or in the program environment, and because the set of types provided in the language is the same as those provided in the data base system, no conversion is needed when data is moved from one environment to the other.

Another important feature of the type system is the ability to specify constant or dynamically varying relation and domain names. For example, the following program fragment declares Rel to be a relation bound to the existing data base relation EMP.

```
begin
  declare Rel: Employee=relation('EMP');
    ⋮
end;
```

If the relation were not constant, e.g., if its name were entered at a terminal, the program fragment would be

```
begin
  declare Rel: Employee,
          Rname: string(15);
  write("What is the relation name?")
  read(Rname);
  Rel: =relation(Rname)
    ⋮
end;
```

where *relation* is a function which takes a string argument and returns a relation as result (or returns *undefined* if no such relation exists). In either case the type of the relation is specified so that operations on Rel can be type-checked, and the program code in the block can be the same. The only change is in the way the relation is bound to Rel. Because the programmer has explicit control over the conversion of the input string into an object of type relation, the existence of the named relation can be tested and an appropriate action taken if it does not exist. This cannot be done easily in any existing language.

The last aspect of the type system to be discussed is type extensibility. Several researchers have mentioned that a type extension facility would be valuable so that types other than the typical primitives (e.g., integers, reals, and character strings) can be placed into a data base record. The proposed language will allow arbitrary fixed length structured objects, except those including pointers or relations, to be a component of a data base record. Providing this feature is not particularly difficult if the data base system supports a typing mechanism which can be extended to include generic functions.*[39]

* Recent work in this direction has been reported.[28,32]

* Generic functions have multiple definitions for an operator where the particular definition invoked at a call is determined by the arguments (e.g., + has several definitions, including definitions for integer, real, complex or mixed arguments).

Data base operations

There are several ways that data base operations can be made more convenient, consistent, and more closely related to existing constructs in programming languages. Our interest in this research was motivated by the difficulty one author of this paper had expressing complicated queries in SEQUEL. This led to the design of a procedural query language, described in detail elsewhere.[26] In the following discussion, an overview of the query constructs is presented.

Suppose that we wish to print the names of all employees whose manager is Kathy Fallon. This is written as

```
for x in Rel st x.manager='Kathy Fallon' do write(x.name);
end
```

and read "for each record x in the relation Rel, such that x's manager is 'Kathy Fallon', print x's name."* The variable x is known only in the scope of this statement and is bound to each record in the relation satisfying the qualification. The qualification clause (*st*) is optional.

We believe that this construct is cleaner than those used in many existing data base languages. The binding of language environment variables to data base objects is more consistent and the control structure is more natural, say, than requiring explicit testing of a variable shared by the data base system and the program environment to determine if another record exists.[3]

A query which requires the join of two relations may be written as a nested *for* construct. For example, a list of all employees who earn more than their managers could be obtained by writing

```
for emp in Rel do
  for mgr in Rel st emp.manager=mgr.name do
    if emp.sal>mgr.sal then write(emp.name) fi
  end
end
```

Suppose one wanted to construct a temporary relation having employee records for all people working in department 50. This could be accomplished by using the *for* construct to append qualifying tuples to a (temporary) relation variable.

Alternatively, the *for* statement can be used in its short form

```
begin
  declare Reltemp:employee;
  RelTemp:=[all | Rel:dept=50]
    ⋮
end
```

which says "construct a relation composed of those records in Rel such that dept is 50 and assign it to RelTemp." The construct on the right hand side of the assignment operation is an example of a *relation constructor*. The keyword *all* indicates that all fields of the record are selected. A relation constructor causes a copy of each record to be made. If only the name and salary fields were needed, the expression would be

```
[name,salary | Rel:dept=50]
```

Of course, to assign this value to RelTemp, the type specification for RelTemp must be changed.

The value returned by a relation constructor may contain duplicate records. Such objects are called bags,[27] or multisets.[23] If the value is assigned to a relation variable, then duplicates are removed. However, there are situations in which the value is useful with duplicates retained, e.g., when a function such as average is used as in AVG([salary|rel]). To explicitly remove duplicates from the value, two vertical bars ("||") are used. A relation constructor may be used directly in a *for* statement without having been previously bound to a relation variable. This is demonstrated by the next example which intermixes query iteration, relation constructors, and functions which take relations as arguments to print a list of all departments and the average salary of employees in that department.

```
for x in [dept || Rel] do
  write(x.dept,AVG([salary|Rel:dept=x.dept]));
end
```

This is read "for x in the set of distinct departments from Rel, print x and the average salary for those employees in department x".

The iterative construct is also used to update individual records as shown in the next example in which all employees are given a 10 percent raise.

```
for x in Rel do
  x.salary:=x.salary * 1.1;
end
```

As in most relational systems, the relation is not actually changed *until all iterations are completed* because the storage structure for the relation may require that records be physically moved when a field is changed, in which case a record could be updated more than once. One solution, used in some set theoretic languages, is to make a temporary copy of the set over which the iteration variable ranges.[13] This would not be practical in this environment because of the size of relations and the time needed to make a copy. Alternatively, the problem may be solved by keeping all changes in a separate file until the end of all iterations.[34] This also solves the problem of keeping a data base consistent after certain kinds of crashes.

Compilation

The linguistic benefits provided by an integrated environment will be of little utility in practice unless reasonably efficient code can be produced. Here, we discuss a number of compilation techniques which can be utilized in order to ensure that programs in the language have an efficient realization. The topics discussed are: variable binding time,

* The use of a *for* statement to sequence through a collection of data objects has been proposed before by programming language designers[13,17,21,30,31] but is absent from existing data base languages.

partial evaluation of procedures at compile-time, and program optimization.

Variable binding time

Binding time is the time at which a variable is bound to an entity, e.g., a specific relation to a variable of type relation. Whether this binding occurs at compile-time or run-time influences both run-time efficiency and program flexibility. Figure 1 shows a graph of binding time of variables in data base queries versus the degree to which these queries are compiled for two relational data base systems.

Compiling is more efficient in execution time and may be more efficient in execution space, while late binding allows more flexibility. Notice that these two systems make explicit commitments, to flexibility (INGRES) or to execution efficiency (SEQUEL). By using compilation and optimization techniques developed for implementing programming languages, it is possible to develop a system that operates in the grey region of the graph. When enough parts of a language construct are fixed (e.g., the relation name is constant) code as efficient as possible can be compiled.[22] Otherwise, less efficient code is compiled. This means that the tradeoff between efficiency and flexibility can be controlled by the applications programmer. Furthermore, it means that only those programs that need more flexibility must pay for it in terms of efficiency. Of course, in those cases where code is compiled to access a specific relation, programs may have to be recompiled if the definition of the relation changes.

Partial evaluation

A second compilation technique which can be used is the partial evaluation of procedures at compile-time (procedure closure). In SEQUEL, all relation names are viewed as either constants in the program text (in which case compilation is performed) or as strings "read in" at run-time (in which case no compilation is performed). With this organization it is impossible to pass a relation name to a procedure and to compile queries issued from the procedures which use this relation name. However, with global flow analysis techniques[16] combined with procedure closure techniques,[37] a programmer may be given a number of choices as to how such a procedure call should be compiled. These include:

1. compile one procedure body using only the type information about the relation,
2. compile distinct procedure bodies for each of the different (constant) relations passed to the procedure using type information as well as specific information about the relation, or
3. expand certain calls "in-line" so that no call is actually made.

Providing a programmer with a facility such as this gives one considerable control over the tradeoff between execution time and space.

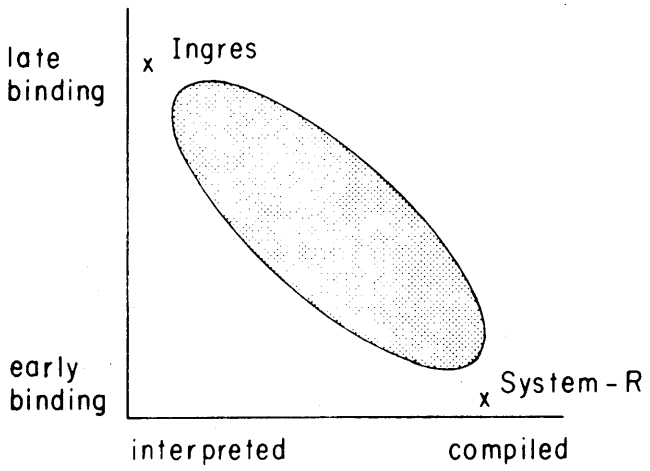

Figure 1—Binding time versus compilation

Optimization

The use of an integrated language opens up many possibilities for optimization. The goal is to reduce the number of calls on the data base system (and subsequent disk accesses) by combining many queries into one, removing queries from loops, eliminating temporary relations, and so on. This can be achieved through the application of traditional programming language optimization techniques (e.g., code motion, common subexpression elimination, and loop fusion).[1] However, the potential payoff from such optimizations is much greater in data base applications than in typical programs because the removal of a disk access represents a savings many orders of magnitude greater than the removal of, for example, an assignment statement.

Beyond traditional types of optimizations, possibilities exist for more complex optimizations using techniques similar to those used in experimental programming systems which have program verification capabilities.[38] In this case, semantic information available in an abstraction containing relations (e.g., integrity constraints) and information about the physical organization of the data can be used to perform sophisticated optimizations.

Abstraction

Data abstraction facilities have been found useful in developing programs that involve complex data structures.[11,24,40] It seems reasonable to consider extending such facilities to handle relational objects and operations. Another reason for exploring such a facility is because it may provide a structuring mechanism for current data base concepts such as views, integrity constraints, and triggers[3,12,19,33] which are all related to abstraction. Currently these facilities appear in data base systems in an unstructured fashion which often makes it difficult to determine how they interact and relate to one another. A better approach would be to make them all aspects of a single abstraction mechanism.

A view permits a programmer to conceive of a data base in terms of virtual relations. This allows fields, or complete relations, to be operated on even though they might not exist physically. This is similar to the notion of uniform reference that is being explored in programming languages.[14] Another use of views is to prevent a programmer from seeing certain columns of a relation. Again this is similar to a programming language concept (see the *private* attribute in Mesa[15]). A problem with using views is that it is not always clear how a value to be stored to a virtual field should be decomposed and stored into the fields that are physically present. Another problem is that it is not always clear what action should be taken if a value is to be assigned to a field which would cause the record to fall out of the view. Some data base researchers propose to solve these problems by establishing defaults where unambiguous alternatives are possible and disallowing the operations otherwise. An alternative solution, which we are currently investigating, is to acknowledge the difficulty of establishing defaults and instead provide convenient tools for allowing the implementer of the abstraction to specify the semantics explicitly.

Triggers are data base operations which are invoked automatically when certain primitive operations are performed, e.g. when a tuple is deleted from the employee relation the count of employees in the removed employee's department is decremented by one. In the context of a data abstraction facility it would seem more reasonable to associate this operation with the abstract operation "fire" than with the deletion operation itself.

Integrity constraints are assertions which characterize what it means for the data base to be in a correct and consistent state with respect to the semantic meaning of the data. For example, a constraint might be that all the names in the data base must be a subset of those in the employee relation.[19] Currently, such constraint information is used in an enforcement sense, i.e., a constraint is checked after a data base operation (or a group of operations) are performed. Often these checks are very expensive. It may be possible to use this information as assertions to be proved to hold about the set of abstract operations which are permitted on the data base. For those constraints which cannot be proved to always hold it may be possible to automatically determine additional information which should be retained in order to simplify enforcement.

CONCLUSIONS

We have attempted to show that an integrated approach to providing data base access from a programming language can yield a better programming environment for data base applications than previously available. We are currently in the process of designing a language with this philosophy for use with the INGRES[20] system. Other research groups are also working on similar problems.[5,25,29,36] We believe that this research represents a significant step towards a better understanding of the relationship between programming languages and data base systems.

Conversion of high-level sublanguage queries to account for database changes*

by STANLEY Y. W. SU and MICHAEL J. REYNOLDS
University of Florida
Gainesville, Florida

INTRODUCTION

Over the past few years, technological advances in database management have introduced many new research and development problems. The problem of "application migration" of a database management system is one of them. It can be grossly divided into two closely related subproblems: the problem of database translation and the problem of application program conversion due to database changes. There are many reasons for database reorganization and restructuring. Some of these are (1) the change of the use environment of a DBMS, (2) the upgrading of hardware and software facilities, (3) the change from one database system to another, (4) the installation of a new DBMS, (5) the modification of an existing system for efficiency purposes, and (6) the change of database semantics. The database translation problem has been tackled with some success by the works reported in References 7-9, 13-16, 18, 20-24, 29.

Some database changes, both structural and semantic ones, may require that the set of application programs written for the old database be modified or converted to account for the changes either for semantic reasons or for efficiency purposes. A well-designed DBMS, which is data independent, should normally not be affected by the changes made on the physical structure and access strategy because these types of database changes can be handled simply by changing the mappings from the external model to the conceptual model and from the conceptual model to the internal model.[6] However, few existing database systems are truly data independent. Physical placement of data and access strategies are often carried into the application programs.[3,4,12] Furthermore, some semantic changes of database will inevitably cause changes in both the schema and the subschema which the data sublanguage directly interacts.

Very often, the sublanguage statements as well as the host language statements need to be modified. As with the area of database translation, application program conversion could feasibly be implemented by the user or system programmer, however, the task is such an enormous one that the personnel's time is not effectively optimized. Therefore, a need for some type of program conversion system is definitely warranted.

* This research is supported by NSF Grant MCS 76-10075.

The work on application program conversion is still in its infancy. In the paper by Su,[25] a brief review of some existing works related to this problem was given. An attempt was made to analyze the problem and to identify the tasks which need to be undertaken to obtain some kind of automatic or semi-automatic aid for program conversion. In the same work, a general model of program conversion as it is related to database translation was presented. It was proposed that two stages of conversion are involved with the program conversion problem in the DBMS environment:

(1) Sublanguage query conversion whereby query analysis and modification occur due to schema and subschema changes, and
(2) Host language program conversion whereby the tracing of program logic, the identification of variable relations and program-subprogram structure represent some of the needed analyses.

Since the problem of program conversion is such a complicated one, we have decided to narrow our initial investigation to a restricted area in the first stage of program conversion, i.e., the sublanguage query conversion. In order to get a better handle on the problem, the following assumptions and restrictions are made: (1) The data model used in the DBMS is the relational model.[5] (2) The subschema is identical to the schema of the database. (This assumption does not nullify the problem investigated here because of the types of database changes considered here.) (3) The DEFINE language[10] is used as the data description language. (4) The CONVERT language[19] is used as the data mapping language. The CONVERT language is designed for processing and converting hierarchical trees called "forms." It is borrowed here for relational processing because relations are special cases of general "forms." (5) The relational sublanguage SEQUEL[1,2] is used to formulate the source and target queries. Only the basic patterns of the language are considered.

The objectives of this investigation are as follows: (1) To study the effects of all the CONVERT operators, (2) to design the algorithms for collecting data from the input source to construct the data tables to form the translation dictionary, (3) to study the techniques for analyzing a limited yet general SEQUEL query patterns, and (4) to design a

translation algorithm in detail (i.e., to the level of algorithm description which is one step short of the actual coding) to support the analysis and translation of queries.

This paper is a short version of a technical report printed in May, 1977.[26] Related to this work, two independent works on program conversion (Su and Liu[27] and Housel[11]) take a more general approach to the program conversion problem. Both works advocate the use of an abstract representation of program semantics and the semantics of data translation operators.

In the subsequent section, we shall first describe several types of database changes and illustrate the problems of sublanguage query conversion with examples which involve the use of CONVERT operators and SEQUEL's basic mappings. A translation process is then detailed in the third section and an example of query conversion is provided in the fourth section to clarify and illustrate the translation process step-by-step. A conclusion and the future work are given in the last section.

SOME ORGANIZATIONAL AND SEMANTIC CHANGES OF A DATABASE

We shall describe in this section some organizational and semantic changes and illustrate how these changes can be brought about by the CONVERT operators and their effects on the SEQUEL queries. This description and illustration should give the reader a feel of the sublanguage conversion problem we are dealing with and of the CONVERT and SEQUEL languages used in this study. The data changes described here constitute only a small subset of possible changes and the description of the languages is not complete. The interested reader should refer to the original papers on the language.[1,2,19]

In the following presentation we shall use the following relations for illustration purposes.

EMP (E#, ENAME, SEX, MGR)
PROJECT (P#, PTITLE, BUDGET, DEPARTMENT)
E-P (E#, P#)

A. A Large Relation is Split into Several Relations

This type of organizational change may occur in a DBMS for data access efficiency and data security reasons. For example, the PROJECT relation may be split into several small relations, one for each of the departments handling the projects. This may need to be done because it was observed that most of the application programs access departmental projects separately and the use of different security constraints are required for different departments' projects. To perform such a database translation, the following CONVERT statements can be used. Here, we assume that there are three departments only.

```
PROJ-D1←SELECT (P#, PTITLE, BUDGET FROM
        PROJECT:
        PROJECT.DEPARTMENT=ACCOUNT-
        ING)
PROJ-D2←SELECT (P#, PTITLE, BUDGET FROM
        PROJECT:
        PROJECT.DEPARTMENT=SALES)
PROJ-D3←SELECT (P#, PTITLE, BUDGET FROM
        PROJECT:
        PROJECT.DEPARTMENT=PURCHASING)
```

Each SELECT statement selects the tuples satisfying the DEPARTMENT qualification and creates a new relation with a different name. Note that the DEPARTMENT information now becomes implicitly specified by the new relation names.

The effects of this type of database changes are many. A SEQUEL query for accessing the tuples of the original PROJECT relation such as

```
SELECT    *
FROM      PROJECT
WHERE     BUDGET>50K
```

would have to be converted into the following structure.

```
SELECT    *
FROM      PROJ-D1
WHERE     BUDGET>50K
U
SELECT    *
FROM      PROJ-D2
WHERE     BUDGET>50K
U
SELECT    *
FROM      PROJ-D3
WHERE     BUDGET>50K
```

The retrieved result is still different from the original query because the department information is not explicitly specified in the new database. The DEPARTMENT field and value need to be added into the records retrieved by each SEQUEL basic mapping (the SELECT-FROM-WHERE block). This can only be done if the conversion system stored the DEPARTMENT information of PROJ-D1, PROJ-D2 and PROJ-D3 files during the analysis of the CONVERT operators. Queries making use of the DEPARTMENT information or retrieving the information will have to be specially handled.

B. Several Relations are Combined into a Single Relation

This type of database reorganization is necessary in order to eliminate the unnecessary duplications and to facilitate the access of related data scattered in several relations. This is often required when changing a conventional file system into a database system.

To reverse the operation given in (A), the following CONVERT statements can be used.

```
CONCAT (DEPARTMENT: ACCOUNTING ONTO
  PROJ-D1 AT BUDGET)
CONCAT (DEPARTMENT: SALES ONTO PROJ-D2
  AT BUDGET)
CONCAT (DEPARTMENT: PURCHASING ONTO
  PROJ-D3 AT BUDGET)
PROJECT←MERGE (PROJ-D1, PROJ-D2, PROJ-D3)
```

The CONCAT operator expands the relations by inserting the department data to the right of the BUDGET field. It makes the DEPARTMENT data explicit in each project relation. Here, the arguments, DEPARTMENT: ACCOUNTING, DEPARTMENT: SALES and DEPARTMENT: PURCHASING, are used in place of relation names which are required in the original CONVERT syntax. The effect of this type of change to the SEQUEL queries is that references made to several relations should be changed so that reference can now be made to the same relation. This generally causes a compression of the number of basic mappings to a single mapping such as the reverse operation of the example shown in (A).

C. Changes of the mathematical mappings between/among Entities

A database can be said to contain data about some entities and their associations. Several mathematical mappings between/among entities have been identified: (1) one-to-one association between two entities or within one entity, (2) one-to-many association between two entities or within one entity, (3) many-to-many associations between two entities or within one entity and (4) many-to-many associations among more than two entities. Each type of association can be changed to any other types due to rule or policy change of an enterprise using the database. For example, the rule which allows many employees to participate in a project and an employee to participate in many projects (many-to-many associations between EMP and PROJECT entities) can be changed so that one employee can only participate in one project but one project can be participated in by several employees (thus, a one-to-many association between PROJECT and EMP entities). To represent the new semantics, the relations EMP (E#, ENAME, SEX, MGR, P#) and PROJECT (P#, PTITLE, BUDGET, DEPARTMENT) would be sufficient. If the database contents have been changed by data deletion so that one employee participates in only one project and it was further assumed that the data of employees not participating in any project are to be deleted, the CONVERT operator, GRAFT, can be used for this database change. GRAFT provides a means of combining two or more relations into one when specific conditions are satisfied. For example, the following statement

```
NEW←GRAFT (E-P ONTO EMP: E-P. E# =
  EMP.E#)
```

would create a new relation, NEW (E#, ENAME, SEX, MGR, P#), which contains the data of each employee plus the project he participates in. If this relation is used to replace the EMP and E-P relations in the target database, the program translator needs to know at least three things: (1) the data of those employees who have not participated in the projects have been deleted from the database, (2) the EMP relation has been expanded to include P# data and has been renamed, and (3) the many-to-many association has been changed to a one-to-many association.

A SEQUEL query which retrieves the project numbers of all projects participated by SMITH from the source database will have to be modified as follows:

```
SELECT  P#                          SELECT  P#
FROM    E-P              ⟶         FROM    NEW
WHERE   E# IN                       WHERE   ENAME='SMITH'
        SELECT  E#
        FROM    EMP
        WHERE   ENAME='SMITH'
```

The nested mappings on the left are compressed and modified to account for the database changes as shown in the new query on the right. In this example, the translation analyst will have to be informed of the possible loss of data due to the deletion caused by the database change. If the facts of data deletion have been recorded, the program conversion system can tell the analyst precisely what data are missing by running the new query against the new database.

D. Adding or Deleting Entities and/or Associations

This type of database change requires the modification of schema and subschema and often requires changes to the application programs. It reflects the dynamic nature of a database to meet the new requirements of migrating applications. Adding new data generally will not affect the application program in a well-designed DBMS. Nevertheless, it can affect the storage operations (delete, insert and update) of some existing systems. For example, in DBTG's network model, if a new record type is added into a database as the AUTOMATIC member of an owner-coupled set whose owner was in the database, a deletion statement involving the owner in an old application program may have to be modified so that the new record occurrences will not be mistakenly deleted because of their AUTOMATIC membership specification. Deleting data (entity and association data) from database will always entail changes to the sublanguage statements as well as the host language program itself. Any reference to the deleted data will have to be taken care of by the conversion system. The translation analyst needs to be informed of the deletion and references to the deleted data can be taken out of the program if agreeable to the analyst. However, this kind of program modification may cause a chain of reactions to other program statements since they may make use of the deleted data or those data which depend on the deleted data. Furthermore, some deletions may render the sublanguage statements meaningless. For example, a set of sublanguage statements

may originally be designed to process data about two entities through their association and the association of these two entities might have been deleted. The statements would no longer be meaningful. In this situation, the statements should be taken out and the translation analyst informed of the program changes made.

The foregoing discussion represents a sample of a large number of situations in which changes in the subschema and thus the application programs are either required or desirable. It also illustrates the types of changes needed to be made in the sublanguage queries due to database changes. In the examples given, we consider only the effects of a single database conversion operator in isolation. In reality, the problem is much more complex than what has been presented since a set of CONVERT operators might have been applied to the source database. In this situation, the program conversion system has to keep track of all the possible effects on each domain and each relation of the source database. It also has to keep track of the conditions under which each relation in the target database is created and how it is related to the source relations. Sizable data need to be collected from the description of source and target databases and from the database conversion operators applied.

A SEMI-AUTOMATIC ANALYSIS PROCESS FOR SUBLANGUAGE QUERY CONVERSION

The entire analysis process is divided into six stages as illustrated in Figure 1.

A. *Stage 1—Translation Dictionary Development*

The contents of the translation dictionary represent information extracted from the source and target database descriptions and from the data mapping operators original applied to generate the target database. The DEFINE data descriptions and the CONVERT statements represent the two sources from which the information in the dictionary is constructed. The information is useful in the conversion of all source database queries. It guides the formal translation algorithm (Stage 5) in the construction of new queries which will account for the database changes. The translation dictionary contains seven tables.

(1) TABLE NAME REASSIGNMENTS (TNR): This table is used primarily to determine if any source database table names have been changed during the data conversion process. It has the following format: TNR(SOURCE_TABLE_NAME, TARGET_TABLE_NAME). Changes in database table names occur mainly in the CONVERT language ASSIGNMENT statement, however implied changes are also possible in just about all of the CONVERT language statements as shown in the following examples. The source tables renamed are underlined.

```
TABLE0 ← EMP(EMP#,DEPT,STATUS)
SLSPR2(DEPT#,TOTSALES) ← SALES(DEPT,
TOTSLS)
TABLE1←SELECT(DEPT,NAME FROM DPTTBL:
        DPTTBL.D# = SUP.D#)
TABLE2←SLICE(E#,EMPNAME,SALARY FROM
        PERSONNEL)
TABLE3←GRAFT(INVNTY ONTO PTS:
        PTS.P# = INVNTY.P#)
TABLE4←CONCAT(TBL10,TBL20 ONTO TBL30 AT
        S#)
TABLE5←MERGE(SERVICE1,SERVICE2)
TABLE6←SORT(TSBLONE BY S#,P#)
TABLE7←ELIM-DUP(TABLETWO)
TABLE8←CASE(TABLE15.SEX='Male','Female')
        (SELECT(E#,'1', FROM TABLE15)
         SELECT(E#,'0', FROM TABLE15))
```

The contents of this table is needed mostly in the reassigning process of the FROM clause of a SEQUEL language basic mapping. The SEQUEL language FROM clause refers to the database table from which the query in question will derive its results.

(2) DOMAIN NAME REASSIGNMENT (DNR): This table records the changes on the source domain names. The data is used primarily during Stage 4 to develop the query pretranslation reference tables which will be described later. The table has the following format: DNR (SOURCE_DOMAIN_NAME, TARGET_DOMAIN_NAME). Changes in the database domain names occur mainly in the CONVERT language ASSIGNMENT statement, however implied changes are also possible in just about all of the CONVERT language statements. Some examples are given below. The respective source domain names are underlined.

```
DATABL(STAFF#,PART) ←——— DATATLB(EMP#,ITEM)
EXMPTBL ←——— TABLE20(S# RENAME TO SUPPLIER, P# RENAME TO PART
TABLE25 (DPMT,IDNET) ←——— SELECT(DEPT,NAME FROM DEPTTBL)
TABLE26 (BOOK#,CATLG) ←——— SLICE(SERLNM, INDEX FROM LIBRYTB)
TABLE27 (EMP#,SEX) ←——— CASE (EMPTBL.SEX='MALE', 'FEMALE')
                         (SELECT(E#, '1', FROM EMPTBL),
                          SELECT(E#, '0', FROM EMPTBL))
```

The contents of this table is needed mostly in the reassigning process of the SELECT, WHERE, AND, and OR CLAUSES of a SEQUEL language basic mapping. All of these clauses of the SEQUEL basic mapping contain database domain name references which relate to the database table present in the FROM CLAUSE of the very same basic mapping.

(3) TABLE DOMAIN USAGE (TDU): This dictionary

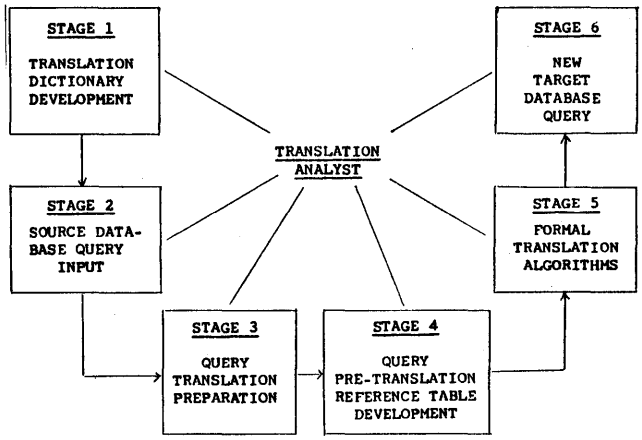

Figure 1—Stages of query analysis and conversion

table has the dual purpose of specifying all of the domains which a database table contains and all of the database tables which contain a certain domain (Figure 2).

This example shows database table TABLE1 as containing domains EMP#, MGR and SALARY; PERSONNEL as containing domains EMP# and MGR: and, PRODUCT as containing domains EMP# and SALARY. This dictionary table helps in the query conversion process by making sure that all references to database tables and domains in the target database are legitimate. It also helps in the reassigning of domain names and table names of SEQUEL basic mapping which have had extensive name reference changes.

(4) TABLE CONVERSION INDICATORS (TCI): This table specifies the CONVERT operators which have been applied on the relations during data conversion. The data is useful for determining the order of execution of the formal algorithms in stage 5 of the analysis process. The structure of this table is illustrated in Figure 3.

(5) CASE ASSIGNMENT DEFINITIONS (CAD): The CONVERT CASE ASSIGNMENT statement allows for varied operations to occur over different instances of a database table. In essence, it may be desirable to code a value or values of a given domain of a database table in a different manner for usage in the target database. Therefore, these new values need to be stored in the CAD table so that when the source domain values are referred during the query conversion process, the new values may be inserted in their place. For example, the following CONVERT statement recodes the sex field of the Personnel table (male=1, female=0) and changes the domain name from SEX to SEX-CODE and the table name PERSONNEL to TABLE 1,

```
TABLE    1    (EMP#,AGE,SEX-CASE(PERSONNEL.SEX='MALE','FEMALE')
                CODE,RACE)←(SELECT(EMP#,AGE,'1',RACE FROM PERSONNEL),
                            SELECT(EMP#,AGE,'0',RACE FROM PERSONNEL))
```

The above statement causes two entries in the CAD table shown in Figure 4.

The CAD table is accessed by the formal query conversion algorithms only after all source database table and domain names have been reassigned to their corresponding target database references.

(6) GRAFT CONVERT INFORMATION (GCI): This table is related to the CONVERT GRAFT operation. Entries in the GCI table simply show which database table was grafted onto which table during data conversion. The information present in this table contributes greatly to the restructuring process of source database queries. In general, source queries using database tables which have been grafted together may be able to be restructured into a much simpler query.

(7) SELECT OCCURRENCE CONDITIONS (SOC): This table holds information concerning the conversion of source tables which were operated upon by the SELECT operator. For example, the following two SELECT operations will produce the entries shown in Figure 5.

TDU

	TABLE1	PERSONNEL	PRODUCT
EMP#	1	1	1
MGR	1	1	0
SALARY	1	0	1

Figure 2—Table for domain usage

TCI

	ASSIGNMENT	SLICE	SELECT	GRAFT	...	CASE ASSIGNMENT
EMP	1	0	1	0		0
SALES	0	1	0	1		0
TABLE1	0	0	0	0		1

Figure 3—Table for conversion indicators

CAD

TARGET TABLE NAME	TARGET DOMAIN NAME	SOURCE DOMAIN VALUE	TARGET DOMAIN VALUE
TABLE1	SEX-CODE	MALE	1
TABLE1	SEX-CODE	FEMALE	0

Figure 4—Table for case assignment

```
SELECT(S#,DES,SNAME FROM
  SLSPR:SLSPR.S#>10)
SELECT(P#,PNAME,SUPL FROM PTS:PTS.P#=50)
```

The information in the SOC table is used to determine if a query which makes reference to relations that have been operated upon by the SELECT operator will produce any result.

B. *Stage 2—Source Database Query Input*

This stage deals with the analysis of the source query to determine if the query is one of the appropriate structures capable of being operated upon by the formal conversion algorithm; and, to verify the labeling of the SEQUEL basic mappings present within the source query since the elementary unit of conversion by the formal translation algorithm is the basic mapping. Because of the degree of structural flexibility within the SEQUEL language and the original concern to narrow down the problem to a manageable size, it was decided to curtail the number of acceptable query structures. The acceptable SEQUEL structural patterns are shown below. It is felt that the structures selected are generalized enough to allow for the processing of a wide range of source queries.

ACCEPTABLE SEQUEL QUERY PATTERNS

TYPE I: BASIC MAPPING WITH NO POSSIBLE NESTING REFERENCES:

```
SELECT   "Domain Name(s)"
FROM     "Table Name"
WHERE    "Conditional Phrase"
AND      "Conditional Phrase"
OR       "Conditional Phrase"
```

TYPE II: BASIC MAPPING WITH POSSIBLE OUTER AND/OR INNER REFERENCE MAPPINGS:

```
[POSSIBLE OUTER
 MAPPING—
 TYPE II STRUCTURE]=
                    SELECT   "Domain Name(s)"
                    FROM     "Table Name"
                    WHERE    [POSSIBLE INNER MAPPING—
                    AND       TYPE II STRUCTURE OR
                    OR        CONDITIONAL PHRASE]
```

TYPE III: BASIC MAPPING WITH CONNECTING INTERSECTION AND/OR UNION OPERATORS:

```
SELECT   "Domain Name(s)"
FROM     "Table Name"
WHERE    [POSSIBLE INNER MAPPING—
AND       TYPE II STRUCTURE OR
OR        CONDITIONAL PHRASE]
∪,∩
SELECT   "Domain Name(s)"
FROM     "Table Name"
WHERE    [POSSIBLE INNER MAPPING—
AND       TYPE II STRUCTURE OR
OR        CONDITIONAL PHRASE]
. . . . . further segments are possible
```

NOTE: in all of the structural types presented above, the AND and OR clauses are optional.

For ease of description and because the formal translation algorithms need to be specific in addressing the basic parts of a query, it is necessary to develop some terminology associated with the contents and structure of a SEQUEL query. We will refer to a basic SEQUEL mapping as a "segment." Therefore, depending upon the nesting factor of a query structure, a particular basic mapping can be defined within a query by its *level* and *segment* numbers. There can be as many levels as appropriately needed for an application. The level within a query changes only when an outer or inner mapping occurs in the query itself. Different basic mappings used in one level are noted as different segments. For example, the query presented below would be labeled as follows:

```
[LEVEL 1          SELECT    SALES,TAX
 SEGMENT 1] ____  FROM      TABLEONE
                  WHERE     DEPT=
[LEVEL 2                    SELECT    DEPT
 SEGMENT 1]_________________FROM      STORETB1
                            WHERE     MGR='ALAN'
                            ∪
[LEVEL 2                    SELECT    DEPT
 SEGMENT 2]_________________FROM      STORETB2
                            WHERE     LOCTYPE=2
                  AND       SALESMAN=
[LEVEL 2                    SELECT    SALESMAN
 SEGMENT 3]_________________FROM      TABLETWO
                            WHERE     SALARY≥11000
```

The information content of each segment (basic mapping) within each and every level of a query is coded and saved so that mapping relationships and information may be available for the formal algorithm. The following information is derived for every segment within a given level (Figure 6): In order to label the information provided above in its level and segment context, the following syntax will be used:

[ABBREVIATED REFERENCE NAME, L,S]

Now, for a full understanding of the meaning of the query labeling terminology, an example will be presented. Note that since some of the label references provided are optional in the SEQUEL query syntax, the value in such a case where there is an applicable information will be 'null.' Say the query in question was the following:

```
SELECT   EMP#,CODE
FROM     TABLEONE
WHERE    DEPT=5
AND      SALES+COMM<1000
AND      MGR='ALLEN'
∪
SELECT   EMP#
FROM     TABLETWO
WHERE    E#=
         SELECT    E#
         FROM      TABLETHREE
         WHERE     SUM(SALES)=10,000
         AND       DEPT+CODE=5
         OR        SALARY
                     +COUNT(T#)=20
         OR        MARK=1
```

SOC

SOURCE TABLE NAME	SOURCE DOMAIN NAME	SPECIAL CONDITION	
		VALUE	OPERATOR
SLSPR	S#	10	>
PTS	P#	50	=

Figure 5—Table for selection conditions

INFORMATION DESCRIPTION	ABBREVIATED REFERENCE NAME
LEVEL NUMBER	L
SEGMENT NUMBER	S
OUTER MAPPING REFERENCING CLAUSE DOMAIN	OMRCD
SELECT CLAUSE DOMAIN (S)	SELDOM(N)
FROM CLAUSE TABLE	FROMTBL
WHERE CLAUSE DOMAIN (S)	WHRDOM(N)
WHERE CLAUSE ARGUMENT	WHRARG
AND CLAUSE (S) DOMAIN (S)	ANDDOM(C,N)
AND CLAUSE (S) ARGUMENT	ANDARG(C)
OR CLAUSE (S) DOMAIN (S)	ORDOM(C,N)
OR CLAUSE (S) ARGUMENT	ORARG(C)
INTERSECTION-UNION CONNECTION	INTUNC

Figure 6—Information contents for each segment

Then the following labels represent some examples of information which could be derived from the example query:

```
[SELDOM(1),1,1]    = 'EMP#'
[SELDOM(2),1,1]    = 'CODE'
[FROMTBL,1,1]      = 'TABLEONE'
[WHRDOM(1),1,1]    = 'DEPT'
[WHRARG,1,1]       = '5'
[ANDDOM(1,1),1,1]  = 'SALES'
[ANDDOM(1,2),1,1]  = 'COMM'
[ANDDOM(2,1),1,1]  = 'MGR'
[ANDARG(2),1,1]    = 'ALLEN'
[OMRCD,1,1]        = 'null'
[INTUNC,1,1]       = 'U'
[SELDOM(1),1,2]    = 'EMP#'
[FROMTBL,1,2]      = 'TABLETWO'
[OMRCD,1,1]        = 'E#'
[WHRDOM(1),1,2]    = 'E#'
[FROMTBL,2,1]      = 'TABLETHREE'
[WHRDOM(1),2,1]    = 'SALES'
[ORDOM(1,2),2,1]   = 'T#'
[ORARG(2),2,1]     = '1'
```

C. *Stage 3—Query Translation Preparation*

Stage 3 of analysis determines which translation procedures need to be used in converting each and every basic mapping within the query. There are four separate procedures designed to carry out the translation task. The order and number of procedures to be used in converting a basic mapping depends totally upon the source database table being referred to in the FROM clause. Using the TCI table, it is possible to search for the source database table to determine which CONVERT operations were performed. The selection of procedures and their order of execution depend on the CONVERT operators applied on the source database table as illustrated by the flowchart in Figure 7. Thus, if TABLE 1 of a segment were operated upon by the CONVERT operators SORT and CASE ASSIGNMENT, PROCEDURE1 and PROCEDURE3 would be called to translate the segment.

D. *Stage 4—Query Pre-Translation Reference Table Development*

During this stage, a set of reference tables is set up based on the analysis of a source database query. For each basic mapping in a query, the following number of tables are established. Their contents are described below.

REFTB1

This reference table contains information about the domain(s) used in the WHERE clause of a basic mapping. Each tuple of REFTB1 contains a WHERE clause domain (or corresponding domain name reassignment) and the target database table in which the domain can be found. This information can be extracted from the TDU Dictionary Table.

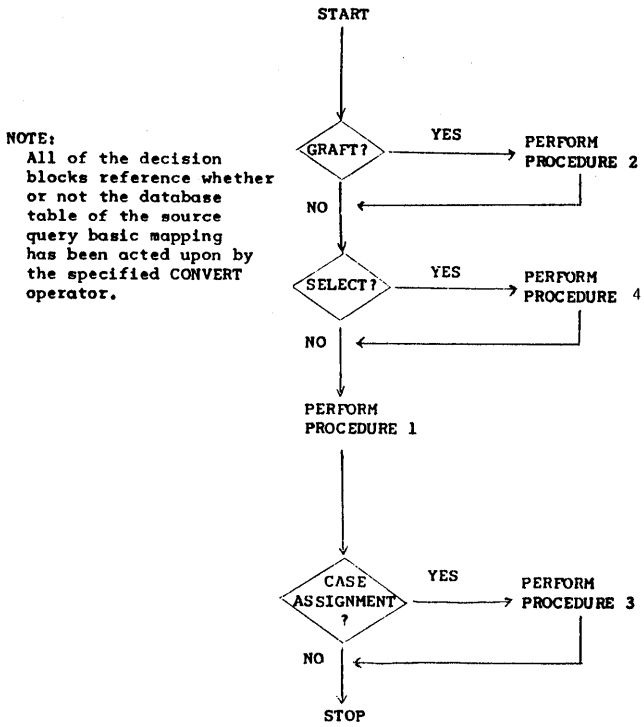

Figure 7—Program selection and execution sequence

REFTB2.n

This is a set of reference tables (n=0,1,2, . . .) each of which is set up for an AND clause of the basic mapping. The information stored in these reference tables concerns the domain or domains used in the AND clauses and the target database tables in which they are contained.

REFTB3

The contents of this reference table are derived from an analysis of REFTB1 and REFTB2.n tables. It is primarily used to determine if there is any target database table which contains all of the domains present within the WHERE and AND clauses of the basic mapping.

REFTB4.n

This set of tables (n=0,1, . . .) has the similar contents as the REFTB2.n except that the tables relate to the domain(s) in the OR clauses of the basic mapping.

REFTB5

The contents of this reference table are derived from an analysis of the target database tables which are present in REFTB3 and REFTB.n. It is used to determine if there is any target database which contains all of the domains present within the WHERE, AND and OR clauses of the basic mapping.

REFTB6 THROUGH REFTB19

These reference tables hold information concerning the domain(s) of the SELECT clause of the basic mapping being analyzed. It is assumed that a maximum of 14 domains can appear in a SELECT clause. Each table contains the name of a domain, all its domain reassignment names and the target database tables in which they can be found.

REFTB20

The contents of this table are generated by an analysis performed over REFTB6 through REFTB19. It lists the names of all target database tables in which all the domains used in the SELECT clause can be found.

Q.C.T.

This is a special reference table whose initials represent "Query Conversion Table". It is used directly by the translation algorithm to restructure the source database query. Its contents are developed through an analysis of REFTB5 and REFTB20. Query changes due to domain and table name reassignments are noted in this table.

The above set of tables are different from the Dictionary Tables generated in Stage 1. The dictionary tables hold information concerning the entire source database and the data conversion information; whereas, the reference tables contain data related to one source query. Examples of the reference tables are given in the next section where the entire translation process is illustrated by an example.

E. *Stage 5—Formal Translation Algorithm*

Stage 5 uses the data established in the dictionary and reference tables to convert each of the basic mappings in the source query. The basic mappings are processed sequentially from top to bottom (i.e., the segment with the lower level number first). As mentioned earlier, there are four main procedures used for query translation. These procedures have been written in PL/1-like statements which describe the algorithms of conversion and are given in a master's thesis by Reynolds.[17] PROCEDURE2 is designed for taking care of the effect of applying the GRAFT operator. PROCEDURE 3 and 4 are concerned with CASE ASSIGNMENT and SELECT operations respectively. PROCEDURE1 is a general procedure which handles the conversion of basic SEQUEL mappings to account for database changes introduced by other CONVERT operators.

A sizable number of subroutines and functions have been defined for accessing data from the dictionary and reference tables, for testing the data conditions specified in the basic mappings of the source query and for generating the basic mappings of the target query. These routines and functions are described in the original report.[26] They are not given here because of their length.

F. *Stage 6—New Target Database Query*

This stage is concerned with the formation of the new target database query. The labeling techniques and inner workings of the translation procedures make the final construction of the new target query rather simple to derive. There are only two distinct ways in which a query's input structure may be modified: expanding a basic mapping into two mappings and contracting two basic mappings into one. These two basic structural changes are handled by RESTRICT3 and RESTRICT5 routines.

RESTRICT3 is concerned with query transformations caused by changes in data access paths. When a query structure conversion of this type occurs, the nesting factor or total number of levels present within the query increases. While this expansion is taking place, the function also readjusts the labeling criteria of all basic mappings within the source database query to compensate for the transformation. All reference tables are also reassigned so that they are associated with the correct basic mappings. There is no need to develop reference table information for the newly created basic mapping levels. RESTRICT3 ensures the correctness of these particular basic mappings.

RESTRICT5 is concerned with query transformations caused by the use of the GRAFT operator on database tables during the data conversion process. In a structural conversion of this kind, the nesting factor or total number of levels present within a query decreases. RESTRICT5, like RESTRICT3 also readjusts the labeling criteria of all basic mappings within the source database query to account for this structural contraction. All reference tables are either reassigned or redeveloped so that proper association is recovered.

Thus, with all structural conversions being taken care of by RESTRICT3 and RESTRICT5, the same basic mapping processing sequence developed during Stage 2, modified by any added and/or deleted basic mappings, can be used to construct the new target query. This stage is performed after all basic mappings of a source query have been processed by Stage 5.

AN EXAMPLE ON THE SUBLANGUAGE QUERY CONVERSION

A query conversion example presented within this section is given in order that the reader may obtain a clearer understanding of the analysis process and the translation algorithm. More examples of different degrees of complexity can be found in a Master's thesis by Reynolds[17] where the degree of complexity of the examples is varied depending upon which CONVERT operators were used on the database tables referenced by the queries and the query structure itself. For our example, we shall first present, by illustration, the source database contents, the CONVERT operations used on the source database and the newly formed target database contents. The query will then be put through the analysis process and the results of the stage-by-stage analysis will be given. The Stage 5 results are only summarized. They show the outcome of tracing the procedure steps and functions.

                  OR        RACE = 'A'
        AND       SALARY ≥  9000
```

CONCLUSION AND FUTURE RESEARCH

Although the data independent property of a well-designed DBMS allows many types of database organization and restructuring at both logical and physical levels without causing changes to the application programs, there are situations where modification of application programs is unavoidable and is more beneficial in terms of system efficiency than using the mapping software associated with the schema and the subschema. As illustrated and argued in an earlier section, drastic reorganizations of the physical database, changes of the semantic associations among data entities and addition and deletion of semantic associations and entities often entail changes to the schema, the subschema and therefore the application programs of a DBMS.

The existing data sublanguages, SEQUEL is an example, depend heavily upon the data model and the data submodel used. The sublanguage statements make direct references to the domain names, entity relation and association relation names and, to a certain degree though different from model to model, contain access path specifications to the data to be searched or processed. Thus, most changes made in a subschema would immediately terminate the life of application programs. To really increase the life span of application programs, it is necessary to make the data sublanguage more independent of data models and submodels. How we can achieve this in language design remains to be investigated.

At this stage of our investigation, we have worked out the algorithm for translating limited yet general language patterns in SEQUEL to account for the database changes introduced by CONVERT operators. This algorithm is described in four procedures written in PL/1 like statements. These procedures have been tested based on hand simulation of a large number of queries running against target databases produced by different sets of CONVERT statements. No actual coding of these procedures have been carried out because we believe that it will not add anything more to what we already can learn from the present work and it is not necessary for meeting our objectives stated in the Introduction at this stage of research. Based on our work and analysis in a somewhat restricted scope, we are quite confident to conclude that it is possible to implement a conversion system to either convert sublanguage statements automatically or provide assistance to the translation analyst in identifying the statements which need to be modified or the possible loss of data when running the old program against the new database. This can be done if the database translation task is carried out orderly by a well-defined database conversion language and the sublanguage used is well structured like SEQUEL. In our work, we found that the data tables in the translation dictionary are adequate for query conversions and the database changes due to all the CONVERT operators can be accounted for by query conversions. The algorithm worked out in this work does not have any general application other than the conversion of a subset of SEQUEL queries. Nevertheless, it is believed that the general methodology and analysis process presented can be useful for future works on other languages even though it is clear that the idiosyncracies of the languages (the sublanguages as well as the data mapping languages) have to be accounted for.

Besides the previously mentioned problem of designing a data language which is independent of the data models and submodels, the following problems seem to be worthwhile investigating. First, the access paths to the desired data in the source database can be very much different from the paths in the target database. In general, there are many access paths to the desired data. The selection of the shortest access path for forming the target query, i.e., the optimation of access path selection, needs to be further researched. Second, the selection of a proper access path that will be consistent with the semantics of the new database is an interesting problem. Any transformation of the source query not only has to preserve the original meaning of the query but also has to incorporate the data conditions based on which the target data files are formed. Some way of proving the correctness of the converted queries based on the semantics of the source queries and the target database would be a task of great importance.

Another problem under our current investigation is based on the following observation. The basic semantic patterns, such as one-one, one-many, many-many associations between/among entities, existing in different database systems are often the same even though different systems may use a different data model for user-database interface. In a given model, the representation of a basic semantic pattern is more or less fixed (e.g., a many-to-many association is represented by two entity relations and an association relation in the relational model,[5] by two owner-coupled sets defined over two record types (for two entities) and a link record type in DBTG's model[3,4] and by two physical databases with proper logical parent pointers to support two logical views of the n:n association in IMS[12]). Since the sublanguage statements for processing the entities and their association depend upon the data representation as defined in the subschema, the access paths to the desired data in each basic semantic pattern should be restricted. The sublanguage patterns for carrying out the access paths can be exhaustively delineated. When a semantic pattern of data has been changed in a database translation, it should be possible to determine first the proper representation of the new data at the subschema level and then the sublanguage patterns which will do the same job as the source language pattern for the source data semantics. Furthermore, it should be possible to determine the pattern of data access in one source language and generate the corresponding pattern of data access in another language once the same data semantic pattern has been identified. Investigation of a generalized program conversion system and of the problem of converting application programs in one database system to that in another system is in progress. Research results along this line of thought are reported in References 27 and 28.

Guidelines to software conversion

by PAUL OLIVER
Department of the Navy
Washington, DC

BACKGROUND

Data processing installations preparing to undergo a system transition are faced with several difficulties; prominent among these being the transition of the current workload to a new system.

A report by the General Accounting Office[1] published in September 1977, states that the annual Federal Government cost of modifying computer programs to enable them to execute correctly on a computer different from the one for which they were originally devised is estimated at more than $450 million. Comparable industry-wide figures are not available, but it is reasonable to assume that the overall cost of software conversion is significant. Furthermore, this is a non-productive cost; conversion per se results in no direct improvement in an organization's ability to fulfill its mission.

Research and development efforts are under way at several universities and research laboratories to determine ways and means of producing portable software, i.e., software which is machine and configuration independent over a set of computer installations (e.g., see References 2 and 3). At the same time, industry is reacting to the problem in a variety of ways, including a softening of architectual differences (e.g., there are some half dozen IBM 370 "derivatives") and an improvement in emulation capabilities. Until such efforts bear practical fruits, data processing organizations will periodically be faced with the prospect of a software conversion effort. Such an effort is invariably faced with distaste and apprehension.

These are several reasons why system conversion is such a disruptive process. First of all, programmers must be shifted from their regular assignments to the conversion task. This is true whether or not an outside contractor is used to assist in the conversion. Proper conversion requires documentation, and old documentation is often found to be inadequate, even in well managed installations. Aggravating this condition is the fact that the programmers who originally coded the system are frequently no longer with the organization. It is also a sad fact that very few software development specifications include provisions for portability, even though techniques for reducing the impact of system changes on software are known and documented. Finally, conversion often will take place in conjunction with the implementation of a new system, thereby adding to the concomitant disruption.

Conversion is a many-faceted enterprise. An organization preparing itself for a conversion needs to consider not only the conversion process itself but also its management, the technical problems to be faced, the relationship of the conversion costs to the cost evaluation of the new systems being considered, the procurement of conversion support services, cost and time estimates, conversion alternatives (such as emulation), and training of personnel. A complete discussion of all of these topics is beyond the scope of any single paper. We will concentrate therefore on the description of the conversion process itself and the technical difficulties associated with it. The emphasis will be on what needs to be done rather than on how to do it. This emphasis reflects a value judgment on the part of the author; namely, that most of the ignorance regarding conversion has to do with the process itself. All too often organizations mistakenly liken conversion to development, fail to plan and prepare properly, and invariably are overly parsimonious in the allocation of resources to the conversion effort.

Before proceeding, the following definitions are provided in order to set the scope of this paper:

> "*Conversion*: By conversions we mean any change made to a program or system of programs solely for the purpose of enabling such a program or system to execute correctly on a computer different from the one for which they were originally devised. *Translation* refers to a largely automated process of conversion in which the original programs themselves serve as adequate specifications for the new programs to be produced. *Recoding* is similar to translation except that the process is largely manual. *Reprogramming* refers to a conversion which may entail a system redesign (e.g., batch to on-line) but no significant functional redesign. *Redesign* refers to a conversion effort which involves functional redesign and is therefore akin to new development."

CONVERSION PROJECT OVERVIEW

Preparation

The first step in the preparation for conversion is the requirements analysis. A review of the planned differences between existing systems and the converted system is par-

ticularly important if the language dialect being converted to has new language modules (which may be fruitfully used in the converted system), or major changes to input-output modules. It will also be necessary to identify the degree to which the compiler being used differs, in its implementation of the language, from the standard specifications for that language.

Tasks, schedules, resource requirements, and end products must be identified. Schedules and resource requirements are particularly difficult to gauge. It is generally a good idea to obtain contractor support in preparing time and resources estimates, since broad experience in conversion is required in making such estimates. The review of existing programs may reveal some which will require no conversion. It is doubtful that there will be many of these. The rest must be collected together with accompanying files and documentation, and placed in the hands of a conversion team.

Finally, the specifications of system changes must be defined. Data file changes may be required; file and record sizes, field contents, file organization, access keys, sort keys, access methods, storage media, and labeling conventions are all likely candidates for change. The conversion will present an opportunity for some needed system restructuring; programs to be combined, intermediate files eliminated, or sort/merges which may be deleted if the restructuring involves a shift from tape to DASD residence for certain files. Also carefully specified must be any processing logic changes which are necessitated by differing language dialects.

Software tools must be identified and developed. Software must be available to load data, copy programs, create extracted versions of test data, perform data and file conversions, compare tests results for validity, and measure tests for reliability. Procedures must be developed and controls and quality assurance standards must be specified.

Programs must be collected in a uniform way to ensure that the correct version (release) on every program is being converted. The software indicated above may be used to create test libraries and to control this step. A procedure for maintenance change inclusion must be developed, and a reference base for changes is hereby established.

Adequate test data must be prepared which will exercise an acceptable portion of the converted programs. Each program should have a set of known inputs which produces known outputs in order to validate each program. Ideally, unit test data can also be used for system testing.

Finally, all related materials must be collected. This includes program and system documentation (flowcharts, narratives, run-books, data layouts), inventories of files and programs, source listings, program assemblies (listings), and a directory of every item's physical location.

Production

As subsystems become ready for actual conversion the translation process begins. This is true even if systems are to be eventually modified. That is, the conventional wisdom is that program translation (i.e., a one-for-one, or close to it, conversion) should precede any modification. This is done to avoid intermingling, and thereby compounding any translation errors or effects with modification errors or effects. The success of the conversion will be closely related to the adequacy of the controls which are applied during the production stage. Controls must be established for the receipt, handling, and distribution of all materials, for the copying and analysis (to ensure the correctness of the copy process) of program tapes; and for the definition and use of job control language programs.

The translation process itself will be partly automated. Many features of programming languages lend themselves to automatic translation, using commercially available or in-house developed utilities. Unfortunately, a large portion of the input-output coding will have to be hand-translated, and in some cases the process will necessarily have to be closer to modification than translation.

Thorough unit and system tests should follow the translation phase (and will have to be repeated after the modification phase, if any). It is generally advisable to desk-trace the programs in a gross way, i.e., through job control, housekeeping, and initial input statements. A monitor which intercepts and analyzes abnormal terminations would be an extremely useful tool during testing. The monitor should be capable of displaying the instruction causing the abnormal termination, the data being processed at that time, and of providing snapshots of selected data/program areas. Also useful would be a file-compare utility to determine the validity of the outputs produced by the translated program and a monitor which could recognize units of untested code. Once a translated system has been successfully tested any required modifications can take place. These may include system restructuring (combination of common subroutines, sort/merge utilities, etc.), changes in logic, and changes in data files.

Finally, the entire process must be thoroughly and carefully documented. The precise form of the documentation will depend on the installation's standards, but should include at least the following:

Converted source programs
Flowcharts of the converted systems
Listing of all job control language programs used
Standard file labels
File conversion parameters
Operating instructions and technical notes
Unit and system test reports

The following is a step-by-step summary of how a production team should perform the translation of programs:

a. Materials are received by the production team and processed by a Control Section. Each tape is analyzed to ensure readability, and copied to backup tapes. Test data are converted to target machine format. Standard job control code is generated. Task estimates and a schedule for the program translation are created by a resource management system.
b. The source program is converted to the target language

by a multi-step process, using appropriate software tools. It has been found useful to first convert the source code to some intermediate language to permit standardized analysis and manipulation. This is particularly true if the conversion is to involve several source and target languages. The eventual restructured intermediate language program is then converted into properly formatted target language code. The target program listings and other documentation are collected and given to the project manager, who assigns the program to an analyst for completion of the documentation.

c. Corrections are made to the target program, again using appropriate software tools. The program is compiled until all diagnostics are resolved. Two programmers should then desk check every line to verify logical equivalence to the source program.
d. Testing begins with the aid of a cross-reference program, a tool to trap processing exceptions and allow continued processing, and a file compare program to verify output data equivalence. Unexecuted code is identified and carefully desk checked.
e. Unreferenced code is located and identified. Old data and procedure names are replaced where required by new names. The source code is formatted to installation standards to ensure the uniform appearance of all programs.
f. When program translation is completed, system enhancements are applied, and maintenance changes are identified and implemented.
g. The completed programs are returned to the project manager for a quality control check. The material is then processed by a control section and prepared for shipment to the implementation group. Backup copies of programs are stored on tape, along with microfilmed copies of listings for future reference.

Implementation

Implementation of the converted system should not take place until the systems software to be used has reached a satisfactory level of stability (this will be a subjective decision). The conversion manager should anticipate changes (upward) in the resources required to compile and execute the converted programs, and should allow for these changes in order to avoid serious degradation in throughput.

Unit and integration testing should be repeated on converted programs and test data once these are installed on the target system. Once this testing is satisfactorily completed, maintenance changes are applied and tested, problems are corrected, and retesting is performed. This process is repeated until all tests are successfully passed. It should be noted that this inclusion of maintenance changes entails the generation and conversion of production test data to be used in the testing process. Note also that no further changes must be applied to the production programs at this time.

In the meantime, the production database itself is converted and tested, and the operating system control language production stream is generated. Finally, production testing using the final version of programs, data, and control language programs takes place (acceptance testing), followed by an appropriate period of parallel testing.

Software tools

The description of the conversion phases included several references to software tools. A complete inventory of such tools is expensive, and this would be one of the factors which must be taken into consideration when contemplating an in-house conversion, since this inventory would not be of great value after the conversion.

There are several ways in which a software support inventory could be characterized, the simplest of which is according to the three principal conversion stages in which they are used:

a. Preparation: A file contents analyzer, a data extractor and modifier, and a data generator can all be used for creating test data. Utilities will also be required for creating backups of all programs, and for maintaining a current version of the software inventory to be converted and producing statistics (e.g., average program sizes) as required.
b. Production: The production stage will require software to perform source code to intermediate code translation, to analyze and restructure the intermediate code, to perform intermediate code to target code translation, and to translate test data files. Utilities will be needed to generate the operating system control stream and to apply code corrections to translated code. Additionally, software to produce cross-reference listings, to trap and identify exceptions, to identify unexecuted code, and to perform file comparisons will be needed for testing. A de-compiler or depatcher will be needed if the conversion is from an assembler language to a higher level language.
c. Implementation: Software to validate the results of parallel testing, to identify and implement maintenance changes, and to convert the production data base is required.

Additionally, software aids will be useful in the management of the conversion project. As a minimum, software tools are needed for resource management (identify programs and categorize by source and content, estimate resource requirements, and monitor progress), and standards enforcement (format programs to installation standards, replace old names with standard names, etc.).

Managing the conversion project

A conversion project is only slightly different from any other software production project with respect to its management. Careful planning is required, the project must be initiated and, once initiated, it must be controlled. Finally,

there is a completion phase. If there is a significant difference between a conversion project management and a production project management it is one of emphasis; a conversion project requires (and allows for) more discipline and stricter adherence to procedures. If properly executed, a conversion is very much an assembly-line type of operation, where the total effort is broken down into well-defined tasks which are more dependent on experience and strict adherence to procedures than an innovation and ingenuity for their successful completion. This is true partly because of the high degree to which the conversion process can be automated. It should also be noted that many of the ground-rules for software production do not apply to conversion. For example, manpower and time are not generally interchangeable in a software production project, but, within bounds of good taste, they are in a conversion project.

Productivity rates also differ widely between conversion and development. Software development seems to proceed at some 12-20 lines per man-day for general application software, while conversion may proceed at rates as high as 400 lines of code per man-day.

A word of warning regarding project organization—a common mistake is to make the conversion staff a part-time group which participates in conversion activities but whose members continue to report to their parent organizations. This is an ingenious way to make a mess of the conversion, particularly since it will be nearly impossible to attribute responsibility for the mess to any one person.

The specific makeup and size of the conversion staff will vary with the conversion type and magnitude. The following membership, without specific quantities, is suggested for a large-scale project which will require contractor support. Following each staff category is an indication of the role of that category:

a. Project Leader

   (1) Planning
   (2) Project initiation
   (3) Project control
   (4) Project termination

b. Contracting—staff support advising on

   (1) Type of contract
   (2) Necessary clearances
   (3) Terms and conditions
   (4) Scheduling

c. Operations

   (1) Present status and future needs
   (2) Performance specifications
   (3) Scheduling
   (4) Inventory
   (5) Computer resources

d. Systems Programming

   (1) Inventory
   (2) Sizing a job
   (3) Performance specifications

e. Application systems developers

   (1) Inventory
   (2) Sizing
   (3) Performance specifications

f. Support programming—software tools for

   (1) Inventory
   (2) Quality control
   (3) Production
   (4) Testing

g. Material Control

   (1) Quality assurance
   (2) Backup inventory
   (3) Materials transmittal

h. Clerical—supports entire team

i. Analysis & Programming

   (1) Production
   (2) Testing
   (3) Implementation

Figures 1 and 2 suggest the organizational relationships among the staff components, and Appendix A lists the major tasks to be performed in the form of a checklist.

CONVERSION PROBLEMS

General

A conversion project results in a very large volume of material, and this results in control programs. Staffing required for the conversion project will not be needed at the culmination of conversion and will be diverted from ongoing development and maintenance. Furthermore, there will be periods of peak requirements. This will create serious management problems.

Machine time will also encounter periods of peak loads. This, unfortunately, conflicts with growing production due to the cutover of subsystems. Machine time availability takes on an inverse relationship to conversion requirements. In many cases, conversion requirements plus production requirements become more than the total of machine availability. This causes costly delays in the conversion schedule.

Low resources requirements estimates are caused by a lack of understanding of the conversion process. An esti-

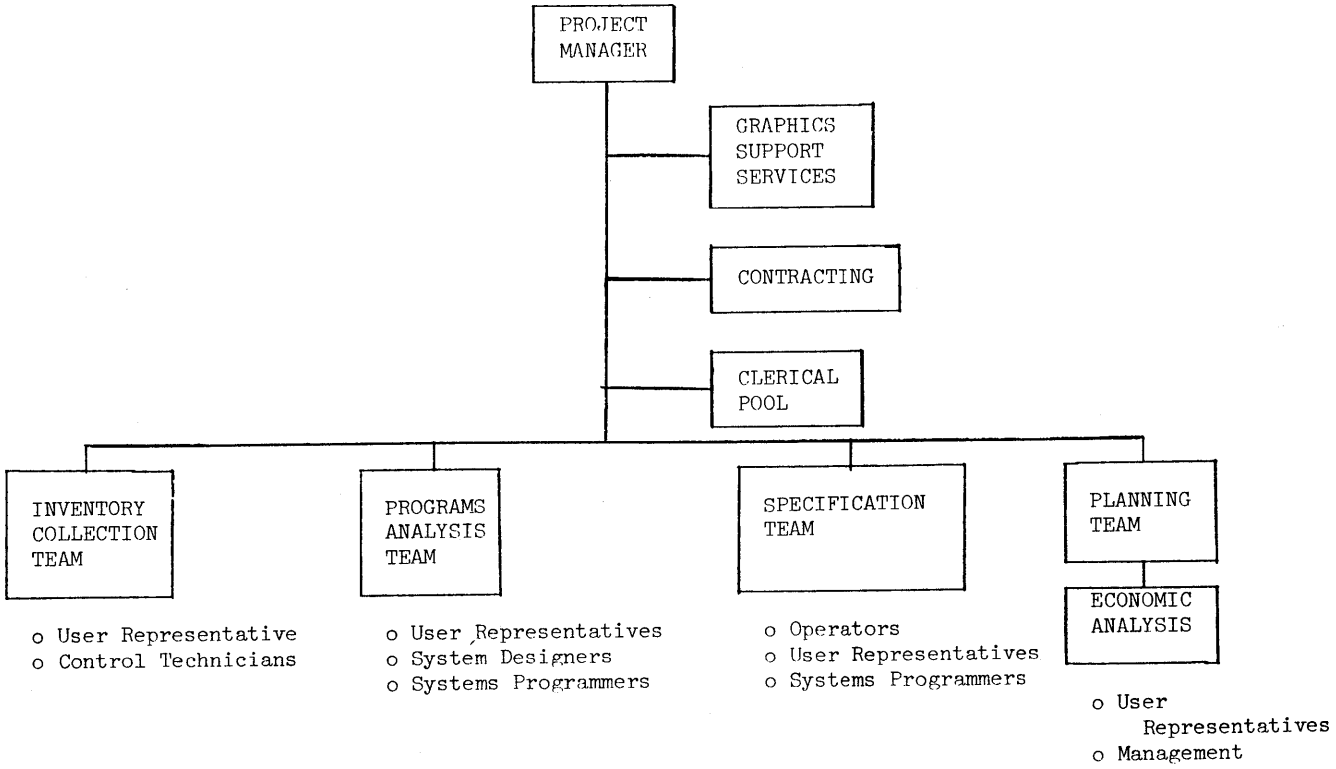

Figure 1—Conversion project organization (Feasibility analysis and planning)

mator may take a few programs, convert them, and attempt to extrapolate the requirements for the whole job. This projection is inaccurate because it represents a straight line relationship (which never really exists) between conversion volume and resource requirements. This mistake is of course the same one which has plagued production time estimators for years. As in software production, size has a special effect on conversion time and costs which render a linear relationship invalid. For example, a competent programmer, properly supported by a set of software tools, can convert 500 lines of COBOL source code per day. This suggests that a 10,000 line program could be converted in 20 days, whereas experience shows that some 36 days would in fact be required, and that this number could go up to 104 days if the conversion is from an assembler language with complex file structures and large file volumes. Another program in estimating is the tendency to exaggerate the extremes by making simple tasks appear too simple, and difficult one too difficult.

Technical

A complete discussion of all the technical problems of conversion is beyond the scope of this paper. What follows is a brief discussion of some of the differences in machine architectures and file structures which can impact conversion.

Computer words vary in the number of characters that they contain causing problems in numerical accuracy and data movement. The accuracy program can be dealt with by increasing arithmetic precision, but this will increase storage requirements as well. The program in data movement is that programs can often refer to the storage of words or characters. When we translate these programs, the net effect is inconsistent treatment of data. A UNIVAC 1108 with a 36-bit word has six 6-bit characters. If we were converting to an IBM S/370, the 1108 program would move six characters in moving a word while the S/370 programs would move four characters in moving a word. To solve the program we have to determine whether or not the code refers to character data. This process often involves lengthy analysis, which requires personnel time, reduces automation, and increases time and costs of conversion.

Machine condition indicators are internal switches that are set for special conditions, e.g., overflow, zero divide, or invalid data. Problems arise when the source machine sets an indicator and the target machine either does not, or does so under slightly different conditions. For example, the 1401 would treat a space as a zero when doing any arithmetic. An IBM 370 will cause an interrupt called a data exception (OC7) when any non-numeric data appear as an operand in an arithmetic statement. This condition must be corrected in the translated program.

The format and the amount of information that is specified to define a file varies among languages. Some languages may

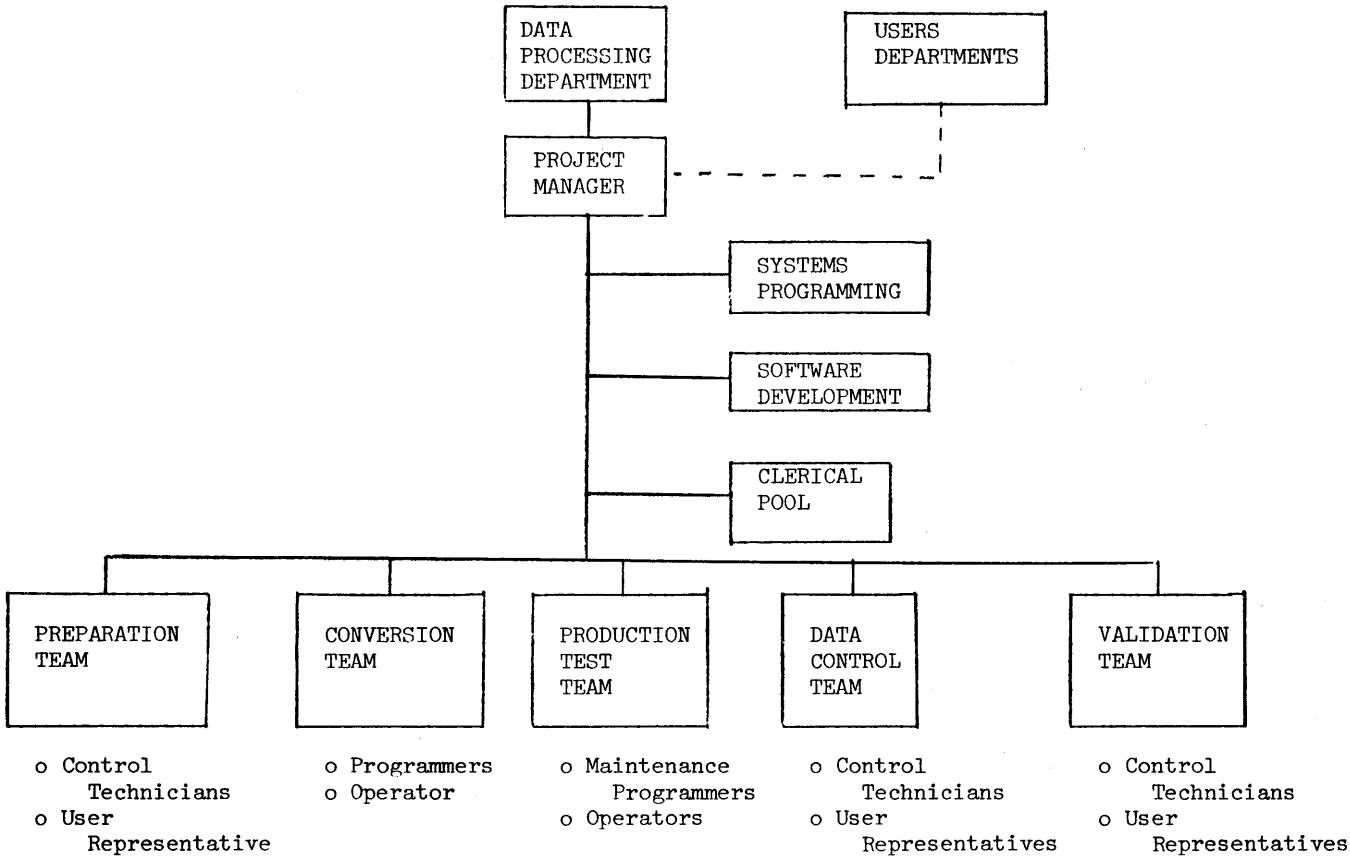

Figure 2—Conversion project organization (Post-planning)

require very little information to be specified, while other languages will require a great deal of information like record length, block size, or labels. Often there is even a wide variance between programs written in the same language because a language will allow, but not require certain specifications, or there will be different ways to define and specify file information in the same language, e.g., standard macros, user macros, or no macros (user-coded I/O).

The specifications of a file may be defined implicitly or explicitly. Explicit definitions are required in a COBOL program. An implicit definition might occur in an assembler program where a file is defined only by its use. Thus, the program and all references to the file must be analyzed to determine the appropriate file definitions. A similar problem also arises in data definition. A data item could be defined explicitly as a character field or not defined at all. All assemblers allow a programmer to specify arithmetic and/or binary operations on any data field. The actual use of a data item defines its implicit attributes. These may differ from their defined attributes in both data type and field length. When there is a discrepancy, an alternate definition must be generated to accommodate the circumstances. This condition is further complicated when implicit usages change because of word size variances.

No "standard" format exists for the recording of variable length records on tape or disk. Some of the ways in which the records are delineated are by delimiting records by special characters to indicate the stopping or starting point of each record, recording the variable length records as fixed length records by padding their length to a maximum consistent length, or inserting byte or word counts at the beginning of each record.

File organization becomes a consideration on any nonsequential file. Generally, indexed files contain pointers to indicate sequencing. Problems arise because variances are encountered in the location of the pointer, the format of the pointer, and the meaning of the pointer (some access methods will use actual track addresses, while others will use a relative record number within the file). The conversion of an indexed file includes getting the disk file onto tape, converting the pointer to the new format, and reloading the file to disk. The manner in which an indexed file is processed usually varies by language and machine. The differences may involve module communication or linkage to the access method for the system. Many direct access applications are developed using an algorithm to compute and determine the location of records on disk. For example, the disk addressing techniques of a source machine may be determined by an algorithm based on bytes per record, records per track, or tracks per cylinder. When converting to a relative addressing technique, or just a disk file with different characteristics, one or all of the above disk parameters could change.

The functions of OPEN and CLOSE in a program will vary. A tape-oriented program may OPEN and CLOSE each tape reel as a separate file; this coding must be eliminated when converting to a concatenated or disk file. Almost all I/O systems have different techniques for handling I/O errors. They also have different error recovery routines. Differnces in these routines must be examined and handled. Communication with error routines must also be dealt with.

Data is frequently represented in different ways on the source and target machines. Often the differences can be easily dealt with, but representation differences can present significant problems. This for example, the BCD (Binary Coded Decimal) and EBCDIC (Extended Binary Coded Decimal) character sets have bit patterns for numbers (0-9) that have a greater binary value than the letters. Several other character sets do not maintain this same relationship and the bit pattern for the numbers has a lower value than for the letters. Conventions and requirements for representing (or not representing) signs on numeric fields often differ between machines produced by the same vendor and always differ between machines produced by different manufacturers. For example, on some machines a negative amount on character numeric fields is indicated by a "a negative zone" and all other numbers are represented by "no zone". On an IBM S/370 there are "−zones," "+zones," and "no zone" fields. On some systems a packed decimal number must always have a sign in the right four bits of the field. The Honeywell 8200 does not require a sign. If a sign is present, it can be from one to four bits long and will appear in the left of the word, not necessarily adjacent to the field. Various Job Control Languages (JCL) are used to relate an application program to the hardware's operating system. Each is usually unique to a computer system. All functions that a program performs with the source operating system must be converted to functions to be performed by the target program and/or operating system. Differences among JCL may exist with regard to inter-module communication. Information (data) is often passed between subroutines within a running program. Sometimes, the data is left in a "common" area of memory by both the calling and the called subroutines. Communicated data must then be isolated and the address of the data passed between modules. Differences may also exist in the roles of the application program and the operating system. In the past, with programs running sequentially in computers, the operating system allowed the program to determine its own hardware usage, file allocation, core allocation, and time requirements. When multiprogramming, these functions are removed from the application programs and supplied by the operating system

In addition to system differences, the differences created by individual organizational programming practices can create significant problems in a conversion effort. In fact, these represent the major factor impacting cost. Sometimes installations using low level languages do not have stringent programming standards. This often results in non-uniform, inconsistent programs. COBOL or PL/I forces a certain degree of standardization. The transformation process must be designed to handle each of the different circumstances and to produce code in a standard high level language. Insufficient, out-of-date or non-existent documentaton is a significant problem for most conversions. The conversion process does not require extensive documentation since we use the source program as the specification for the target program, but system level documentation (or job/file flow) is needed to restructure a system and record layouts are required for file conversions. Systems are often designed with specific hardware/software limitations or user options in mind. Examples are the use of checkpoint/restart for a program that runs too long, using overlays because of core limitations, using a disk file instead of a tape file because of a shortage of tape drives, or running a sort separately instead of as an exit in our application program. Many of these conditions can be changed to improve efficiency when the program or system is converted.

Appendices B and C outline some specific sources of conversion difficulties which may occur in COBOL and FORTRAN programs, respectively. Reference 4 gives an excellent survey of transferability problems of programs written in these and other languages, and Reference 5 suggests techniques to be used in minimizing FORTRAN conversion problems.

CONTRACTING FOR CONVERSION SERVICES

Success in conversion is in large measure dependent on experience and few if any data processing organizations possess this experience. There is little reason why they should—conversion is not an ongoing enterprise. The experience required is not of the "we have three professionals who have gone through a couple of conversions" type. Rather, experience, to be useful, must involve an entire team who has performed enough conversions to become proficient in the techniques and tools to be used, and predictable in its productivity and performance quality. Such experience is most apt to be found in software services or conversion services contractors. Generally, it would be wise for organizations to avail themselves of contractor support for conversion. This is true particularly since, contrary to popular opinion, the software producers are *not* the best qualified people to convert the same software. If anything, they are the worst qualified, since they probably cannot resist the temptation to "improve" the system while converting it.

Contracting methods vary greatly. The best, most sound, contracting is probably done by the U.S. Government under its Federal Procurement Regulations.[6] Useful guidelines can also be obtained from Reference 7. The following are offered as general factors to be considered.

The first step in a procurement is the same as the first step in the conversion planning, namely, a requirements analysis. Once this is done, the contracting personnel can begin to plan for the type of contract which may be required by the specifications, the time required to prepare a request for proposals (RFP) to potential contractors, the time required for negotiations and evaluation of proposals, and the time required to make an award. The availability of funds must also be determined at this time. Our experiences in-

dicate that the procurement may take from 22 to 38 weeks to complete.

The technical staff can ease the burden of the contracting staff by preparing a complete procurement request (PR). This will include a thorough statement of the scope of work (supplies and services, etc.), reporting requirements, property or facilities to be provided to the contractor, and a list of prospective sources of support. Upon receipt of the PR the contracting officer can assemble his procurement staff which, for large or complex procurements may include negotiators, a cost/price analyst, an inspector, legal counsel, and auditors.

A complete discussion of contractor evaluation methods is beyond the scope of this paper, but the principal ones are listed below:

- Cost only—pick low bidder among qualified ones. If the specifications are adequate this is not as bad a method as it is reputed to be.
- Cost plus "desirables"—the basic bid price is modified up or down according to the quality or number of "non-mandatory" items a contractor purposes. This is a superficial way of giving "bonus points" which has little to recommend it in this author's opinion.
- Cost evaluation plus technical evaluation—it is common to attempt to combine "cost points" with "technical points" to determine a winner. This is usually motivated by a desire to substitute subjective judgment for a sound evaluation. One legitimate way of incorporating a technical evaluation into the overall evaluation scheme is to use the results of a technical review to determine a "technical competitive range," to eliminate all bids falling outside this range, and to make the award to the lowest of the remaining bids.

ESTIMATING CONVERSION COSTS

Conversion costs for an in-house conversion (i.e., performed entirely by a staff of programmers from the organization undergoing the conversion) cannot be accurately estimated. The difficulties of estimating production efforts are well-known. Yet, software production is something which programmers do all the time. They do not do conversion all the time. Furthermore, the in-house staff does not have the tools and procedures required, and even if it acquires them it has little or no previous experience in using them.

One can determine reasonable estimates of conversion costs if a contractor is used for the production stage, which is the most costly of the various conversion stages. The various tasks associated with planning and implementation can be itemized, resources required for each of these are estimated, and this results in a cost estimate for these portions of the conversion.

Estimates for the production stage can be derived by reviewing past conversion efforts and prices bid on these efforts. The Federal COBOL Compiler Testing Service has compiled a substantial data base of cost and productivity figures. A complete description of the resulting cost model would require an entire paper itself, and will therefore not be presented here. A few figures can however given general indication of potential costs.

- The cost of converting a line of COBOL code (to COBOL) may range from $.40 to $6.00, with $.40-2.00 being a most likely band, and $.65-1.00 being a good average figure for reasonably clean COBOL programs requiring no extensive file restructuring on additional documentation. FORTRAN to FORTRAN conversion costs are similar to COBOL-COBOL costs.
- Data on PL/I to PL/I conversion is scarce, but indications are that such a conversion would be 10-20 percent costlier than a COBOL-COBOL conversion. Assembler code—COBOL/FORTRAN will cost from $2+ to $8 per source line.
- Productivity figures range from 300-500 lines per man-day in FORTRAN-FORTRAN or COBOL-COBOL down to 20-100 lines per man-day in an assembler-COBOL/FORTRAN conversion.
- Extensive documentation (user guides, narratives, etc.) can cost up to 40 percent of the total per line cost. In-house costs for planning, preparation, and implementation can be up to 50 percent of the total costs.

There are also several qualitative observations which can be made from an analysis of a sizable conversion data base:

- Conversion costs are more dependent on the source machine than on the target machine.
- Knowledge of the application is not critical in performing the conversion; but information regarding the application must be available as required. (Redesign is of course excepted here.)
- Known complexity will not unduly influence costs, but complexity which comes as a surprisse can cause havoc.
- None of the above holds for real-time systems.
- Conversion of data base systems is not well understood.
- Conversion estimates should not be attempted by people who do not have access to a sizable data base of information and who do not do this on a regular basis.
- Cost models consisting of a handful of formulas based on a handful of parameters are worse than useless; they are dangerous because they give the impression of authority.

CONCLUSION

Conversion is a disruptive, largely non-productive process which must nevertheless be faced at some point in the life of a data processing organization. This paper has presented some ideas which might be of assistance to someone contemplating a conversion, the most important of which are

that conversion requires careful planning, and that it should not be attempted without the services of professionals.

APPENDIX A—SYSTEM CONVERSION CHECKLIST

PLANNING
- Collect inventory and define scope of work
- Analyze differences between source and target systems
- Develop conversion plan and schedule
- Estimate resource requirements
- Assign conversion responsibilities

PREPARATION
- Develop or acquire software tools required
- Collect and package programs
- Prepare adequate test data
- Create test output using test data
- Collect related materials

PROJECT CONTROL
- Standardize conversion procedures
- Establish reporting requirements
- Monitor project status
- Assure quality of converted programs

PRODUCTION
- Convert source code
- Code corrections required
- Prepare test job control
- Format programs to standard
- Convert test files

TESTING
- Conduct unit test
- Conduct system test
- Conduct parallel test
- Ensure accuracy of converted programs
- Ensure test data adequacy

INSTALLATION
- Implement maintenance changes
- Prepare production job control
- Convert production files
- Cutover to production

APPENDIX B—COBOL PROGRAMMING PROBLEM SOURCES

GENERAL:
- Requires operator intervention in processing
- Requires operator consol input(s)
- Has checkpoint/restart capabilities
- Contains an interface to database system
- Requires object code patches not incorporated into the current source
- CALLS to an assembler or other non-COBOL language subprogram
- Uses overlays or segmentation

IDENTIFICATION DIVISION ENTRIES:
- Entries out of order with respect to the ANS COBOL Standard
- ENVIRONMENT DIVISION Entries
- FILE CONTROL
- I-O-CONTROL
- DATA DIVISION Entries
- FILE SECTION
- RECORDING MODE
- BLOCK CONTAINS 0
- USAGE IS COMP-1 short precision floating-point data

INTRODUCTION

The scope of the conversion problem

There are two factors that make conversion necessary: changes in users' functional requirements and changes in their performance requirements. These changes may necessitate the acquisition of new software and hardware, which in turn, may require changes to the existing data programs. For example, the acquisition of a database management system to replace a file management system requires the integration of the original files into a database system and modification of the programs to interact with it. The replacement of a current DBMS with a new database system to provide additional functionality may require a different way of logically structuring the information (its data model) and a different kind of language interface. The establishment of a communication network between differing systems to implement data sharing will require dynamic (i.e., in real time) conversion of data between different nodes in the sense that the same item will repeatedly undergo conversion as it is needed, or alternatively, it requires conversion of programs when they travel to different nodes to access data there. Even when the acquisition of new software or hardware is not warranted, changes in a users' functional and performance requirements can require data and program conversion.

What makes conversion difficult is the proliferation of data models and levels and styles of DBMS interfaces, internal data representation, and hardware architecture. In this section of the report we will examine the technology that has been developed to perform conversions, analyze the areas which require new or improved techniques, and consider strategies for minimizing the need to convert as well as for streamlining those conversions which must be undertaken. Over the past six years, research and development has primarily centered on the problem of converting in non-dynamic environments. The first part of the second section surveys tools and technology currently available for the conversion of data organization. More recently database program conversion—probably the most difficult part of the conversion problem—has received attention. It is reviewed in the second part of the second section, which considers the research directions being taken by current research. The final component of the second section analyzes the status of the entire technology. The third section explores the factors affecting conversion, the approaches for reducing the need to convert data and applications programs, and the impact of new software and hardware technologies on conversion. The fourth section summarizes the trends in conversion needs and tools.

* This is a report of the Conversion Technology Panel which met under the aegis of the ACM/NBS Workshop, "Database Directions—The Conversion Problem". A complete report covering the other panels—Management Objectives, User Experience, and Standarization—will be forthcoming from the National Bureau of Standards.

Components of the conversion process

When conversion is necessary, users will be required to extract data from their source environment and restructure them to the form required for the target environment. While the extraction and restructuring may themselves be complex, these processes are frequently complicated further by the undisciplined nature of the source data. For example, data may exist in duplicate or contain numerous errors and multiple inconsistencies. The whole process of extracting it from its source, "cleaning the data," restructuring them to a desired form, and loading them into the targeted environment is generally referred to as *data conversion* or *translation*.

After a data conversion, particularly one involving extensive restructuring, the application programs which process the original data may not run correctly against the new data. If the amount of restructuring has been small, only a simple modification may be required, while extensive rewrite or redesign may be required when restructuring has been extensive. The process of modifying the programs to process the restructured data is referred to as application program conversion or translation. (In this report we do not consider the problem of converting programs not related to a change in data structure.) Let us discuss data conversion and application program conversion a bit further.

Concepts of data conversion

In brief and conceptual terms, the data translation or conversion process can be represented diagrammatically in Figure 1. As shown in this diagram a data translation system generally requires three components: a reader, a restructurer, and a writer. While the capability of each component depends on the individual design of a data translation system, the function of the reader in general is to access data from its source environment to prepare it for further processing. The accomplishment of this process unquestionably depends on the description of the data. Thus a data description language is needed for this purpose. The writer is the functional inverse of the reader, its function being to put the transformed data into the target environment. It too requires a description of the data structure and shares with the reader the need of a data description language. The function of the restructurer is quite different from that of the other two components. This component in general is responsible for the extraction of data from its source or internal forms and restructuring it to a desired format or structure. Usually a translation description language is required to effect this process.

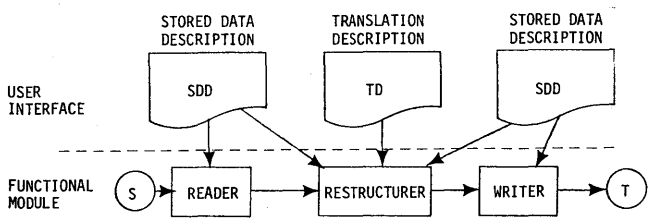

Figure 1—Schematic data conversion process

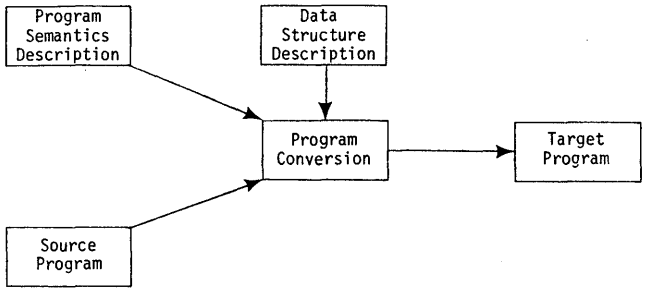

Figure 2—Program translation

In a data conversion system where limited application is intended, the three components may not be distinguishable, nor is the need of the two languages clear. For example, if one wishes to create a conversion system merely to translate EBCDIC characters into ASCII, one can create a simple system with one component and a simple data description language embedded in it. However, if development of a broadly applicable data translation system is the goal, it is clear that one must have a reader and writer capable of accessing and creating data in all kinds of environments and a powerful restructurer capable of all manner of manipulating data and of creating some data as well. Implicit in this application is the need for versatile data translation description languages.

Concepts of database program conversion

Figure 2 represents a general approach to database program conversion or translation. To convert a program it is necessary to determine the functions of the program, and its semantics. Programmers making assumptions about the state of the data may not and currently need not state these assumptions explicitly in their programs. Therefore, it will usually be necessary to provide more information about the semantics of the program than can be extracted from the program text and its documentation. Also needed in the program conversion process is information about the data structure the program originally ran against, the new structure it must run against, and how the two relate. These descriptions could be the same as those used to drive the data translation process. The program, the description of its semantics, and the description of the data conversion are inputs to the program conversion process. It uses them to determine the data originally accessed and how to accomplish the same access in the new structure, and it produces a new program to do this. Currently, the conversion process is accomplished through a combination of manual translation, emulation, and bridge programs. An automatic or semi-automatic program conversion technology is only in the early stages of research.

CONVERSION TECHNOLOGY

In the previous section, we discussed the general concepts of data and program conversion. In this section we shall discuss the technology by which a conversion is achieved.

Since most of the conversion results have been achieved in data conversion, we focus on this aspect and limit our discussion on program conversion to those cases which are the result of a data conversion.

Data conversion technology

Currently, the common approach to data conversion is to develop customized programs for each transfer of data from one environment to another. This approach is inherently expensive; the programs are developed for use only once and their development costs cannot be amortized. Further, the reliability is poor as one is likely to make errors as data is passed from program to program. For a large data conversion effort, this latter effect can indeed be quite unmanageable, as the tracing to the source of an error in the data at a particular point can be extremely complex. An alternative is to search for a broader approach for data conversion with a generalized system. We shall now describe such systems in more detail.

Problem discussion

Data exist in many varied and complex forms; Figure 3, an expanded form of the diagram in Figure 1, indicates some of the transformations that need to take place in a data conversion. This diagram illustrates the capabilities needed by the read and write process in a data conversion system.

The purpose of the unloading of data from its source is to reduce the complex physical structure of the source database to a very simple physical structure, namely a sequential data stream. The source database contains not only the information that interests the user, but also a large amount of control information that is specific to a particular system. This control information is used by the system for such data management functions as overflow chaining, index maintenance, and record blocking. In many systems, when a record is to be deleted it is marked or flagged but not actually deleted. During the unload transformation, all of this system specific information is deleted. Another factor that causes complexity in the unloading process is the frequent use of pointers in a source system. Pointers are used for two basic purposes: (1) to represent relationships that exist between record instances and (2) to implement alternative access paths to the data. During the unload transformation, the second class of pointers may be discarded without loss of information. The first class of pointers, however, maintains information that must be preserved during the transformation.

The purpose of the reformat process is to create a common data form of the source data for the restructuring step in the conversion process. In the case of a simple sequential file, not under DBMS control, it may enter the conversion process at this point. Depending on the design of a system, this step may involve editing (i.e., encoding or recoding of items), limited data extraction, correction, and the like. Since the goal in this step is to create a data structure of the source data without the system-dependent information, the mapping between the input and the output of the reformat process can be considered to be generally one-to-one. While

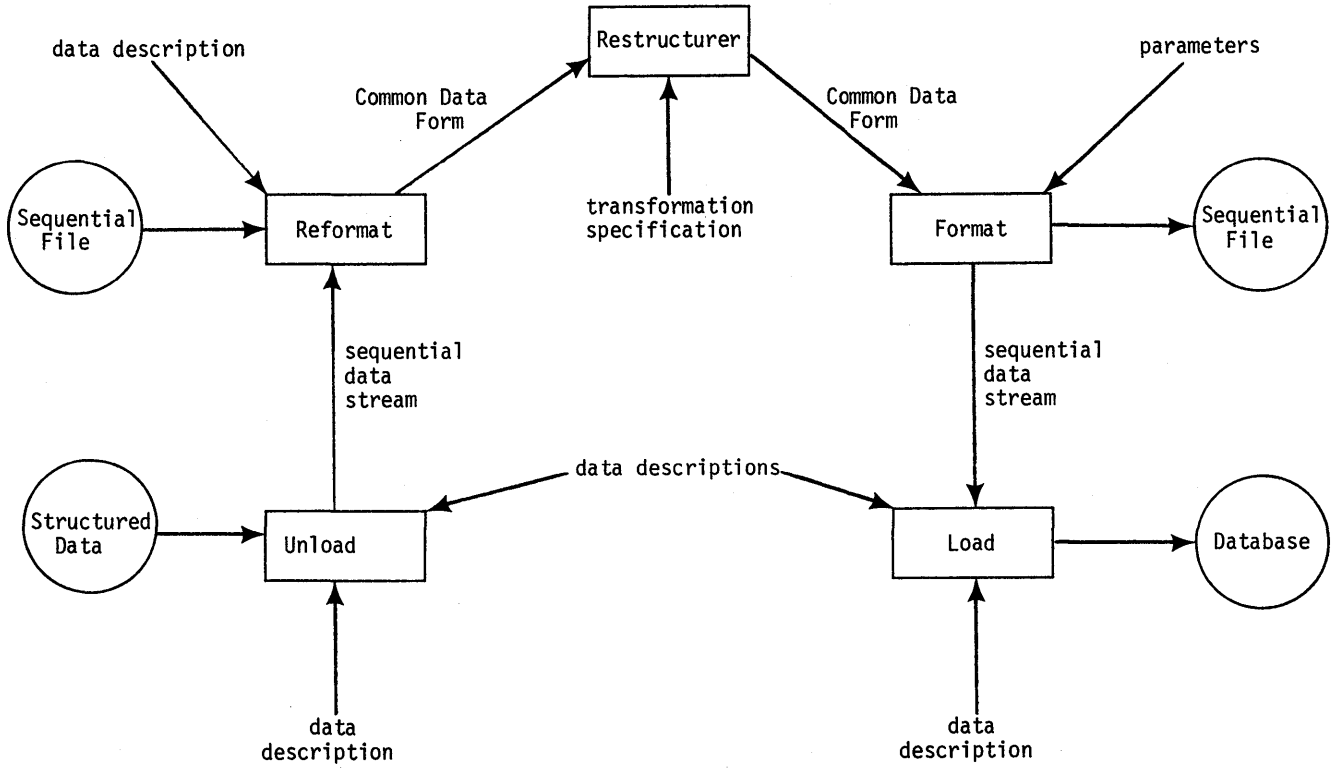

Figure 3—Schematic data conversion process

this step looks simple functionally, its actual specification and implementation can be quite complex. For example, an application program may use the high order bits of a zoned decimal number for its own purposes, knowing that these bits are not used by the system. The specification of nonstandard item encodings is a difficult problem in data conversion.

The load process is the counterpart of the unload process and needs no further clarification. Note that, however, the use of a common data form provides additional benefits, such as easing the portability problem.

The restructuring process is undoubtedly the most complex process of a generalized data conversion system. The languages for this mapping process can be quite different (for example, some procedural and other nonprocedural) and the models used to represent the data in the conversion system are also quite divergent. (For example, some use network structure; others use hierarchical structure). More will be said on this topic later in this section.

Let us now turn to discuss the issue of implementation briefly. Generally there are two techniques. One can build the system using an interpretive approach or the generative approach. In the interpretive approach, the action of the system will be driven by the descriptions written in the system's languages via the general interpreter implemented for the particular system. In the generative approach the data and mapping descriptions are fed into the compiler(s) which generates a set of customized programs executable on a certain machine. The merits of each of these approaches will also be discussed later in this section.

We shall next turn our attention to the tools that have been developed for data conversion. We shall first discuss the tools currently available and then the research and development work in progress.

Available conversion tools

Currently all available tools are limited in capability. Because it is impossible in this short report to provide an exhaustive survey of all the vendor developed conversion tools, we will highlight the spectrum of capabilities available to the user by providing examples from specific vendor shops.

The vendor's repertoire of conversion tools begins at the character encoding level of data conversion with the provision of hardware/firmware options and continues through the software aids for conversion and restructuring of databases.

Depending on a diversity of conditions, the need to develop software tools varies from vendor to vendor. Probably the most prevalent file conversion tool is a COBOL foreign file processing aid. This type of facility allows the direct reading or writing of a particular class of files such as EBCDIC tapes or Honeywell Series 200/2000 files within COBOL. Although a relatively widespread facility, its capabilities are nevertheless limited. For example, some do not handle unlabeled tapes, while others cannot process mixed mode data types. Aside from the work of Bakkom and Behymer,[1] which was aimed toward achieving a general conversion bridge with a particular vendor, to our knowledge there are no vendor supported *generalized* file translation tools.

In contrast to the above file translation tools, tools have been developed that have their main applications in a database environment. One example of a database conversion aid is the I-D-S/II migration aid provided by Honeywell. Because of the large volumes of data involved and the fact that the user cannot afford to shut down his whole data processing shop, a co-existence approach was adopted. The first step is to reformat the I-D-S/I database into the I-D-S/II format, making the necessary data type conversions and pointer mechanism adaptions. This step allows the database to be processed in the I-D-S/II mode, but not optimally. Additional steps in this migration include the generation of the additional I-D-S/II pointer fields (I-D-S/II requires "Prior & Header" chain pointers, which are allocated in step 1 but not filled in) and the restructuring of the I-D-S/II (coexistence) to the more sophisticated capabilities of I-D-S/II.

Some database restructuring tools specific to a particular DBMS have been developed by DBMS users. One example of this type of tool is REORG,[2] a system developed at Bell Laboratories for reorganization of UNIVAC DMS-1100 databases. REORG provides capabilities for logical and physical reorganization of a database using a set of commands independent of DMS-1100 data management commands. A similar capability has been developed at the Allstate Insurance Company.

In addition to the above, there are also software companies and vendors who will do a customized conversion task on a contractual basis.

Data conversion prototypes and models

Over the past seven years a great deal of research on the conversion problem has been performed, with the results summarized in Figure 4. Projects were initiated at the University of Michigan, the University of Pennsylvania, IBM, SDC, and Bell Laboratories, as well as by a task group of the CODASYL Systems Committee. In many cases there was interaction and cross-fertilization between these groups and some consensus on appropriate architectures for data conversion was reached. The individual achievements of these groups is discussed below:

The CODASYL Stored-Data Description and Translation Task Group

In 1970 the CODASYL Systems Committee formed a task group (originally called the Stored Structure Description Language Task Group) to study the problem of data translation. The group presented their initial investigation of the area in the 1970 SIGMOD (then SIGFIDET) annual Workshop in Houston.[3] In 1972 the group was reformulated as the Stored-Data Description and Translation Task Group and a general approach to the development of a detailed model for describing data at all levels of implementation was presented.[4,5] The most recent work of the group specifies the data conversion model and presents an example language

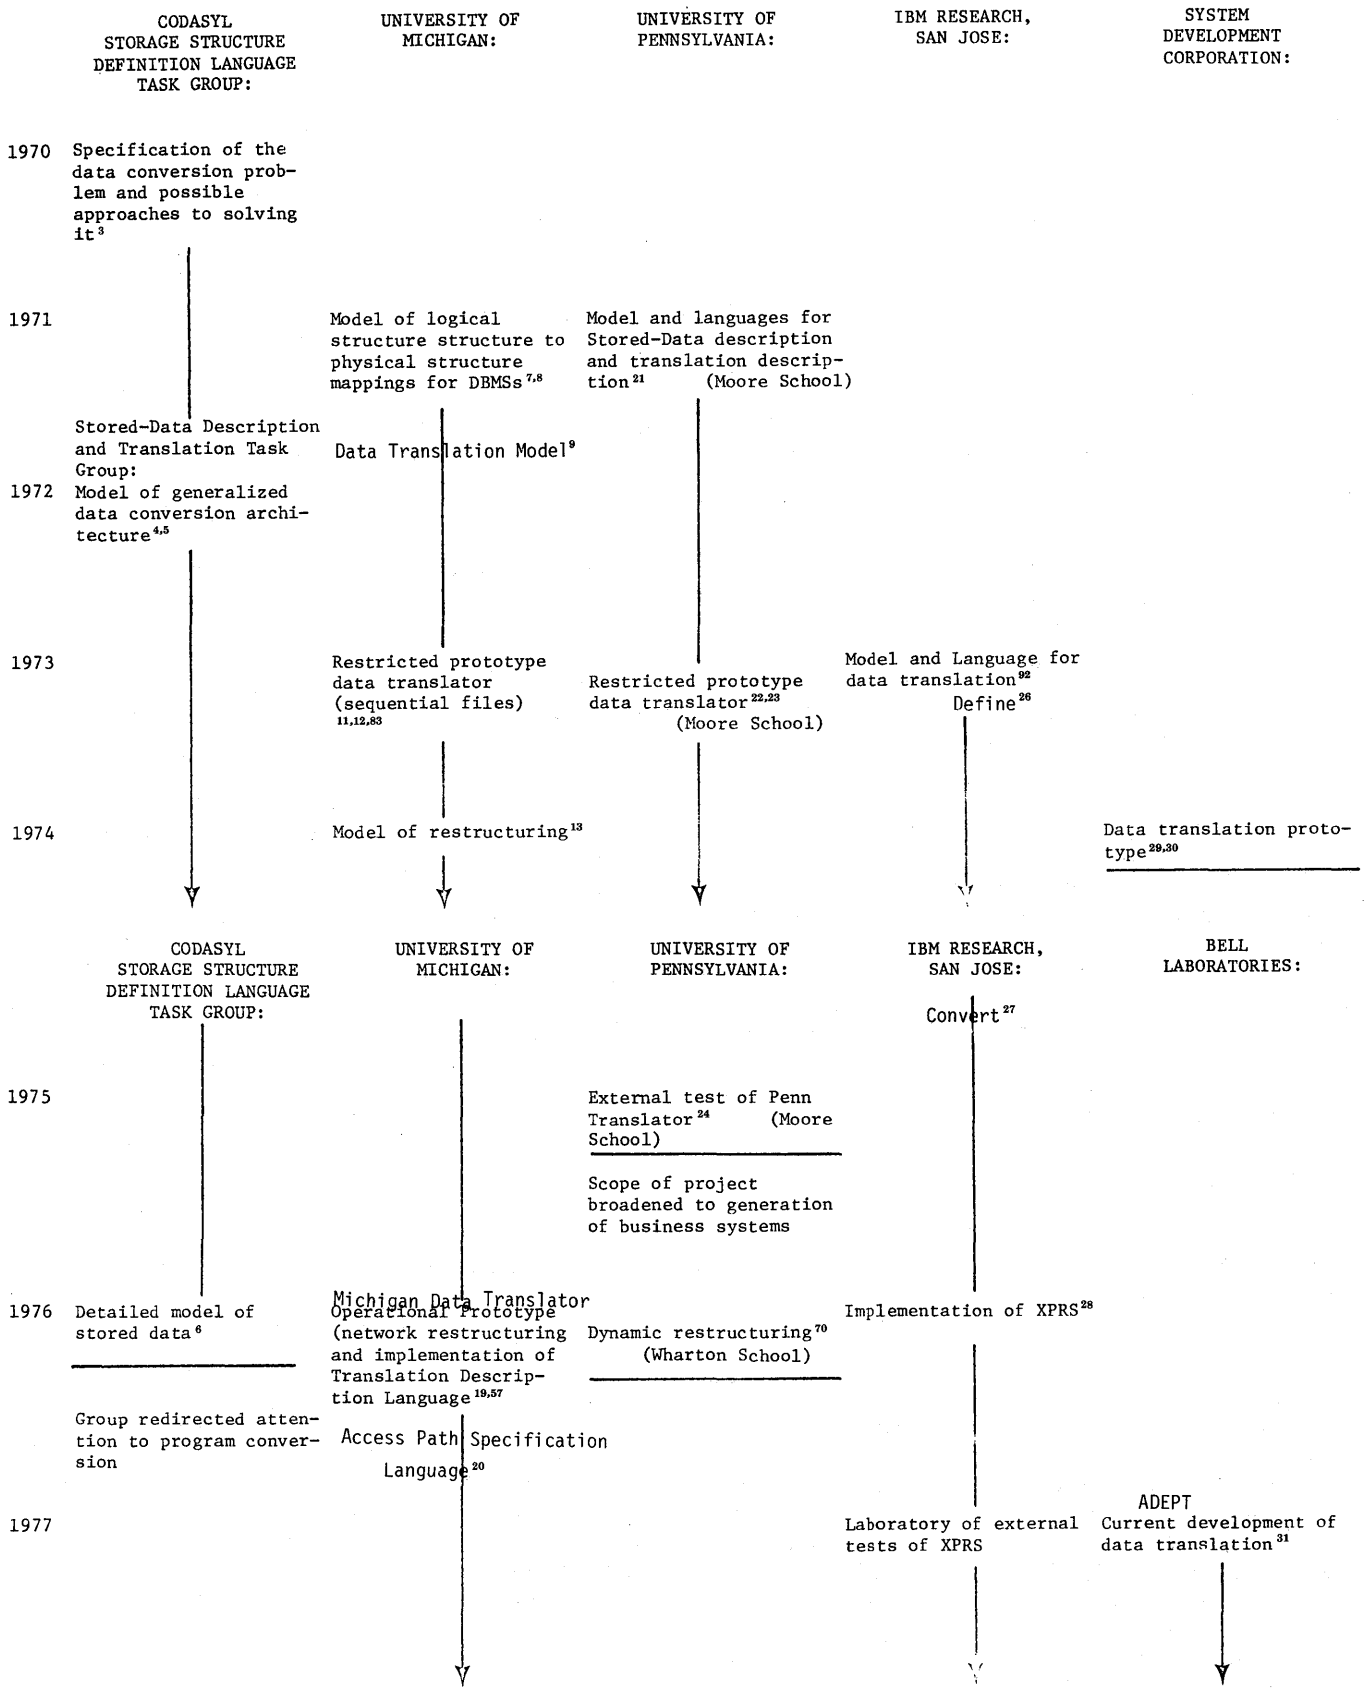

Figure 4—Summary of the development of data conversion models and prototypes

for describing and translating a wide class of logical and physical structures.[6] The stored-data definition language allows data to be described at and distributed to the access path, encoding, and device levels.

The University of Michigan

The nonprocedural approach to stored-data definition set forth by Taylor and Sibley[7,8] provided one of the major foundations for the development at the University of Michigan (see Figure 4) of data translators. In concert with Taylor's language, a model and design for a generalized translation was initiated by Fry, et al.[9]

The translation model was tested in a prototype implementation of the Michigan Data Translator in 1972,[10,11] and the results of the next implementation, Version I, were reported by Merten and Fry.[12]

In 1974, the work of the Data Translation Project of the University of Michigan focused on the database restructuring problem. Navathe and Fry investigated the hierarchical restructuring problem by developing several levels of abstractions, ranging from basic restructuring types to low level operations.[13] Later, Navathe proposed a methodology to accomplish these operations using a relational normal form for the internal representation.[14] Version II of the Michigan Data Translator was designed to perform hierarchical restructuring transformations, but the project did not implement it. Instead, the research was directed into the complex problem of restructuring network type databases. To address this problem Deppe developed a dynamic data model—the Relational Interface model—which simultaneously allowed a relational and network view of the database.[15] This model formed the basis of the Version IIA design and implementation of generalized restructuring capabilities.[16–18] Another component necessary for the development of a restructurer was the formulation of a language in which to express the source to target data transformations. This language, termed Translation Definition Language (TDL), evolved through each translator version beginning with a source-to-target data item "equate list" in the Version I Translator to the network restructuring specifications of Version IIA. While the initial version of the TDL was quite simplistic, the current version, the Access Path Specification Language,[19,20] provides powerful capabilities for transforming network databases.

The University of Pennsylvania

Concurrent with the work at the University of Michigan, Smith at the University of Pennsylvania (see Figure 4), also took a data description approach and developed a stored-data definition language (SDDL) for defining storage of data on secondary storage devices, and a translation description language (TDL)[5,21] and three levels of database structures, the logical, storage, and physical, are described using the SDDL. In order to describe the source-to-target data mappings a first order calculus language was used. Following from this work, Ramirez[22,23] implemented a language-driven "generative" translator which created PL/I programs to perform the conversion. One of the first reports on the utilization of generalization translation tools was provided by Winters and Dickey.[24] Using the translator developed by Ramirez, they installed it on their system, and applied it to conversion IBM 7080 files.

IBM Research, San Jose

In 1973 another major data translation research endeavor was initiated at the IBM Research Laboratory in San Jose, California. Researchers in this project—initially Housel, Lum, and Shu, later joined by Ghosh and Taylor—adopted the general model as specified in Figure 1 but made several innovations. First, in the belief that programmers know well the structure of the data in a buffer being passed from a DBMS to the application program, the group concentrated its effort on designing a data description language appropriate for describing data at this stage. Second, regardless of the data model underlying any DBMS, the data structure at the time it appears in the buffer of an application program will be hierarchical. The general architecture, methodology, and languages reflecting these beliefs is reported in Lum et al.[25]

In addition, the group in San Jose felt that, while it is desirable to have a file with homogeneous record types, it is a fact of life that many of today's data are still in COBOL files in which multiple record types frequently exist within the same file. As a result the group concentrated on designing a data description language which can describe not only hierarchical records (in which a relational structure is a special case) but also most of the commonly used sequential file structures. This language, DEFINE, is described by Housel et al.[26]

The philosophy of restructuring hierarchies is further reflected in the development of the translation definition language CONVERT, as reported by Shu et al.[27] This language, algebraic in structure, consists of a dozen operators, each of which restructures one or more hierarchical files into another file. The language possesses the capability of selecting records and record components, combining data from different files, built-in functions (e.g., SUM and COUNT), and the ability to create fields and vary selection on the basis of a record's content (a CASE statement).

A symmetric process occurs at the output end of the translation system. Sequential files are created to match the need of the target loading facility. The specification of this structure is again made in DEFINE.

A prototype implementation, originally called EXPRESS but renamed XPRS, is reported in Reference 28.

System Development Corporation

Another restructuring project reported by Shoshani[29,30] was performed at The System Development Corporation in 1974-1975. In order to avoid the complexities of storage structure specification (i.e., indexes, pointer chains, inverted tables, and the like) they chose to use existing facilities of the systems involved. In particular they advocated the use of query and load (generate) facilities of database management systems. However, when such facilities do not exist, reformatters from the source (e.g., index sequential file) to a standard form and from the standard form to same output file had to be used. Given that databases can be

reformatted to and from a standard form, they concentrated on the problem of logical restructuring of hierarchical data bases in this form.

The language used in the above project for specifying the restructuring functions (called CDTL—Common Data Translation Language) was designed to be conceptually simple. For the most part it provides functions for specifying a mapping from a single field (or combination of fields) of the source to a single field of the target. For example, while a DIRECT would specify a one-to-one mapping of source items to target items, a REPEAT would specify the repetition of a source item for all instances of a lower level in the target hierarchy. In both cases only the source and target fields need to be mentioned as parameters. In addition there are more global operations, such as the INVERSION operator, which causes parent/dependent record relationships to be reversed. The system also supported extensive field restructuring operators, where individual field values could be manipulated according to prescribed language specifications. Since most of these operators are local, there is the possibility that they could be used in combinations that do not make sense globally. Therefore a further component of the system was built to perform "semantic analysis," which checks for possible inconsistencies before proceeding to generate the target database.

Bell Laboratories

The Bell Labs data translation system ADAPT (A DAta Parsing and Transformation system), currently under development, is a generalized translation system driven by two high-level languages.[31] One language is used to describe the physical and logical format and structure of the data and to provide various tests and computations to be used while parsing the source data and generating the target data. The second language is used to describe the transformations which are to be applied to the source data to produce the target data. Extensive validation criteria can be specified to apply to the source and target data.

Two processing paths are available within the ADAPT system: a file translation path and a database translation path (see Figure 3). A separate path for file translation is provided in response to real-world considerations. Many types of conversion do not require the capabilities and associated high overhead involved in using a database translation path.

Related work

Additional research effort is being devoted to the development and acceptance of a standard interchange form. An interchange form would increase the sharing of databases and provide a basis for development of generalized data translators. The Energy Research and Development Administration (ERDA) has been supporting the Interlaboratory Working Group for Data Exchange (IWGDE) in effort to develop a proposed data interchange form. The proposed interchange form[32] has been used by several ERDA laboratories for transporting data between the laboratories. Additional work on development of interchange forms has been pursued by the Database Systems Research Group at the University of Michigan.[33]

Navathe[34] has recently reported a technique for analyzing the logical and physical structure of databases with a view to facilitating the restructuring specification. Data relationships are divided into identifying and nonidentifying types in order to draw an explicit schema diagram. The physical implementation of the relationships in the schema diagram is represented by means of a schema realization diagram. These diagrammatic representations of the source and target databases could prove to be very useful to a restructuring user.

Application program conversion

So far we have concentrated on the data aspects of the conversion problem; it is necessary to deal as well with the problems of converting the application programs which operate on the databases. Program conversion, in general, may be motivated by many different circumstances, such as hardware migration, new processing requirements, or a decision to adopt a new programming language. Considerable effort has been devoted to special tools such as those to assist migration among different vendor's COBOL compilers, and general purpose "decompilers" to have been developed to translate assembly language programs to equivalent software in a high level language. While progress has been made developing special purpose tools for a limited program conversion situation, little progress has been made in obtaining a solution to the general problem of program conversion. With this fact in mind, this section focuses on the modifications to application programs that arise as a consequence of data restructuring/conversion.

Problem statement

There are three types of database changes which can affect application programs:

- alterations to the database physical structure, for example, the format and encoding of data, or the arrangement of items within records.
- changes to the database logical structure—either
  1. the deletion or addition of access paths to accommodate new performance requirements, or
  2. changes to the semantics of data, for example, modification of defined relationships between record types or the addition or deletion of items within records
- migration to a new DBMS, perhaps encompassing a data model and/or data manipulation language different from the one currently in use.

The actual impact of these database changes on application programs is a function of the amount of data independence provided by the Database Management Systems. Data independence and its relationship to the conversion problem are discussed elsewhere.[59] We assume here that data independence is not complete and that therefore some degree of

program conversion is required in response to database schema changes. In fact, whereas most commercial database management systems provide application programs with insulation from a variety of modifications to the physical database, protection from logical changes—particularly at the semantic level—is minimal. Examples of semantic changes that are likely to have a profound effect on application programs include:

- Changes in relationships between record types, such as changing a one-to-many association to a many-to-many association or vice versa.
- Deletion or addition of data items, record types, or record relationships.
- Changing derivable information ("virtual items") to explicit information ("actual items") or vice versa.
- Changes in integrity, authorization or deletion rules.

There are various properties of database application programs that greatly complicate the conversion problem. For instance many database management systems do not require that the record types of interest (or possibly even the database of interest) be declared at compile time in the program; rather these names can be supplied at run time. Consequently at the compile time, incomplete information exists about what data the program acts on. Other troublesome problems occur when programs implicitly use characteristics of the data which have not been explicitly declared (e.g., a COBOL program executes a paragraph exactly ten times because the programmer knows that a certain repeating group only occurs ten times in each record instance). Complexity is introduced whenever a data manipulation language is intricately embedded in a host language such as COBOL. The interdependence between the semantics of the database accesses and the surrounding software greatly complicates the program analysis stage of conversion. Because of these considerations, substantial research has been devoted to alternatives to literal translation of programs. In particular some currently operational tools utilize source program emulation or source data emulation at run time to handle the problem of incomplete specification of semantics and yet still yield the effects of program conversion.

Current approaches

In this section, we discuss two main techniques currently employed in the industry. These techniques are commonly used but unfortunately not documented in the form of publications.

DML statement substitution

The DML statement substitution technique, which can be considered an emulation approach, preserves the semantics of the original code by intercepting individual DML statements calls at execution time, and substituting new DML statement calls which are correct for the new logical structure of the database. Two IBM software examples which provide this type of conversion methodology are (1) the ISAM compatibility interface within VSAM (this allows programs using ISAM calls to operate on VSAM database), and (2) the BOMP/DBOMP emulation interface to IMS. This program conversion approach becomes extremely complicated when the program operates on a complex database structure. Such a situation may require the conversion software to evaluate each DML operation against the source structure to determine status values (e.g., currency) in order to perform the equivalent DML operation on the new database. Necessary for the generalization of this approach is the development of emulation code for the following cases: maintain the run time descriptions and tables for both the original and new database organizations, intercept all original DML calls, and utilize old-new database access path mapping description (human input) and rules to dynamically determine what set of DML operations on the new database are equivalent to each specific operation on the source database.

Although this approach is straightforward in concept, it has several drawbacks. The drawbacks can be categorized as degraded efficiency and restrictiveness. Efficiency is degraded primarily because each source DML statement must be mapped into a target emulation program, which uses the new DBMS to achieve the same results. The increased overhead in program size and/or processing requirements can be significant.

The drawback of restrictiveness comes about because the emulation approach inhibits the utilization of the increased capabilities of the new DBMS and/or data structure through the modeling of the old methods. Additionally dependence upon the old program semantics limits the sets of permissible new data structures must support all of the semantics of the source program if the source program is to continue to execute in the same manner. It should be noted that the rules can be quite complex, even for the limited situation of which the data structure changes preserve semantic equivalence. Therefore, in some instances, just the limited task of determining if a change in data structure (given no change in the data model) will support a set of source programs will be an extensive task.

Bridge program

The second method in use today is sometimes referred to as the Bridge Program Technique. In this technique, the source application program's access requirements are supported by reconstructing from the target database that portion of the source database needed. Data reconstruction is done by means of "bridge programs." The source program is then allowed to operate upon this reconstructed portion of the source database to effect the same results that would occur if the source database were not modified. Of course, a reverse mapping is required to reflect update and each simulated source database segment must be prepared before it is needed by the application program.

This approach suffers from the same types of disadvantages inherent in the emulation approach. Efficiency problems for complex/extensive databases and programs performing extensive data accessing can make this method prohibitively expensive for practical utilization. This technique is generally found as a "specific software package"

developed at a computer installation rather than as a standard vendor supplied package.

Current research

Differing from the DML statement substitution and bridge program techniques, current research aims toward developing more generalized tools to automatically or semi-automatically modify or rewrite application programs. The drawbacks of the existing approaches described above can be avoided by rewriting the application programs which would take advantage of the new structure and semantics of a converted database and by using a general system to do the conversion rather than using ad hoc emulation packages and bridge programs.

Research on application program conversion is still in its infancy. Consequently, there are very few published papers on this subject. A handfull of works are described here in the order of the dates of publication. Mehl and Wang[35] presented a method to intercept and interpret DL/1 statements to account for some order transforms of hierarchical structures in the context of the IMS system. Algorithms involving command substitution rules for various structural changes have been derived to allow the correct execution of the old application programs. This approach works only for a limited number of order transformation of segments in a logical IMS database. Since it is basically an emulation approach, it has the drawbacks discussed in the previous section.

A paper by Su[36] gives a general model of application program conversion as related to database changes resulting from a database transformation. An attempt was made to identify the tasks required for the automatic or semi-automatic conversion of application programs due to database changes. Two main points are stressed in the paper: (1) the need for extensive analysis of an application program including the analysis of program logic, data variable relations, program-subprogram structure, execution profile, etc., and (2) the use of database translation operators to determine what program transformations are required to account for the effects of these operators. The idea of the use of a common language to describe the operations of source queries and the data translation statements is also proposed.

An approach to the transformation of DBTG-like programs in response to a database restructuring was proposed by Schindler.[37] The approach is based on the concept of code templates, which are predefined sequences of host language—DML statements (roughly analogous to assembly language macros). Application programs can be written as nested code templates. The code templates are devised so that each one corresponds to an operator in the relational algebra. An application program is then mapped into a relational expression, transformations are performed on the expression to accommodate the database restructuring, and a new program is generated by mapping the transformed expression back into code templates. This approach suggests that a level of logical data independence may be achieved through current programming technology.

The work by Su and Reynolds[38] studied the problem of high-level sublanguage query conversion using the relational model with SEQUEL[39] as the sublanguage, DEFINE[26] as the data description language and CONVERT[27] as the translation language. Algorithms for rewriting the source query were derived and hand simulated. In this study, query transformation is dictated by the data translation operators which have been applied to the source database. The purpose of this work was to study the effects of the CONVERT operators on high-level queries. Only restricted types of SEQUEL queries were considered. It is clear from this work that a general program conversion system should separate the data model and schema dependent factors from the data model and schema independent factors; and an abstract representation of program semantics and the semantics of data translation operators need to be sought so that data conversions at the logic level (especially the type which changes the database semantics) and the DBMS level can be attempted.

Two independent works carried out about the same time by Su and Liu[40] and Housel[41] take a more general approach to the application program conversion problem. The former work is based on the idea that the same data semantics (a conceptual model) can be modelled externally by various existing data models (relational, hierarchical and network) using different schemas. Application programs are mapped into an abstract representaton which represents program semantics in terms of the primitive operations (called access patterns) that can be performed on data entities and associations. Transformation rules are then applied on the abstract representation based on the types of changes introduced by the data translation operators. The transformed representation is then mapped into another intermediate representation (called access path graphs) which is dictated by the external model and specific schema used for the target database. This representation is then modified by an optimization component and used for the generation of target programs. It is stressed in this work that the semantics of both the source and target database be made explicit to the conversion system and be used as a basis for application program analysis and transformation. The conversion methodology described is for program conversion to account for data conversion at the logical level as well as the DBMS level.

The work by Housel is an extension of the work on application migration undertaken at the IBM San Jose Laboratory. This work uses a common language for specifying the abstract representation of source programs as well as for specifying the data translation operations. The language is a subset of CONVERT plus some of Codd's relational operators. The operators of the language are designed to have simple semantics and convenient algebraic properties to facilitate program transformation. They are designed to handle data manipulation in a general hierarchical structure called a "form" as well as relational tables. In this system, program transformation is dictated by the data mapping operations applied to the source database. It is assumed in the proposed model that the inverse of these data mapping operators exists, i.e., the source database can be reconstructed from the target database by applying some inverse operators on the target database. More precisely, it is assumed that $M'(T)=S$ where S is the source database, T is the target

database, and M is the mapping function. Thus, program conversion is done by substituting the inverse $M'(T)$ into the specification language statements (the abstract representation of the source program) for each reference to the source database. This process is followed by a simplification procedure to simplify the resulting statements (the target abstract representation of the program). It is pointed out by the author that the assumption on the existence of $M'(T)$ restricts the scope of the conversion problem handled by the proposed approach.

Presently, the Database Program Conversion Task Group (DPCTG) of the CODASYL Systems Committee is investigating the application program conversion problem. The group is looking into various aspects of the problems including decompilation of COBOL application programs, semantic changes of databases and their effects on application programs, program conversion techniques and methodologies, etc.

To this date, the work on application program conversion is still very much at the research stage and more progress has to be made before we can start actual implementation. The problems of automatic application program conversion are multitudinous and extremely complex. Current research indicates that program conversion is possible for some types of data conversion, but the complexity of program conversion depends on how drastically the data have been modified. Further research needs to be undertaken to determine what can be done automatically, what can be done semi-automatically, and what cannot be done at all. A fully automatic tool is hard to achieve. Building semi-automatic systems or systems which provide aids for manual conversion would be a more realistic goal.

Current research directions

The current research has uncovered several problems which need to be further investigated before the implementation of a generalized conversion tool can be attempted. The following issues are believed to be important for future research:

Semantic description of database and application programs

Based on the work by Su and Liu[40] and the study of the DPCTG group, it is quite clear that a program conversion system would need more information about the semantic properties of the source and target databases than the information provided by the schemas of the existing DBMS. Semantic information of the databases is an important source for determining the semantics of application programs which is the real bottleneck of the application program conversion problem. Future research needs to be conducted to (1) model and describe the semantics of application program, (2) study the meaningful semantic changes to databases and their effect on application programs, and (3) derive transformation rules for program conversion which account for the meaningful changes. Several existing works on database semantics[42–46] may provide a good basis for future works on this subject.

Equivalency of source and target programs

Data conversion may alter the semantic contents of the source database. A converted application program may or may not perform the identical operation on the target data as the source program on the source data. For example, it may not retrieve, delete, or update the same data as the source program because some records may be deleted and data relation may have been changed in data conversion. It is not clear at all how we can prove, in general, that a target program generated by a conversion system still preserves the original intent of the source program. Naturally, if the source data can be reconstructed from the target data without losing the original data relations and occurrences, we can establish the equivalence relation between the source and target programs based on the same effect they have on the source and target data.

Decompilation

Program conversion via decompilation is a technique whereby a database application program is first transformed into an operationally equivalent higher order language or an abstract representation and then returned to a usable language level in a converted form. The transformation to a higher order language level is a decompilation process and the process of returning the program to a language level appropriate to conventional compilers is a compilation processs. The underlying concept is that the decompilation to a higher order language can produce a functionally equivalent program that does not contain the DBMS, data model and data dependencies that inhibit the conversion process. That is, the decompiled program has the same "intent" while being unrelated to the changed DBMS environmental conditions. The changed environmental conditions should be easily incorporated into the program during the process of compiling the program back into a form appropriate to the new system.

There is some thought among researchers that this would be the preferred method to effect DML/host language program conversion. It should avoid many of the efficiency/restriction drawbacks inherent in current automated methods, while being more cost effective and less error prone than current manual methods (e.g., program rewrite).

One likely disadvantage to this method is that in order to use it to convert existing database application programs the programs may have to first be manually altered to place DML related code in a structured format. This disadvantage is to be expected because of the ambiguity inherent in the organization of DML/host language programs. However, the development of structured programming templates designed for DML related code should provide a means for creating programs that are convertible by the decompilation method. Structured templates might also provide the needed insight toward the development/selection of an appropriate high level language into which programs can be compiled. Some initial concepts of database program templates have been proposed by the University of Michigan.[37]

Conversion aids

A system which provides assistance to conversion analysts would seem to be a practical tool and a feasible task. Given the information about data changes and semantics of the data, a system can be built to analyze application programs to (1) identify and isolate program segments which are affected by the data changes, (2) detect inefficient code in the programs, (3) produce a program execution profile[47] which gives an estimate of the computation time required at different parts of the program, and (4) detect, in some cases, the program code which depends on the programmer's assumption of data values, ordering of records, record or file size, etc. The data obtained in 1 together with some on-line editing and debugging aids would speed up the manual conversion process. The data obtained in 2 and 3 would be useful for producing more efficient target programs and the data obtained in 4 would help the conversion analyst to eliminate the "implicit semantics" in programs which makes the program conversion task (manual or automatic) extremely difficult. To assist the conversion analysts in identifying ramifications of changes to programs a more complete cross-referencing than that usually produced by today's compilers can be extremely helpful. An example of such a product is the Data Correlation and Documentation system produced by PSI-TRAN Corporation. One technique, sometimes used during a conversion process that has been initiated by a database structure change, is to alter the names of effected database items in the DDL only and use errors generated by the compiler to locate program segments which need to be changed. A more complete cross-referencing system would be a much better tool, if it were available.

Optimization of target program

As the result of data conversion, multiple access paths to the same data may occur. This is because redundant data may be introduced or new access paths may be added in the course of data conversion. In this situation, a conversion system will have the choice of selecting a path to generate the target program. The efficiency of the program during execution time may depend on the selection of optimized access path during program conversion. Also, for reasons of achieving generality, some program conversion techniques proposed[40,41] convert small segments of programs or the equivalent of DML statements separately. It is necessary to do a global optimization or simplification to improve the converted program. Techniques for program optimization related to program conversion need to be investigated.

Analysis of prototype conversion systems

This section analyzes the state of the art of generalized data conversion systems. It summarizes what has been shown to be technically feasible and points out what has been learned in the various prototypes. The prototypes have yielded encouraging results, but some weak points have also emerged. Later sections list some questions that remain to be answered and comment on additional features that will be necessary to enhance usability and analyze some implementation issues which can affect the cases where a generalized conversion system can be applied.

Where do we stand

The prototype systems described earlier have been used in a few conversions. While some of these tests were made on "toy files", a few of the tests involved data volumes from which realistic performance estimates can be extrapolated. This section will summarize the major tests that were done with each of the prototypes.

The Penn Translator

The translator developed by Ramirez at the University of Pennsylvania[22,23] processes single sequential files to produce single sequential target files. Facilities exist for redefining the structure of source file records, reformatting and converting accordingly. Conversion of the file can be done selectively using user-defined selection criteria. Block size, record size, and character code set can be changed, and some useful data manipulation can be included.

The translator was used in several test runs on an IBM/370 Model 165. The DDL to generated PL/I code expansion ratio was 1:4, so coding time was reduced.

A further test of the Penn Translator was conducted by Winters and Dickey.[24] An experiment was conducted comparing a conventional conversion effort against the Penn Translator (slightly modified). Two source files stored on IBM 1301 disks under a system written for the IBM 7080 using the AUTOCODER language were converted to two target files suitable for loading into IMS/VS. Much of the data was modified from one internal coding scheme to another. The conversion required multiple source files to multiple target files.

The conventional conversion took several months versus five months for the generalized approach, a productivity improvement of roughly thirty percent. Time for adapting the translator, learning the DDL, and adapting to a new operating system is included in the five month figure. Without these, an estimate of three months was made for the conversion using the generalized approach.

The SDC translator

The translator described in References 29 and 30 was implemented during 1975-1976. The translator could handle single, hierarchical files from any of three local systems—TDMS, a hierarchical system which fully inverts files; DS/2, a system which partially inverts files; and ORBIT, a bibliographic system which maintains keys and abstracts. Databases were converted from TDMS to ORBIT, from TDMS to DS/2, and vice versa, and from sequential files to ORBIT. TDMS files were unloaded using an unload utility. Target databases were loaded by target system load utilities.

The total effort for design and implementation was about three man-years. The system was implemented in assembly language on an IBM/370 Model 168, and occupied about 40 K-bytes, not including buffer space which could be varied. The largest file tested was on the order of five million char-

acters and the total conversion time was about 1 minute of CPU time per 2.5 megabytes of data.

The work was discontinued in 1976.

The Honeywell translator

The prototype file translator developed at Honeywell by Bakkom and Behymer[1] performed file conversions (one file to one file) among files from IBM, Honeywell 6000, Honeywell 2000, Honeywell 8200 sequential and indexed sequential files. Data types of fields could be changed as well as field justification and alignment. New fields could be added to a record and fields could be permuted within a record. File record format (fixed, variable, blocked, etc.) could be changed and a compare utility was available for checking the consistency of files with different field organizations and encodings. Tests of up to 10,000 records were run. Performance of 15 milliseconds per record was typical (Honeywell Series 6000 Model 6080 computer). The prototype has been used in a conversion/benchmark environment but has not been offered commercially.

The Michigan data translator

Version IIB, Release 1.1 of The Michigan Translator was completed for the Defense Communications Agency in October 1977.[48] It offers complete conversion/restructuring facilities for users of Honeywell sequential, ISP, or I-D-S/I files. Up to five source databases of any type may be merged, restructured or otherwise reorganized into as many as five target databases, all within a single translation. Database description is accomplished by minor extensions to existing I-D-S DDL statements. Restructuring specification is easily indicated via a high level language. Tests performed to date included a conversion of a 150,000 record I-D-S/I database with a total elapsed time of 24 hours (500 milliseconds per record). A given translation can be broken off at any point to permit efficient utilization of limited resources and also protect against system failures. The user is provided with the capability of monitoring translation progress in real time.

XPRS

Test cases with the XPRS system have focussed on functionally duplicating real conversions which had been done previously by conventional methods. Several cases have been programmed. In each case at least two input files were involved. Generally there was a requirement to select some instances from one file, match with instances in another file, eliminate some redundant or unwanted data, and build up a new hierarchical structure in the output. In several cases there was a need for conditional actions based on flags within the data. In all cases, the XPRS languages were found to be functionally adequate to replicate the conversion. A productivity gain of at least fifty percent in total analysis, coding, and debugging time was achieved. Test runs were conducted on several thousand records. Performance was deemed adequate in that XPRS can restructure data at least as fast as it can be delivered from direct access storage. No detailed performance comparisons were made comparing XPRS-generated programs with custom written programs.

Questions remaining to be answered

Given that several prototype data translation systems are operational in a laboratory environment, there is a little question concerning the technical feasibility of building generalized systems. The remaining questions pertain to the use of generalized systems in "real world" data conversions involving a wide variety of data structures, very large data volumes, and significant numbers of people. Three major questions to be resolved are:

1. Are the generalized systems functionally complete enough to be used in real conversions, and if not, what will it take to make them functionally complete?
2. Can the people involved in data conversions use the languages? What additional features are necessary to enhance usability?
3. Overall, what is the productivity gain available with the generalized approach?

Within the next year, prototype systems will be exercised on a variety of real-world problems in data translation, and concrete answers to these questions should be available. The systems being further tested for cost-effectiveness are the Michigan Data Translator, the IBM XPRS system, and the Bell Laboratories ADAPT system.

To date, preliminary results have been promising. A significant sample size on which to do analysis of productivity gain should be available at the end of the year of testing.

A number of factors must be taken into account in measuring the cost-effectiveness of the generalized data translator versus the conventional conversion approach. These factors include:

—ease of learning and using the higher level languages which drive the generalized translators;
—availability of functional capability to accomplish real-world data conversion applications within the generalized translators;
—overall machine efficiency;
—correctness of results from the conversion;
—ability to respond in timely fashion to changes in conversion requirements (conversion program "maintenance");
—debugging costs;
—ability to provide "bridge back" of converted data to old applications;
—ability to provide verification of correctness of data conversion;
—capabilities for detection and control of data errors.

The languages used to drive generalized data translators are high-level and non-procedural; they provide a "user-friendly" interface to the translators. Since the languages are high-level, programs written in them have a better chance of being correct. Experience to date with DEFINE and CONVERT, the languages which drive XPRS, has

shown that users can learn these languages within a week; it has also shown that some practice is necessary before users start thinking about their conversion problem in nonprocedural rather than procedural terms.

In early test cases, the languages which drive generalized data translators have been found to be functionally adequate for many common cases. In those cases where a feature is lacking, a "user hook" facility is often provided. However, forcing a user to revert to a programming language "hook" defeats the purpose of the high level approach, and interfacing the hook to the system requires at least some knowledge of system interfaces. Thus it is important that the high level languages cover the vast majority of the cases in order to succeed; otherwise, users will perceive little difference over conventional approaches.

Facilities for detecting and controlling data errors in the generalized systems are very important, and most of the prototypes do not yet do a complete job in this area. However, the generalized packages offer an opportunity for generalized, high-level methods for dealing with data errors during conversion, and it could well be that once these error packages are developed, they will contribute to even larger productivity gains than have been experienced to date.

The high-level language approach to driving generalized translators should provide the ability to respond to changes in conversion requirements with relative ease. Since large conversions often take one or more years, it is not unusual for the target database design to change or for new requirements to be placed on the conversion system. In other words, in a large conversion effort, the programs are not as "one shot" as is commonly believed. In large conversions, the savings in conversion program maintenance could be significant.

Generalized systems can also be used to map target data back to the old source data form, assuming the original conversion was information-preserving. This capability provides a means for verifying the correctness of the data conversion. In addition, this capability can be used as a "bridge back" to allow users to continue to run programs which have not yet been converted against the data in the old format. Using a generalized system in this way allows phased conversion of programs without impacting user needs during the conversion period.

In an environment where a generalized translator is used regularly as a tool for conversion, costs associated with the debugging phase should be decreased through the use of common software modules. It is unusual in the conventional approach for common conversion modules to be developed. Thus each new conversion system requires debugging.

Usability

The usability of generalized data translation systems must also be evaluated. Experience to date indicates that the languages are easy to learn and use. However, it would be wrong to think that these prototypes are mature software products or that they can be used in all conversions. This section discusses some of the unanswered questions with respect to usability of the current data conversion systems.

One question concerns the level of users of the generalized languages. Current prototypes have been used by application specialists and/or members of a database support group. The systems have not yet been used by programmers, and the question remains whether programmers (as opposed to more senior application specialists and analysts) will be able to use the systems productively. There is no negative data on this point; the systems have not been used widely enough.

At present, all the systems require a user to describe explicitly the source data to be accessed by the read step using a special data description language. These data description languages are generally easy to learn and use; they resemble statements in the COBOL Data Division. However, the writing of the description is a manual process which can be tedious because a person may have to describe a file with hundreds of fields. Ideally, a data conversion system should be able to make use of an existing data description, such as those existing in a data dictionary or a system COBOL macro library. As evidenced by the Michigan Data Translator,[19] it is reasonable to expect that such an interface will be available as data conversion systems evolve. It should be pointed out, however, that a data dictionary or COBOL macro library link may not necessarily solve the problem. Data in current systems is not always fully enough defined to be converted. This is especially true with non-database files. In these files, data definition often is embedded in the record structures of the programs, and a full definition depends on a knowledge of the procedural program logic. Even with existing databases, some fields and associations may not be fully defined within the system database description. Thus, the user can expect a certain amount of manual effort in developing data definitions. If existing documentation is incomplete, this can be a time consuming task, though it probably must be done regardless of whether a generalized package is used or not.

Another area where a user may have to expend effort is in the unload step of the data conversion process. The data description languages used to drive the read step have a limited ability to deal with data at a level close to the hardware (e.g., pointers, storage allocation bit maps, etc.). It is generally assumed that a system utility program can be used to unload source data and remove the more complex internal structures. Another alternative is to run the read step on top of an existing access method or database management system with the accessing software removing the more complex, machine dependent structures. These approaches are acceptable in a great many environments, including most COBOL environments, but there may be cases where neither approach will work. For example, a load/unload utility may not exist, or a file with embedded pointers which was accessed directly by an assembly language program might not be under the control of an access method. For these cases, the user is faced with complexity during the unload step. The complexity associated with accessing the data would appear to be a factor for either the conventional methods or for the generalized approach. However, in cases such as those above, some special purpose software may have to be developed. It should be noted that some research[6] has examined the difficulty of extending data description

languages to deal directly with these more complex cases. The conclusion is that providing the data description language with capabilities to deal with more complex data structures greatly complicates the implementation and has an adverse affect on usability. Thus, special purpose unload programs will continue to be required to deal with some files.

Analysis of architectures

This section discusses some of the different approaches that have been taken in implementing the prototype data conversion systems. The objective is to analyze some of the performance and usability issues raised by the prototypes.

Two approaches have been used in the prototypes—generative approach in the Penn Translator and XPRS, and an interpretive approach in the Michigan Data Translator. In the generative approach, a description of the input files, output files, and restructuring operations is fed to a program generator. From these descriptions, special purpose programs are generated to accomplish the described conversion. In both the Penn Translator and XPRS, PL/I is the target language for the generator. The generated PL/I programs are then compiled and run. In the interpretive approach, tables are built from the data and/or restructuring description. These tables are then interpreted to carry out the data conversion.

In data conversion systems, as in other software, an implementation based on interpretation can be expected to run considerably more slowly than one based on generation and compilation. Initial experience with prototype data translators has shown that there is much repetitive work, strategies for which can be decided at program compilation/generation time. Also, there is a good deal of low level data handling, such as item type conversions. Thus, those implementations based largely on an interpretive approach run more slowly, and the ability to vary bindings at run time does not appear to be necessary. Interpretation was chosen in the prototypes for ease of implementation, and in the future it can be expected that a compilation-based approach or a mixture of compilation with interpretation will be the dominant implementation architecture. However, for medium scale databases, the machine requirements of the interpretive data conversion prototypes are not unreasonable, and overall productivity gains are still possible.

Performance measurements with conversion systems based on the generative approach indicate that generalized systems can be quite competitive with customized programs. In one case, the program generated by the data conversion system ran slightly faster than a "customized" program which had been written to do the same job. However, this example could well be the exception and it would be naive to expect this in general. The reason generalized packages can be competitive is that they often have internal algorithms which can plan access strategies to minimize I/O transfer and/or multiple passes over the source data. "Customized" conversion programs written in a conventional programming language often are not carefully optimized, since the expectation is that the programs will be discarded when the conversion is done.

A second architectural difference involves the use of an underlying DBMS or not. In both the Penn Translator and XPRS, the generated PL/I program, then executing, accesses sequential files, performs the restructuring, and writes sequential files. On the other hand, the Michigan Data Translator functions as an application program running on a network structured database management system. Thus the interpreter makes calls to the underlying DBMS to retrieve data during restructuring and puts restructured data into the new database.

The two approaches offer different tradeoffs. For example, the Michigan Data Translator can make use of the existing extraction capabilities of a DBMS and perform partial translations easily. In addition, since it operates directly within the network data model, a user does not have to think of "unloading" data to a file model and then reloading it back; rather, the user describes a network to network restructuring much more directly.

On the other hand, when converting non-database data to a database, the use of an underlying DBMS as part of a data translator implies a second order data conversion problem—the non-database data must be converted into the DBMS of the data conversion system, which may or may not be difficult. It can be difficult, for example, when the data model of the data being converted differs significantly from the data model of the DBMS upon which the conversion system is based. Also, the use of an underlying DBMS may also require more on-line storage, whereas the file oriented conversion systems can be made to run tape-to-tape. This can be important in very large database conversions.

In the future, one can expect that data conversion systems will offer a variety of interfaces to accommodate various kinds of conversion situations. For example, it is possible to interface the "file-oriented" conversion systems to run as application programs on top of existing database management systems. It is also possible to develop "reader programs" to load non-database data into conversion systems based on a DBMS. In addition, more automated interfaces to data dictionary packages can be expected in order to improve usability and obviate the need for multiple data definitions.

One possible performance problem with generalized conversion systems lies in the unload phase. For reasons of usability, generalized conversion systems usually rely on an unload utility program to access the source data, thus isolating the conversion package from highly system specific data. A potential problem with this approach is that the unload package may not make good use of existing access paths or may tend to access the source data in a fashion which assumes that the data has recently been reorganized (with respect to overflow areas, etc.). In cases where the data is badly disorganized, a customized unload program which accessed the data at a lower level might run considerably faster, and for very large databases might be the only feasible way to unload the data. It is not clear how common this case is, and one can usually make the argument that the

"special" unload software could be interfaced to the generalized package. However, from a practical standpoint, the unloading phase on a very large, badly disorganized database is a performance unknown, and more sophisticated unload utilities may have to be developed as part of the generalized packages.

Summary

Detailed performance and productivity figures for major conversions should be available in about one year. Expectations are that machine efficiency of the generalized packages based on a generation/compilation approach will be acceptable (no worse than a factor of 2) when compared with conventional conversion programs. Additional enhancements to improve usability can be expected, especially in the areas of data error detection and control and interfaces to data dictionary software. If the savings in conversion program analysis and coding times—often fifty percent or more—are confirmed, then the generalized conversion systems will be ready for extensive use.

OTHER FACTORS AFFECTING CONVERSION

In this section we look at the conversion problem from two aspects. First we address the question—What can we do today to lessen the impact of a future conversion. Second, we look to the future to see what effects future technology and standards will have on the conversion process.

Lessening the conversion effort

In order to identify guidelines for both reducing the need for conversion and for simplifying conversions which are required, it is necessary to consider the entire application software development cycle. This is because poor application design, poor logical database design, inadequate use of and inappropriate DBMS selection each could lead to an environment which may prematurely require an application upgrade or redesign. This redesign could, in many cases, require a major database conversion effort.

The set of guidelines specified below is not intended as a panacea. Instead, it is meant to make designers aware of strategies which make intelligent use of current technology. It is doubtful that all conversions could be avoided if a project adhered strictly to these proposed guidelines. However, adherence to the principles set forth by these guidelines could certainly reduce the probability of conversion, and more importantly, simplify the conversions that are required.

With respect to application design and implementation, the more the application is shielded from system software and hardware implementation details, the easier it becomes for a conversion to take place. For example, a good sequential access method hides the difference between tapes, disks, and drums from the application programs which use the access method.

The logical database design should be specified with a clear understanding of the information environment. A good logical database design reduces the need to restructure because it actually models the environment it is meant to serve. Introduction of data dependencies in the data structure should, if possible, be kept to a minimum. An analysis of the tradeoffs between system performance and likelihood of conversion should definitely be made.

Selecting the wrong or non-optimal database management system, given the application requirements, is also a key problem which can lead to unnecessary and large conversion efforts. The prospective user of a DBMS should, for example, carefully evaluate the data independence characteristics of a proposed DBMS.

The underlying principle of the guidelines which follow is that decisions can be made at the system design and implementation stages which are crucial to the stability of the applications.

Application design guidelines

Requirements analysis

Many of the decisions affecting the long-term effectiveness of the application system (database design as well as application programs) are made during the requirements analysis stage of system development. Questions such as what are the functional requirements of the application, who the database is to serve, how the database is to be used, what are the possible future uses of the data, and what are the performance constraints of the application answered at this stage. It is essential that the designer understand the information environment as much as possible at the outset in order to lessen the probability that frequent conversions will be necessary.

Requirements analysis should focus on information needs and should minimize constraints being imposed by the physical environment. Imposing physical constraints at this junction is dangerous since it can distort the designer's view of the true objectives of the application system. The influence of the physical environment should be considered secondarily, in order that the designer be fully aware of the resulting compromises to the logical requirements. This is not intended to imply that consideration of the physical environment is unimportant. Indeed, if the physical environment is ignored the effect could be development of a set of requirements that are impossible to meet within existing physical and cost constraints.

Program design guidelines

There are three underlying principles motivating this discussion of application program design. They are:

- design for maintainability
- design for the application
- data independence

Keeping sight of all of these during the design of the application program will lessen conversion effects by rendering the application as free as possible from physical considerations.

Designing for maintainability implies that the application should be written in a high-level language with a syntax that permits good program structure. Structured programming techniques such as top-down program design and implementation should be used throughout. The system should be modular with relatively small, functionally oriented programs. The programs should all be well commented and organized for readability. Design reviews and program walkthroughs also help to expose errors in the overall design and "holes" in the application logic at an early stage. It has been well documented that these steps help in making program modifications a much easier task.

One error which is often made in designing programs in a DBMS environment is to let the capabilities of the DBMS drive the design rather than the application. This design error can yield programs which are unnecessarily dependent upon the features of a specific DBMS. For example, in System 2000 one can use a tree to represent a many-to-many relationship instead of using the LINK feature. The parent/child dichotomy that results is an efficient but arbitrary contrivance that cannot easily be undone later on. The key principle here is to concentrate on what results are desired rather than on the implementation details of achieving these results. Simplicity and generalization of the design will provide a very high level of interface to the application programmer which will, in turn, minimize the total amount of software, provide the greatest degree of portability, maintainability, device independence, and data independence.

Of extreme importance in program design is the notion of data independence, i.e., insulating the application program from the way the data is physically stored.

Layered design

In the area of application design, the motivating factor for mitigating the effects of a conversion is to insulate logical operations from physical operations. One of the concepts applied to achieve this is layered design. That is, designing the application as a series of layers, each of which communicates with the system at a different level of abstraction. One can visualize this as an "onion," with hardware as its core and layers of successively more sophisticated software at the outer layers. The user interacts with the outermost skin of the onion, at the highest level of abstraction.

If application programs are written at the outermost layers of the onion, then these programs are smaller, easier to understand, and therefore easier to modify or convert than programs written at lower layers. For example, introduction of a new mainframe will require conversion of the software which references the particulars of the mainframe. However, since the layers are constructed so that physical machine and device independence is realized above some level, only the software below that level is subject to modification. To the extent that application programs stay at the outermost layers (i.e., above the critical layer) reduced conversion effects can be achieved.

We can thus summarize the goal of program design as follows:

- to provide the highest possible application interface to the program
- to maximize program independence from the characteristics of the mainframe, peripherals, and database organization
- to maximize portability of the application program through the use of high-level languages
- to maintain a clean program/data interface

Programming techniques

The previous sections of this chapter have focused on the design decisions which should be made to alleviate the conversion problem. However, regardless of how noble these goals are, poor implementation decisions can go a long way towards diminishing the returns of a good design. Equally important to intelligent design is a set of programming techniques and standards which prohibit programmers from introducing dependencies in code. For example, a "clever" programmer may introduce a word size dependency in a program by using right and left shifts to effect multiplication and division. Of course, there are no hard and fast safeguards against using tricky coding techniques; an effort must be made to make the programmer conscious of the consequences of this kind of coding. In particular, a programmer should not be allowed to jump across layers of the onion, such as to use an access method to directly read or write databases.

Database design

Perhaps the most costly mistake a designer can make is an error in the database design because it has a direct effect on the information that is derivable and the application programs that are created. Incorrect or unanticipated requirements can lead either to information deficient databases or overly complex and general design. An inadequate logical design has the potential for complex user interfaces or extremely long access times. A poor physical design can lead to high maintenance and performance costs. Unfortunately, database design is still an art at the present time. Two surveys report the results in the area to date. Novak and Fry[49] survey the current logical database design methodology and Chen and Yao[50] review database design in general. The work of Bubenko[51] in the development of the CADIS system and the abstraction and generalization techniques of Smith and Smith[46,52] show promise.

An accurate logical design can still be unnecessarily data dependent. Dependencies are inadvertantly or deliberately introduced in the interest of improving system performance. In essence, "purity" is compromised to gain processing efficiencies. Since optimization is a worthwhile goal, insist-

ing on absolute purity may be unreasonable. However, the database designer should at least be aware of contrivances and therefore be in a position to evaluate the relative effects a design decision may have. Designers should become sensitive to their decisions by asking: "How will the data model be affected by a future change in performance requirements? Have I done a reasonable job in insulating applications from data structure elements that are motivated strictly by performance considerations?"

Some examples of induced data dependencies in logical database design which may impact upon conversion are:

- The use of owner-coupled sets in DBTG to implement performance-oriented index structures or orderings on records.
- Storing physical pointers (or database keys) in an information field of a record.
- Combining segment types (in DL/1) to reduce the amount of I/O required to traverse a database.

DBMS utilization and selection

Selection of a DBMS can have a major impact on conversion requirements. Of importance in evaluating a DBMS is to consider products exhibiting the highest level user interface.

A high level DBMS is characterized by both a powerful set of functions and a high degree of data independence from the point of view of the application. With respect to functions, that is, the DML, the distinction between "high level" and "low level" has traditionally centered on whether the DBMS provides user operations on sets of records (select, retrieve, update, or summarize *all* the records or tuples which satisfy some conditions) or whether one is restricted to record-at-a-time processing ("navigation"). The DBMS with the "high-level" set operation approach is significantly more desirable than the navigational record-by-record approach.

DBMS prospects should evaluate the data independence characteristics of a proposed product. Systems are preferred which support an "external schema" or "subschema" feature which permits the record image in the application program (the user work area) to differ significantly from the database format. However, the subschema concept is only one aspect of data independence. In general, it is necessary to determine in what ways and to what extent the application interface is insulated from performance or internal format options. For instance, will programs have to be modified if:

- a decision is made to add or delete an index?
- the amount of space allocated to an item is increased or decreased?
- chains are replaced by pointer arrays?

Other conversion related questions about DBMS product include the following:

- Are there adequate performance and formatting alternatives? Are there too many (i.e., unproductive or incomprehensible) tuning options? Are there adequate performance measurement techniques and tools to guide the exercise of these choices?
- Does the system automatically convert a populated database when a new format option is selected?
- Aside from tuning, does the DBMS gracefully accommodate at least simple external changes such as adding or deleting a record or item type?
- Are there other useful high level facilities associated with or based on the DBMS, such as a report writer, query processor, data dictionary, transaction monitor, accounting system, payroll system, etc.?
- Is there a utility for translating the database into an "interchange form", i.e., a machine independent, serial stream of characters?
- Is the vendor committed to maintaining the product across new operating system and hardware releases/upgrades? Conversely, is the vendor prepared to support the product in order of released versions of the operating system, so the user will not be forced to upgrade?
- What hardware environments are currently supported and what is the vendor's policy regarding conversion to another manufacturer's mainframe?
- What programming language interfaces are available? Can the same DBMS features be used if there is a migration, say, from COBOL to PL/1?
- How intelligent is the system's technique for organizing data on the media? Specifically, will performance deteriorate at an inordinate rate as updating proceeds? How often will reorganization (cleanup) be required? does the DBMS have a built-in reorganization utility? How does the user determine the optimal time to reorganize?
- Are the language facilities and data modeling facilities of DBMS adequate for the anticipated long term requirements of the enterprise? What is the risk of having to convert to a new DBMS?
- Likewise, are the performance characteristics and internal storage structure limitations adequate to meet the long term requirements (response times, database sizes) of the enterprise?
- Are there facilities to assist the user in converting data from a non-DBMS environment or from another DBMS? For instance, can a database be loaded from one or more user defined files?

Impact of future technologies and standards on conversion

In this section we discuss trends in computer hardware technologies, DBMS software directions, and standards development, and consider their impact on data and program conversion. Our intention is to make the reader aware of what to expect in terms of conversion problems rather than give a complete assessment of future technologies. Therefore, we discuss only technologies and standards that will impact conversion problems.

The first three parts discuss the areas of hardware, soft-

ware, and standards and their impact on conversion in some detail. The last part summarizes the major points of our assessment without going into detailed reasoning.

Hardware and architectural technologies

The cost and performance of processor logic and memory continue to improve at a fast rate. As a result, overhead costs are more acceptable, especially when such costs save people's time and work, and provide user oriented functions that do not require a computer expert. In particular, one can now think about using generalized conversion tools not only when it is required as a result of hardware or software changes, but also as a result of a changing application that requires a new more efficient database organization. What could have been a prohibitive cost for a database conversion in the past, may not be a major factor in the future.

At the same time, the cost/performance improvement contributes to the proliferation of databases and therefore accentuates the need of generalized conversion tools. The most cost effective is the process of accessing and maintaining data, the more data is collected on computers. Improvements in hardware (as well as software) technologies create more need for data and program conversion. In addition, the emergence of new technologies, such as communication networks, add another level of sophistication to the way that data can be organized and used. Distributed databases, where multiple databases (or subsets of databases) may reside on different machines, require tools for the integration and the correlation of data. Invariably, data will need to move from system to system dynamically, possibly moving between different hardware/software systems. In this environment generalized tools for dynamic conversion will become a necessity.

In recent years two promising approaches to data management hardware technologies have been pursued. One is the specialized data management machine and the other is the backend data management machine. As will be explained next, both approaches can help simplify the conversion problem.

The specialized data management hardware is based on the idea of using some kind of an associative memory device, a device that can perform a parallel access to the data based on its content. Such a device eliminates the necessity for organizing the internal structure of a database using indexes, hash tables, pointer structures, etc., which are primarily used for fast access. As a result, the data can be essentially stored in its external logical form, and the data management system can use a high level language based on the logical data structure only. The conversion process is simplified since data is readily available in its logical organization. Referring to the terminology used in previous sections, the functions of unloading and loading of the database can be greatly simplified. Also, no restructuring will be required because of a change in database use, since the physical database organization can be to a large degree independent of its intended use. In addition, the program conversion problem is simplified as a result of the program interfacing to the DBMS using a high level logical language.

Similar benefits can be achieved if backend machines are used. A backend machine is a special processor dedicated to managing storage and database on behalf of a host computer. The primary motive for the backend machine is to off-load the data management function from the host to a specialized machine that can execute this function at much lower cost. From a conversion standpoint, the separation of data management functions from the host promotes the need for a high level logical interface that provides the advantages discussed above. Another advantage is that it is possible to migrate from one host machine to another without effecting the databases and their management, alleviating the need for data conversion if the same backend machine is used with the new host.

Another hardware technology development is mass storage devices, such as the video disks. These devices would make it cost effective to store very large databases, in the order of 10^{10} characters. The problem of converting large databases is compounded by cost considerations of processing this large amount of data. As a result it is likely that these databases will tend to stay in the same environment for longer periods of time. The use of specialized data management machines or dedicated backend machines in conjunction with these mass storage devices can help postpone the need for database conversion.

Finally, we should mention that there is a growing use of minicomputers in supporting data management functions. DBMSs are now available on many minicomputers, and more development is forthcoming. The proliferation of minicomputers which support databases will only increase the needs for generalized conversion tools.

Software development trends

Much of the work over the last years in the data management area have concentrated on techniques that clearly separate the logical structure of the database from its physical organization. This concept, called "data independence" was introduced to emphasize that users need not be exposed to the details of the physical organizations of the database, but only to its logical relationships. This led to the development of data access and manipulation languages that depend on the logical data model only. The effect of this trend is similar to that of using specialized data management machines and backend machines discussed previously; namely, the simplification of the unload and load functions since the interface to the DBMS is provided at the logical level only, and the simplification in program conversion for similar reasons.

At the user end of the spectrum, it seems reasonable to assume that the diversity of data models (network, relational, hierarchies and other views that may be developed in the future) will be required for many more decades. This is especially true since there are problem areas that seem to map more naturally into a certain model. Furthermore, it is often the case that users do not agree on the same model

for a given problem area. Obviously this state of affairs only accentuates the need to generalize conversion tools that can restructure databases from one model to another. Even with the development of large scale associative memories, data structures will likely provide economic rationales for their contrived use. Another possibility is the use of a common underlying data model that can accommodate any of the user views. However, this approach will still require some type of a dynamic conversion process between the common view and each of the possible user views.

Standards development

There is much work and controversy in developing standards for DBMS. Standards that are oriented to determine the nature of the DBMS are hard to bring about even in a highly controlled environment because of previous investment in application software and database development, and because of disagreement. For example, there is still much controversy whether the network model proposed by the CODASYL committee is a proper one. It seems reasonable to assume that there will always be non-standard DBMSS. Further, even if such a standard can be adopted, different DBMS implementations will still exist, resulting in different physical databases for the same logical database. In addition, one can safely assume that restructuring because of application needs will still be necessary, and that changes in the standard itself may require conversion.

A standard that is more likely to be accepted is one that effects only the way of interfacing to a DBMS. In particular, from a conversion standpoint, a standard interchange data form (SIDF) will be most useful. A SDIF is a format not unlike a load format for DBMSs. Any advanced DBMS has a load utility that requires sequential data stream in a prespecified format. If a standard for this format can be agreed upon, and if all DBMSs can load and unload from and to this format, then the need for reformatting (as described earlier) is eliminated. The conversion process can be reduced to essentially restructuring only, given that unload and load are part of the DBMS function. A preliminary proposal for such a standard was developed by the ERDA Inter-Working Group on Data Exchange (IWGDE).[32] However, it is only designed to accommodate hierarchical structures. Consideration is now given to the extension of the standard to accommodate more general structures (i.e., networks and rebations). We believe that there are no technical barriers to the development of a SDIF, and that putting such a standard to use would alleviate a major part of the data conversion process.

Summary

The reasoning for the points summarized below is given in the previous parts of this section. We will only state here our assessment of the impact on conversion problems.

a. Hardware development will increase the need for generalized conversion tools (in particular, proliferation of minicomputers, computer networks, and mass storage devices).
b. The reduction in hardware costs will make conversion costs more acceptable.
c. Special Hardware DBMS machine will simplify the conversion process (in particular, for load, unload functions, and program conversion) because they promote interfacing at the logical level.
d. Software advances will not eliminate the need for conversion but can simplify the conversion process in a similar way as C.
e. Multiplicity of logical models are likely to exist, thus adding to the need of conversion tools between models.
f. Standards will not eliminate the conversion problem. Even if a standard is followed, the implementations would be different. Also, it is likely that non-standard DBMS will always exist.
g. Standards can greatly simplify conversion. In particular, a standard for interchange data form is likely to come about (will simplify load and unload and eliminate reformatting).

What can we expect in the next five years and beyond in the database conversion area? The state-of-the-art has advanced enough to date to give hope for generalized tools. Within the next five years we can expect more generalized conversion systems to become operational, but some additional work will be required for moving them from one environment to another. We can expect to have a standard form developed and agreed upon. It will probably take longer before manufacturers will see the benefit of adopting a standard form and provide load and unload facilities using it. However, we can expect them to provide some conversion tools to convert databases from other systems to their own. It will probably take as much as ten years before a generalized converter is available commercially, with manufacturers adhering to a standard form. Another area of concern is the application program conversion that is required as a result of database conversion. This topic was discussed in detail earlier. This is a difficult technical problem even within one data model, and still requires much research. It is hard to expect that a generalized solution for this problem will be achieved within the next five years. However, this problem will be elevated to a large extent as hardware and software development trends promote interfacing at the logical level.

INTRODUCTION

The purpose of this paper is to present to the computing community an interim report (as of January 1978) on the work of the CODASYL Systems Committee in analyzing the relationship between database technology and distributed processing. This paper discusses the following topics:

- The motivations for incorporating one or more data bases into a distributed processing environment.
- The current objectives of the Committee's work.
- The network-oriented and database-oriented components, and their relationships.
- The design choices available to the architect of a distributed database environment.
- The technical and administrative issues which arise in such environments.

The Committee hopes that this paper will evoke thoughtful comments from its readers. These will greatly aid the Committee in the preparation of its final report. Comments should be directed to:

Chairman, CODASYL Systems Committee
Box 1808
Washington, DC 20013

PURPOSE/SCOPE OF COMMITTEE'S CURRENT WORK

In accordance with its charter, the CODASYL Systems Committee, in January of 1977, undertook a two-year task examining the implications of database technology in a distributed environment. The Committee is focusing its attention primarily on the impact of extending database management techniques to distributed processing environments.

The scope of this effort is the establishment of a framework for examining these issues, and the formation of baseline concepts and guidelines which will support the continuing development of distributed database management technology. The results of this work will be published at the end of this two-year effort as a Systems Committee Technical Report.

MOTIVATIONS FOR THE DISTRIBUTED DATABASE ENVIRONMENT

In today's evolving data processing technology, a number of factors have generated a trend from centralization toward distribution of data processing functions. Of major importance to the end user is faster, easier access to the data needed for decision making, a need essentially unchanged from earlier, more centralized environments. A further concern of the end user is reliability and security. These user motivations, coupled with the increasing geographic dispersion of the end users within an organization, are generating pressures on data processing and corporate management to distribute data processing and storage capabilities to the location of data origin and/or use. The major benefits derived by distributing these functions focus on increased data availability to the end user and reduced exposure to total system failure due to hardware/software failure.

Historically, the application of computer technology to the information processing needs of an organization have

tended toward the centralization of data processing and storage facilities. Motivations for such centralization of data processing functions have focused on the following:

- *Economies of Scale*—the cost of processing and storage facilities sufficient to handle the local processing requirements of the end user generally exceeded the combined cost of large, centralized computer facilities and a communications facility to provide user access to the central facility.
- *Control*—security, data integrity, and standards administration in a centralized environment generally were less complex than in a decentralized environment.
- *Availability of Data to the Corporate Level*—Although not fully satisfying the needs of the distributed end user, the centralized environment provided easier generation of and access to summary data.

Today, organizations have grown in size and complexity, the users have become more sophisticated in their information needs, and the geographic locations of the origin and use of data have become increasingly dispersed. As a result, the strategy of centralizing the EDP function may run contrary to the objective of availability of data to the end user. Further, a number of technological factors encourage the distribution of data processing and storage facilities.

These factors include:

- *Lower Cost of Processing and Storage Facilities*—recent advances in computer technology and a rapid decrease in hardware cost have reduced or eliminated the cost advantages experienced through centralization.
- *Cost of Communications*—relative to the price/performance gains achieved in computer hardware, communications cost, in terms of price/performance, have remained fairly stable, further motivating decentralization of data processing and storage facilities in order to minimize communications traffic and associated costs.
- *Improvements in Communications Hardware and Software Technology*—though not as dramatic as witnessed in computer hardware and software technology, certain developments in communications technology are motivating factors in the trend toward distributing the data processing function. For example, the needs for control a motivating factor for centralization, can now be accommodated with facilities to "down load" control, software, standard application software, or special procedures to the local processing nodes from a central or controlling node. Additionally, communications technology today readily accommodates the need to access one or more nodes in a distributed environment from a central or controlling node in order to gather summary data.

In summary, technological and price/performance developments in recent years are tending toward distribution of data processing and storage facilities to the geographic location of the origin and/or end use of data. From the perspective of end users, distribution of the data processing function accommodates the need for accessibility to data critical to their decision making responsibilities. This is likely to represent a major motivating factor on the part of management. Further, a move to a distributed database environment may realize real hardware/software cost savings to organizations. Such savings may represent an additional, or perhaps the only, motivating factor.

The CODASYL Systems Committee, recognizing the above factors and concerned with the prevailing perception that database technology is applicable and consistent only with the philosophy of centralization, has undertaken a study of the implications of database technology in a distributed processing environment.

WHAT IS A DISTRIBUTED DATABASE ENVIRONMENT

Considerable attention has been given recently to computer networks and to database technology, but little to the application of database technology in a network environment. The traditional single-site orientation of DBMS and databases must be extended to operate in the context of a network of computer facilities. To provide a basis for discussion and investigation, the committee first laid a careful foundation of terminology. The following paragraphs define network and database related aspects of a distributed processing environment.

The network provides the underlying configuration of computer systems and communication facilities within which data is stored, DBMS's operate, and users access data. A node in the network consists of computer processing facilities (ranging from a large multiprocessor computer to an intelligent terminal) and an associated operating system sufficient for executing user and DBMS processes (programs, queries, etc.). In addition, data and its definition may be stored at a node. The precise structure of a node is an architectural design choice independent of the manner in which the node is connected to other nodes and the extent of geographical separation.

A communications facility is the collection of processes and physical facilities which interconnect the nodes. The communications facility includes knowledge of the physical location of each node, the physical path connections between the nodes, and the protocols to be used in sending messages between nodes. Processes in the communications facility will accept a message from one node and deliver it to another node or broadcast it to some or all other nodes. Two nodes may be connected directly or indirectly through other nodes. A network access process (NAP) exists at every node as the interface between processes at the node and the communications facility. The NAP is that portion of the communications facility which executes on the processing facilities of a node.

A traditional single-site database environment (See Figure 1)[1,2] consists of a database, a DBMS, a database definition ("schema"), and a user schema.* Placing these data-related

* User schema broadly refers to the user's view of the database. CODASYL has called this a "subschema", but, in general, the only requirement is that a mapping exist between the user schema and the "schema." It is not strictly a subset of the schema.

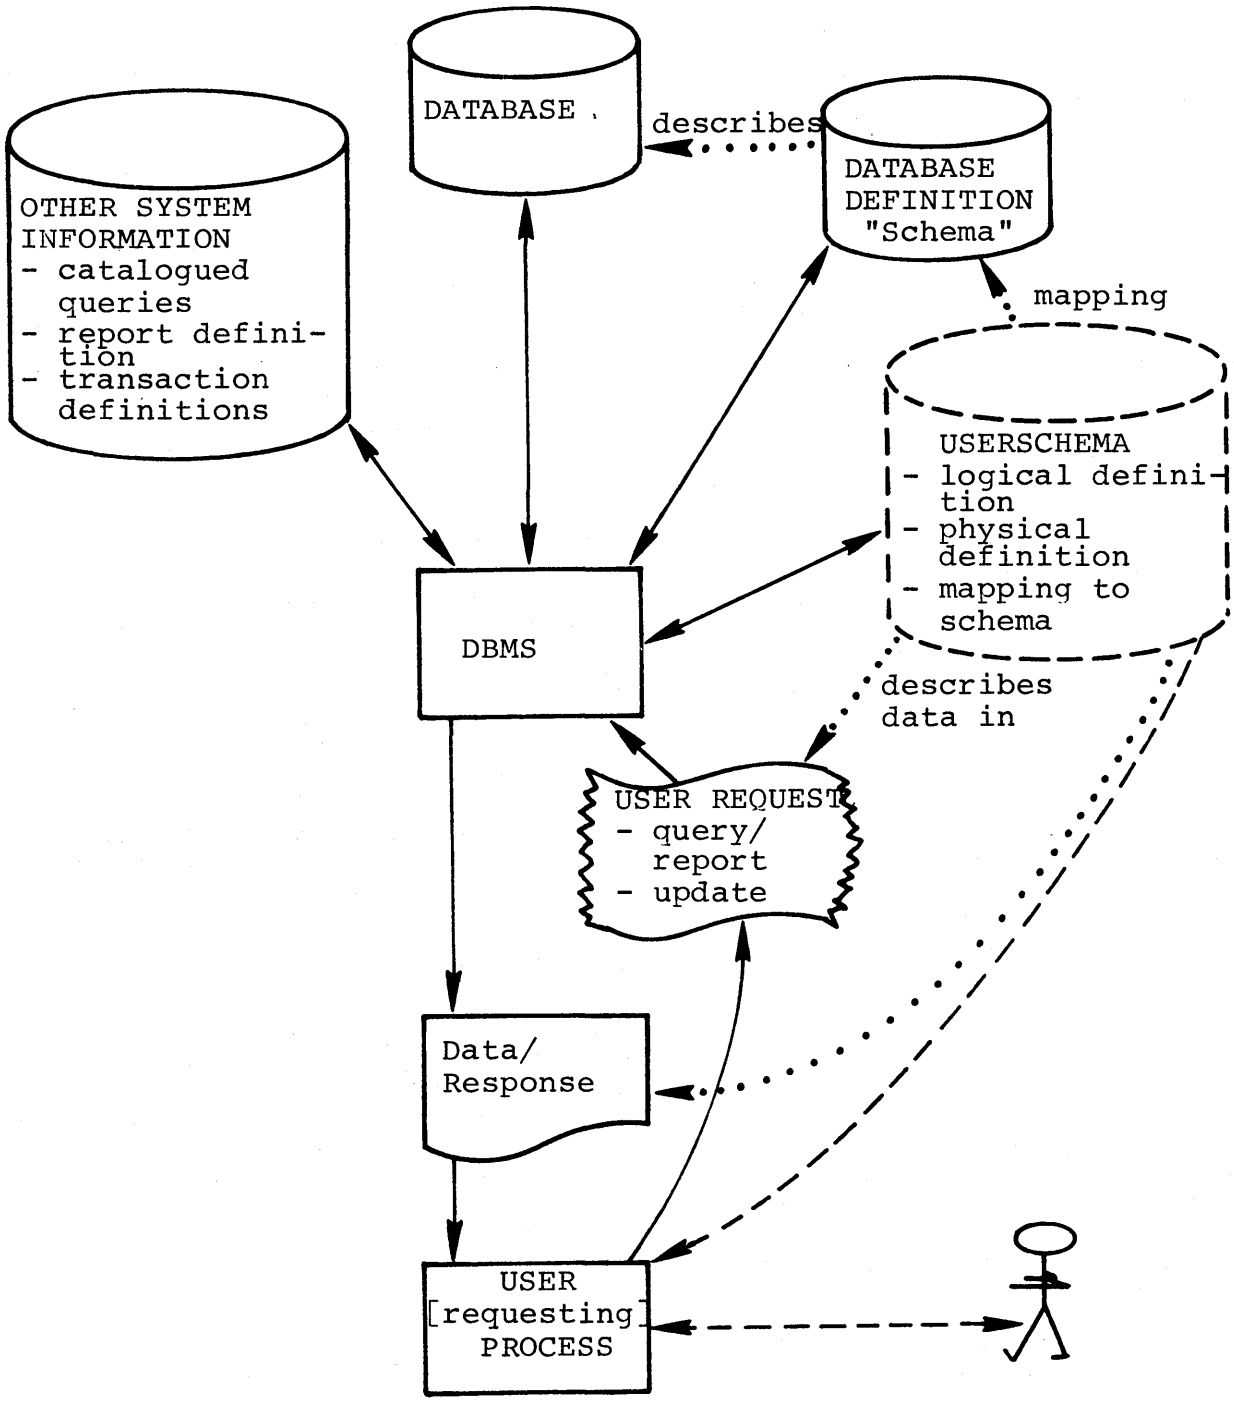

Figure 1—Conventional single-site database environment

components at the nodes in a network environment produces a distributed database environment. The primary architectural design choices relate to the distribution of databases, and the distribution of DBMS functions. All the databases may be stored at one central location (the traditional single site), they may be stored at different nodes, a given database may be broken down into pieces ("partitioned") with the pieces stored at different nodes, or finally, multiple copies of a database or its pieces may be stored at multiple nodes ("replicated"). Whenever a database (or part thereof) is stored, there also must exist appropriate data definition and DBMS capabilities to access and process the data. When the user request and the target database exist at different nodes, DBMS functions can also be distributed and performed at multiple nodes.

The integration of database technology and a network environment leads to new problems and the need for new functions. Perhaps the most important need is for some network-wide intelligence concerning the node location of all the databases in the system, their partitions and their replications. The network data directory serves this function.

When the system receives a user request to access data, a new DBMS function must first determine what data must be accessed and the node or nodes on which it resides. Then it must communicate with another DBMS. Increased heterogeneity within the distributed database environment, i.e., multiple different DBMS's, necessitate a translation of the request. Data conversion may also be necessary if the data is stored in different forms, according to different data structure models or on different hardware/storage devices. These are some of the key technical problems to be addressed by the data processing community in the coming years.

DESIGN ALTERNATIVES

Three levels of perspective

The Committee recognizes three distinct, but nevertheless interdependent, perspectives in providing design alternatives for a distributed database environment.

- Each component of the environment and the interrelationship of components. (See Figure 2)
- The study, in static state, of a node in the distributed environment including its various alternatives for configuration. (See Figure 3)
- The specification of user interaction in a distributed environment, emphasizing the sequence of events and the execution of functions, creating a dynamic model of the environment.

Components and interrelationships

There are five major components within a node of a distributed database environment as illustrated in Figure 2. Non-distributed databases have three of these—the database, the DBMS, and the user process. A distributed database environment requires two additional components—a network DBMS and a NAP. Figure 2 shows three types of nodes:

- A "complete" node with all five basic components.
- A "user" node with only a user process accessing data in the network.
- A "data" node with only those components necessary for data to be made available throughout the network.

Figure 3 provides a more detailed picture of "complete" node. To convert a conventional database environment (See Figure 1) to a distributed database environment requires the addition of the following components:

- Network DBMS
- Network Data Directory
- NAP (described above)

With a centralized database, which is the case in a single-site data processing environment, all the intelligence relating to the database is in one place. A conventional data definition can provide all the information needed for a DBMS to locate and process the stored data.

As soon as data becomes distributed—single, whole databases at different nodes, partitioned databases, or replicated databases—there must exist some information within the system which indicates where the different databases, their partitions, and their replications are stored. This is the primary role of the network data directory.

Network data directory

The network data directory contains information indicating the nodes at which the various units of data reside within the distributed processing environment. For example, given a file name, the network data directory provides the node or an indirect reference to the node(s) at which the file resides. It does not contain information about the physical location of nodes or the routing between nodes; this information is part of the communications facility.

Network database management system

If we assume that a DBMS only includes those functions which relate to a local database and that it has no cognizance of any other data nodes (i.e., a conventional, single-site DBMS), then all other new functions needed in a distributed environment can be packaged in a new system called the Network Database Management System (NDBMS). In the development of a distributed processing environment, it may be desirable to integrate the NDBMS functions with the DBMS, with the NAP, or leave as a separate package. We will be more concerned with the nature of the function and its information inputs, than with any particular packaging approach.

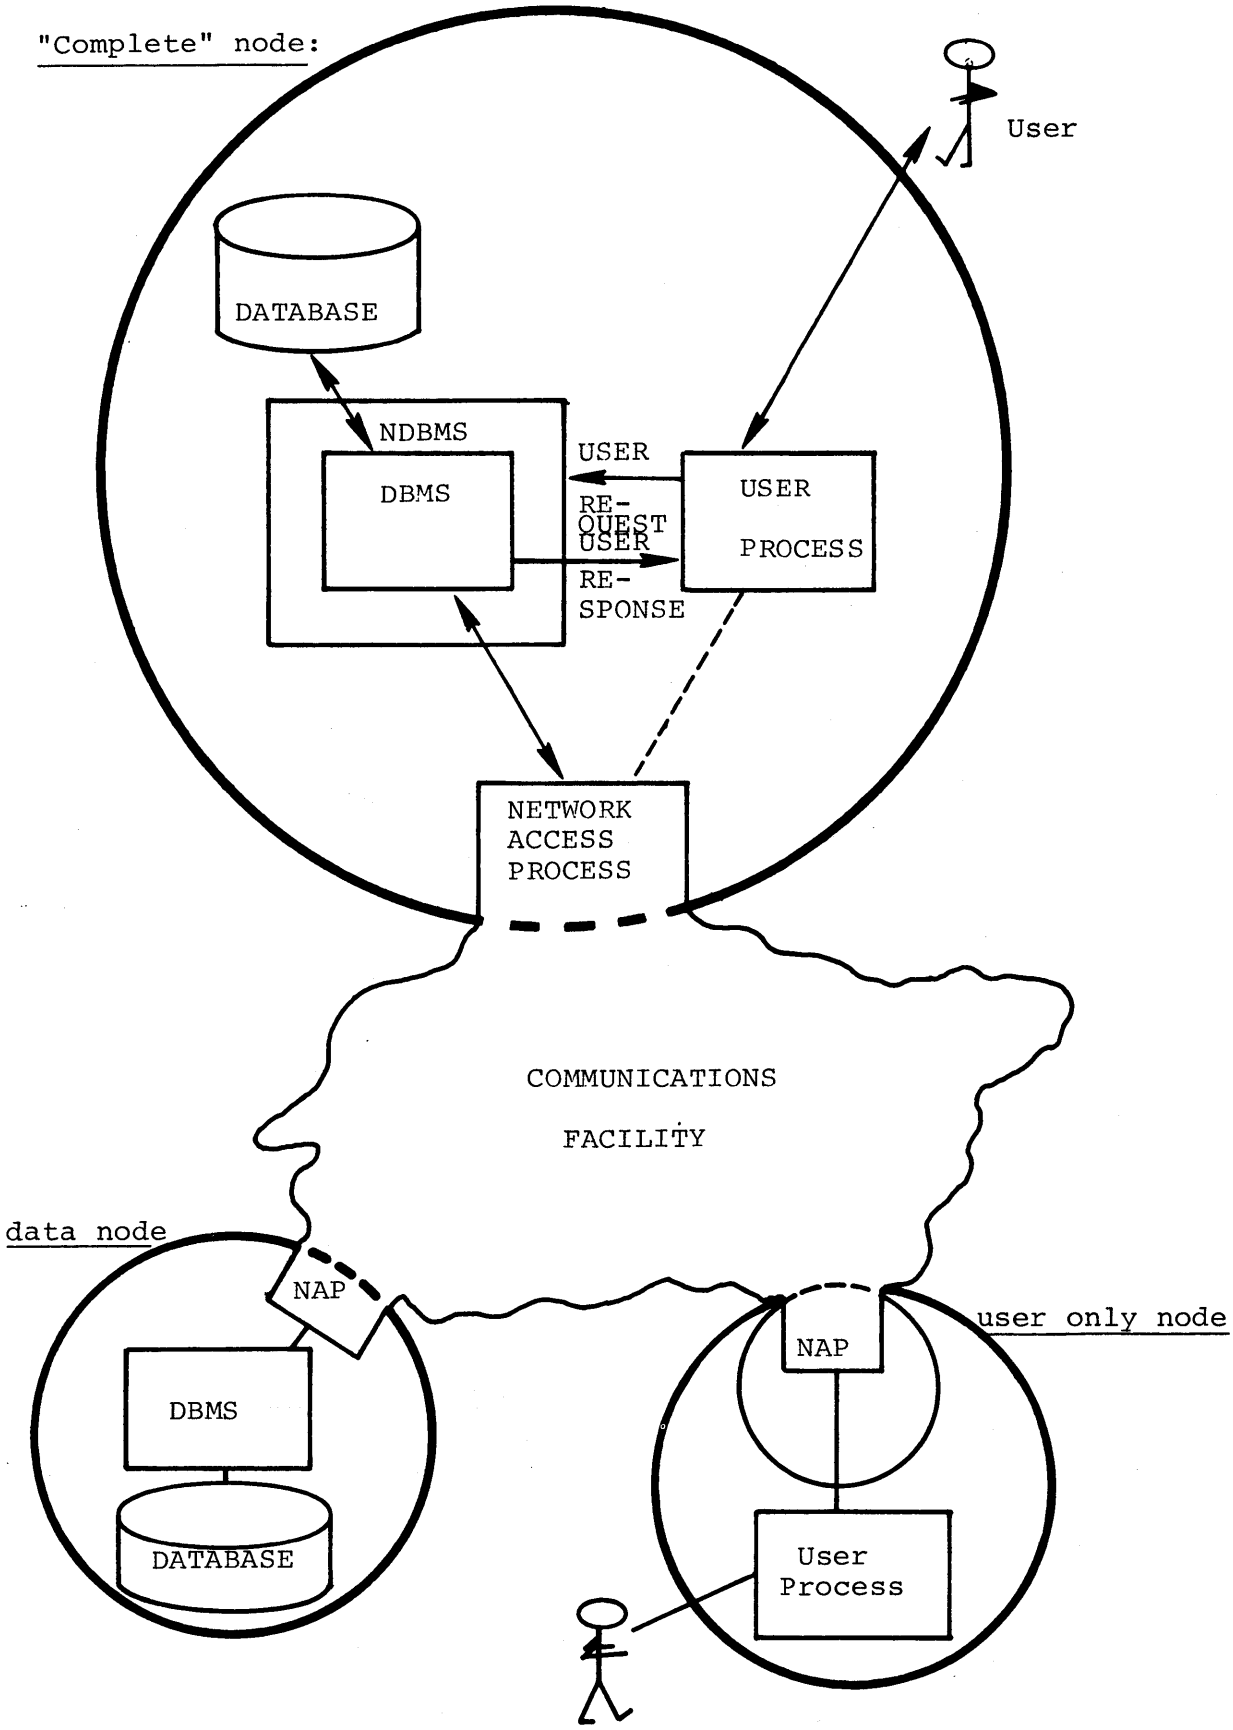

Figure 2—Data and users in a distributed database environment

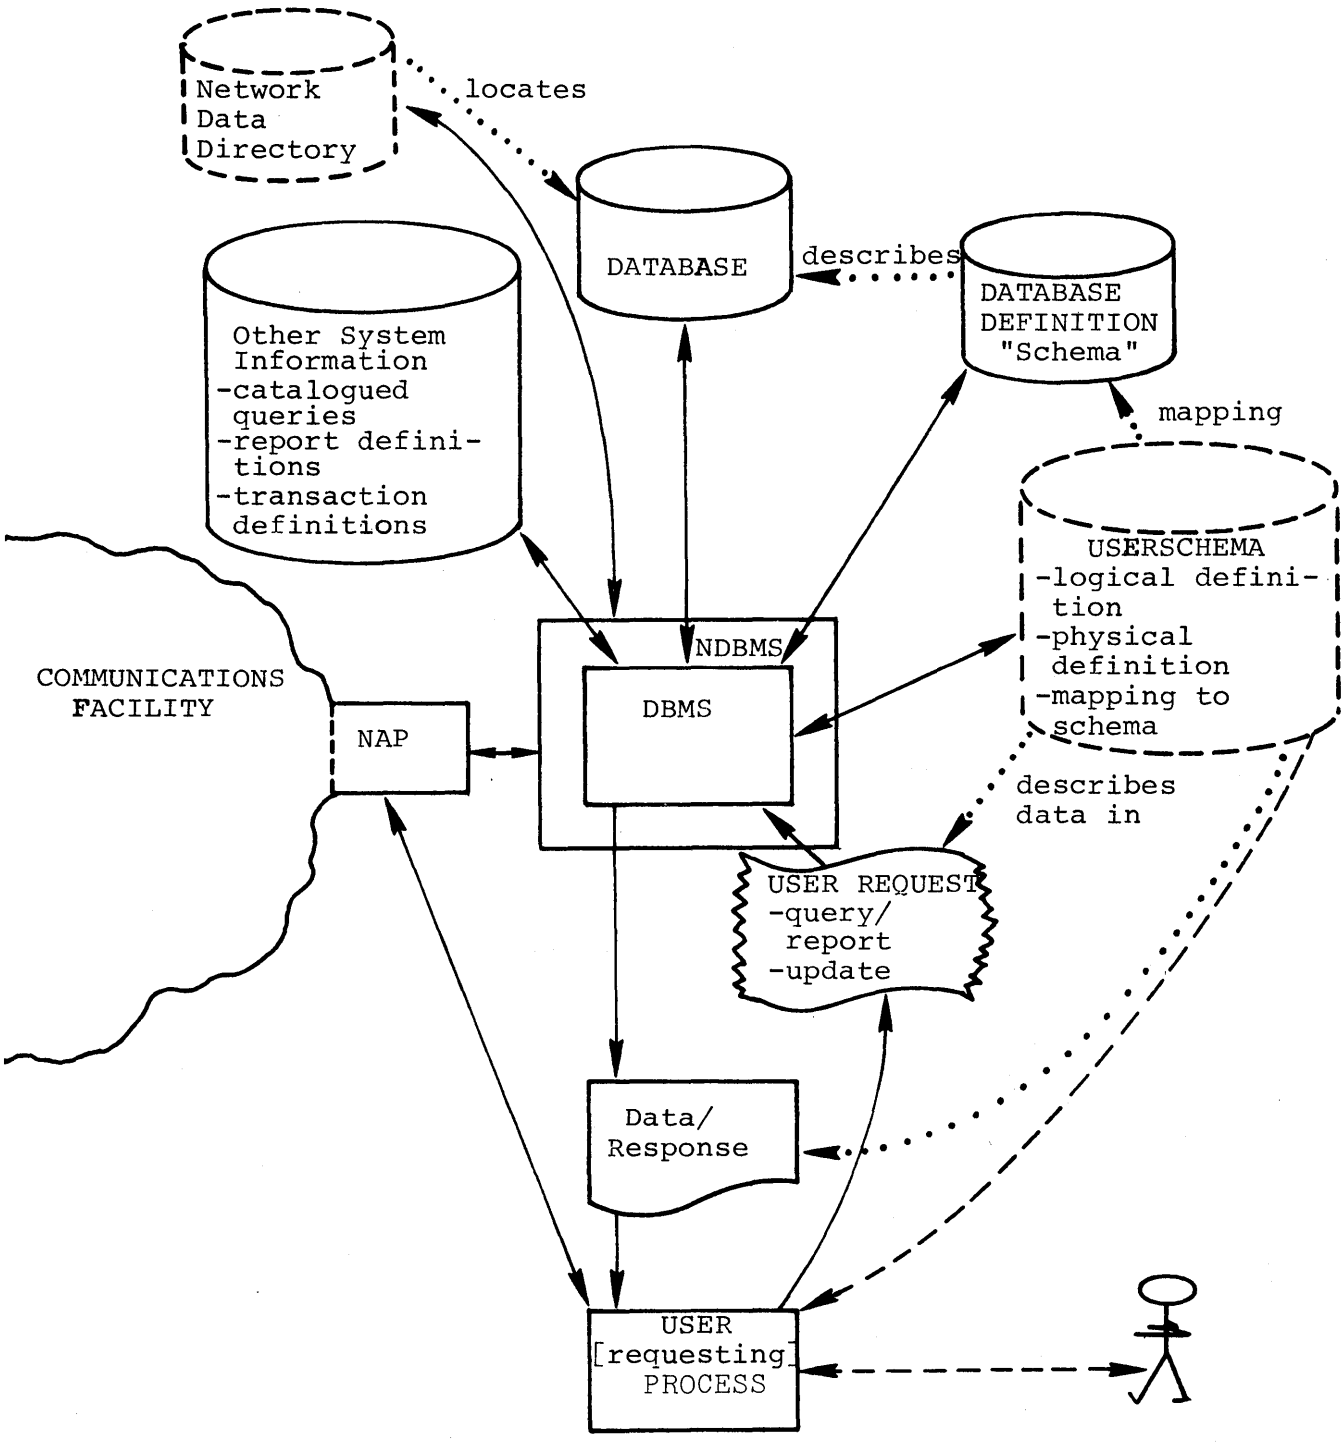

Figure 3—A "complete" node in a distributed database environment

The network DBMS includes at least the following functions:

- Intercept a user request and determine where to send it for processing, or what nodes must be accessed to satisfy the request.
- Access the network directory or at least know how to request and use the information in it.
- Coordinate the processing and response to a user request if it spans nodes, that is, the target data exists at multiple nodes.
- Function as the communication interface between the user process, the local DBMS, and DBMS's at other nodes (via the NAP).
- Provide data and process translation support in a heterogeneous distributed database environment.

Design choices and distribution alternatives

The specification of design choices and distribution alternatives for various distributed database architectures requires a model that will facilitate the study of database related distribution alternatives. If a major component does not exist as a single copy at a single node, then there are multiple alternative design choices as to its distribution to nodes.

- *Replication Versus Partitioning of Components*—the replications of a distributed component (or any piece of a component) are functionally identical copies of the component. Replication introduces the issue of update synchronization.

  The partitions of a distributed component are different and non-overlapping. Under partitioning, the whole of a component consists of multiple pieces which the system must be able to associate. The system must know the relationships among the pieces and be able to manage the whole component and its pieces.
- *Homogeneous Versus Heterogeneous Implementation*—a central issue relative to the replicated and partitioned distribution alternatives regards the relative degree of homogeneity/heterogeneity of the supportive components (namely the DBMS, schema, non-schema and system information) across nodes. If the corresponding supportive components at each node are different (heterogeneous) then the complexity and technological difficulty implementing the system increases. If all components are the same (homogeneous) then it is easier to implement and operate the environment. Given today's technology, the ability to design, implement and operate a distributed environment is greatly facilitated by "standardizing" components at each node. Thus, for example, utilizing the same DBMS uniformly at every node greatly simplifies the design of a distributed environment.

Figure 4 summarizes these design choices:

IMPLEMENTATION \ COMPONENT	Replicated	Partitioned
Homogeneous	The component exists in multiple identical implementations	The component exists only once in the system and has identical implementations
Heterogeneous	The component exists in multiple copies, but in different forms of implementation	The component exists only once in the system, but varies in its implementations

Figure 4—Alternatives for distribution of a component

These simple rules are complicated by observations of existing distributed environments.

- Hybrid distribution alternatives are possible as are time variant ones.
- Not all distribution alternatives are relevant to realistic systems.
- Not all combinations of component distributions are internally consistent or useful.
- Complex interdependencies exist.

TECHNOLOGICAL AND ADMINISTRATIVE ISSUES

Benefits from the distribution of data and its management are not without cost. Benefits resulting from the dispersal of data processing and DBMS capabilities must be balanced against the new technological and administrative problems which result in costs. The solution of these problems will demand a significant cost commitment in terms of additional hardware, software and communications facilities. Similarly, distribution will impact at the administrative level. Data control is complicated since the distributed environment and administrative control must be more highly coordinated. For the purposes of its report, the Committee distinguishes between technological and administrative implications.

The Committee has thus far in its deliberations identified a number of issues which sharply focus the technological implications of distribution. Each of these is briefly described.

Initial implementation problem

The first step in planning for a distributed environment involves careful engineering of the transition from existing operations to the new. Managing the conflicts of heterogeneity creates a significant problem. Often disparate database management systems may be in use, different processing hardware may be installed, and user languages may be incompatible. Conversion from the existing environment to a distributed environment is a technological issue.

Access control

A centralized DBMS facilitates the implementation of security restrictions. Through security mechanisms, protection is afforded against unauthorized, deliberate or inadvertent access to data in the system. One important mechanism used to achieve this goal is access control. In a distributed environment, access control is more difficult to implement because of the necessity of deciding where to locate the control mechanism. The vulnerability of dispersed data may be a real issue. In the extreme, it may be necessary to locate access control with each distributed component, a costly decision. On the other hand, centralizing access control may unduly burden the system with performance inefficiencies. However, if highly sensitive data is localized to specific nodes, higher assurances of strongest access control can be made.

Concurrency

A DBMS must include provisions for the control of concurrent multiple updates to a single record occurrence. In a distributed environment, the record occurrence itself may be partitioned across nodes. The control of concurrency can then become a more complex issue.

Synchronization

A DBMS takes into consideration the management of known redundancies such that a single update affecting multiple copies of the same record occurrence are effected in a manner transparent to the user and such that the database is always at the required level of consistency. The geographic dispersion of replicated copies makes this task more difficult.

Translation problems

In a distributed environment the number of conflicting logical views increases with the amount of heterogeneity in the network. The ability to effect the translation of data, processes, programs, user requests, and procedures from one node to another is a basic requirement of a distributed environment. The ability to implement transparent translation mechanisms presents a technological challenge.

Continuity of operation

An integral part of a DBMS's objective is the ability to operate continuously. This entails specific provisions for the recovery of data and the restart of operations. In a distributed environment this task becomes more difficult when applied to partitioned distribution, and when considered in conjunction with the synchronization issue.

Performance issues

The ultimate goal is to provide information services to the user. Success in measured, in part, in terms of delivery of timely results. The underlying rationale of distribution is availability of data. If the implemented system cannot perform efficiently enough to meet response requirements, the service goals are not met and the system fails. When distribution of components is achieved, there is a risk that the communications overhead incurred in the interest of system integration and control will degrade performance sufficiently to cause the user to question the responsiveness of the system as a whole. The balance between distribution and control will thus be a key performance issue.

Administrative issues

The design, implementation and operation of a distributed environment will be impacted by a number of administrative issues. The fact that these issues cannot be resolved at a technical level make them all the more important and deserving of attention.

Constraints on data flow

The distributed environment introduces the potential for increased amounts of data storage and flow at and across geographically dispersed locations. The assumption that data can be moved subject only to economic considerations is no longer valid. Constraints on the storage and flow of data may be expected from a number of sources, such as:

- *Legal*—governments will legislate constraints on data flow in the form of tariffs and regulatory law.
- *Privacy*—privacy requirements and restrictions will have an effect on the storage and flow of data.
- *International Law*—the flow of data across international boundaries is just beginning to be examined. Responsibility for control, authorization, nature of transmission, rights to impose legal restrictions, traffic constraints, etc., remain to be established.

Coordination and control of data

The administration of data resources is recognized as an important prerequisite for successful implementation of shared use of data. Distribution of data complicates this issue. The development and enforcement of standard practices is more difficult with dispersion, the coordination of common data descriptions is a problem when users are geographically dispersed, and the resolution of conflicting data needs becomes more tedious and time-consuming with distribution.

Organizational issues in administration of data

The emergence of an organizational entity (Data Administration) to address the foregoing issues has provided users with an administrative mechanism to deal with the problem.

In a centralized database implementation, the data administration function has often been organized to be controlled by a senior level data processing officer. In a distributed environment, however, data administration may be potentially exercised at each node in the network. Issues of organizational placement, interaction and coordination must be carefully scrutinized.

User acceptance

The distributed environment must, in the final analysis, serve the user. There are a number of phenomena which may cause concern in this regard.

- Resistance to change.
- Conversion from existing user procedures.
- Potential risk of complexity.
- Organizational realignment.

In a distributed environment each user at every node must find it attractive to participate or the system will fail.

CONCLUSION

The impact of "distributed processing" is already manifested in many sectors of the EDP community. The impact on database technology is significant; the subject of current deliberations of the CODASYL Systems Committee is forging a framework for dealing with these new architectural concepts and is establishing a basis for dealing with the topic on common ground and with clear understanding of the issues and considerations.

Commentary on the CODASYL systems committee's interim report on distributed database technology

by CHARLES BACHMAN

Honeywell Information Systems
Waltham, Massachusetts

The author has reviewed the Interim Report on Distributed Database Technology and is responding from the vantage point of the ANSI/X3/SPARC/Study Group on Distributed Systems. This study group is attempting to establish an architectural approach which will put all aspects of distributed systems into perspective, including distributed databases. The author has been studying this problem as part of Honeywell Information System's investigation for the last three years.

My first comments must be addressed to the overall document which is well written and conveys its message well. I am in agreement with everything in it and will address myself to those aspects which it does not cover at the present time. As an interim report, one cannot criticize it severely for having some gaps. It has been circulated for comment and is soliciting comments so that the final report may be more accurate and more complete. I recommend the reading of this report to all interested parties and urge each reader to comment so that the final report will be as complete as time permits.

The interim report lists a number of motivations for distributed systems. All are valid in one situation or another. There are a couple of additional reasons which I would like to add to the list. The first reason is a human factor reason. This is to permit some element of the business to physically possess the part of the corporate database which holds its part of the data. This gives them the responsibility and the satisfaction of updating their database without removing it logically from the required access by others. Another human factor reason relates to the distribution of the database to reduce its vulnerability to strike action or acts of terrorism. Another reason is the matter of database size vs. computer power. There is no computer on earth which can by itself handle all the data processing for a large corporation. Therefore, processing must be distributed and is already distributed for most of the FORTUNE 500 companies. In most cases they are already physically distributed but not logically integrated and will not be logically integratable until "distributed database facilities" become available.

There should be one item added to the list of reasons for the centralization of data processing. This is to achieve a concentration of expertise sufficient to run a large data processing operation. From an administrative point of view, this is very important. Learning how to distribute the expertise along with distributing the processing and database may be a real roadblock.

From the vantage point of the ANSI Study Group on Distributed Systems, the report seems to lack a certain architectural overview which would put distributed database management into perspective. The ANSI distributed systems reference model begins with the notion that the information processing aspects begins with the notion that the information processing aspects of an enterprise should be viewed as a network of cooperating workstations. Each such workstation is a "location" where a certain kind of work takes place. This workstation may be manual, industrial or computerized. This workstation supports one or more processes which execute the procedures of the workstation and which primarily access the locally stored data. Access to remoted stored data is acceptable, but known to be slower and more expensive. The processes of the workstations cooperate by exchanging messages which request certain actions and transfer such data as appropriate.

Where the process and the data it accesses are in the same machine, data access operates essentially as it did before it was distributed. Where the process and the data are in separate machines, more elaborate mechanisms are necessary. Those described in the CODASYL interim report are representative. One thing which appears missing from the report is any discussion of how processes and data would be partitioned and set up in the various machines in the network. While this is a packaging issue, my current guess is that it is a critical one. Probably, as critical to distributed database access as the "clustering" concept is to the performance of our current centralized database. Simply speaking, clustering is the placing together in the same page as many records of a set occurrence as possible. Where one set has been chosen in favor over another because of the

anticipated frequency of access. Frequency of access is also the heart of the database vs. process distribution questions. It has been said that there are two approaches: (1) take the data to the process and (2) take the process to the data. The carefully preplanned distribution of processes and the data which they are most likely to access to the same machine is the most important step which avoids much of the processing burden associated with distributed processing.

Within the ANSI reference model, three alternate schemas have been discussed to achieve access to distributed databases. From our point of view, the picture presented by the CODASYL interim report describes the most difficult to design and implement. It will also be the least efficient under certain operating circumstances. The three approaches discussed are characterized as;

(1) cooperating user workstations
(2) cooperating storage management workstations
(3) cooperating database management workstations (CODASYL)

All of these approaches assume that a facility for process to process exchange of information is a basic capability of a distributed system. The difference in the three approaches is who is talking to whom and what is the nature of the information exchanged.

The cooperating user workstation approach assumes that the users are knowledgeable of the data file vs. process (workstation) configuration. Thus, if a process cannot get what it needs from the local database, it will formulate a message to be sent to another workstation which is co-located with the data which needs to be processed. When the message arrives at the workstation, a process of that workstation will access the message and carry out whatever local access and updating is necessary and respond with an answering message. When workstations are considered as elements over which the total work load has been divided, then it does not make much difference if one is designed to approve a credit request for a new sales order or whether one is designed to answer questions about the Minneapolis inventory. It is only a slightly further move to design a workstation which receives data manipulation commands as a message text, executes these commands in terms of its local database management system, and sends a response in accordance with its success.

The cooperating storage management workstation approach is based upon the fact that most of our database systems are built as virtual memory systems and do "page turning" independent of the operating system and hardware. When a page is requested by the database management subsystem the storage management subsystem asks whether the page is in a main memory buffer or whether it must be fetched from the disc? If it must come from the disc, then the question is which disc drive and address? With a distributed storage management system, the third question must be asked, my disc or one managed by some other storage management subsystem? If it belongs to someone else, then a message must be formulated with the request. A response message will either return the page, state the process must be waited until the page is available, or stating that a deadlock would result if the process were to be waited. The cooperating database workstation is essentially that one described in the CODASYL Interim Report.

The CODASYL report discusses several kinds of control tables: network directory, concurrency control, integrity control and security control. There is a discussion appearing several places in the report which questions whether these tables should be centralized or distributed. From my point of view, there is only one answer: distributed. The centralized approach has all the problems which the distributed database system is attempting to side-step. e.g., the vulnerability of the entire system to the failure of one element, the congestion problem, etc.). What must be done is to give each node the information about its local resources, process and only information about remote objects of local interest.

One note about the concurrency control is relevant, the problem in a distributed system takes on complexity beyond just the aspect of multi-nodes. Most concurrency control systems have a secondary responsibility to be sure that two or more processes are not waiting for each other in order to access data (deadlock). With the introduction of message exchange between processes, it is possible for process (1) to be waiting for a message from process (2) which is waiting for a record held by process (1) . . . deadlock! It also must be considered that a process may be waiting upon a terminal operator action. If that terminal operator could possibly be waiting on the action of another process in the system, then that anomie must also be included in the path of waiting processes to determine if deadlock exists.

The question was raised concerning the effect upon concurrency if a record were to be split between nodes. This isn't a problem because the assignment and wait logic can work at any level of granularity. It could work at the level of the logical elements: item, item group, segment, record or file. It could work at the level of physical elements: page, group of pages, track, cylinder, or extent. As long as the control is maintained non-ambiguously, it will work. The only difference is the smaller element requires more bookkeeping and the larger elements force processes to wait and possibly be recovered from deadlock when the effective access desired would have caused no interference.

The text described two basically different forms of distribution: distribution of parts of the only copy and distribution of copies of the whole database. Where updating is a pertinent issue, the distribution of copies seems less efficient than distributing parts of the only copy and getting it updated at its only location. We have seen several large systems in the field which have chosen a variation which is worth describing. It could be considered as a form of the multiple copy approach. In this case, major portions of the file are copied and partitioned to be sent to a number of transaction processing machines. These transaction machines handle the on-line daytime processing of their partition of the database. All on-line transactions are also sent to a centralized system where they are batched with additional off-line transactions and reprocessed in a nightly batch run. At the end

of the nightly run, the updated centralized database is again copied and updated partitions are sent to each transaction machine.

So much for the extension of the generalities. The real question is where do we go from here. I see the only satisfactory long term answer in the form of a set of international standards which permit all kinds of computers, software, communication facilities and terminals to be joined together to form an extended network of cooperating workstations. I say extended because the workstations served will need to communicate within companies and between companies and across international borders. No one vendor or one country is large enough, smart enough, or influential enough to go it alone. This is the reason I have supported the ANSI effort and the ISO effort to move toward this standard. We have set ourselves an impossible schedule to reach the goal of international standards. The end of 1978 is the goal for an internationally accepted reference module (levels, protocols and interfaces). The end of 1980 is the goal for the first new protocol and interface standards which will support the interprocess exchange of information. Working groups are being established to study and prepare specifications. One of these is concerned with the distributed database access and control. I expect that the CODASYL System Committee with its members and report will make a significant contribution to making those standards. Are you ready to move and move rapidly? Are you ready to help write and negotiate these standards?

Computer architecture

The recent advances in Computer Technology, providing unlimited possibilities for an ever expanding growth of the application spectrum, have created substantial research activities. The technical sessions in the architecture area of this conference are conceived and planned to expose the profound advances in hardware technology and also to reveal their significant impact on the current and future systems architecture. This series of sessions presents the state of the art and also some of the thought provoking challenges to the designers of the future systems.

The session the "Impact of Semiconductor Technology on Computer Architecture" traces its impact of semiconductor technology on the computer architecture and the emergence of microprocessor systems. It also highlights a discussion on how the future data processing technology would be influenced by the semiconductor technology and the associated problems. The evolution of this technology and future projections are discussed by the leaders of this emerging technology.

The sessions on "Evolution of Architecture" trace the evolution of architectures of well known computer families. These sessions articulate the major challenges and accomplishments of these systems. They also discuss the lessons that these systems have taught and how the future systems would be built. These two sessions would define certain cautious guidelines for the future systems.

In the future the user is expected to be his own architect. By specifying his requirements the future user would be able to configure his system from the off the shelf subsystems. In order to do this certain tools and techniques are needed by the user. The session on "User Impact on Architectures" explores such issues related to user involvement.

In order to define the directions for future large scale architectures it is essential to look back and assess the effectiveness of existing large scale systems. Session on "Large Scale Computer Architectures" looks at the evolution of large scale systems and discusses how effectively these systems have satisfied the user needs.

The dramatic reduction in hardware costs due to the LSI technology make it economically feasible to expand the application spectrum and to cover the areas which are hither to unexplored by developing special purpose architectures.

Session on "Special Purpose Computer Architectures" highlights architectures for one of the important application areas—pattern recognition.

In spite of tremendous advances in computer technology the existing intracomputer standards are in chaos and some are confusing. With the result there exists a large degree of incompatability between the subsystems of various manufacturers thus imposing several artificial constraints on the designers who use these subsystems. The session on intra-computer standards will extend a discussion on the impact of standards on computer architecture. Organizations involved in developing these standards will discuss their current thoughts and focus on how uniform standards could be evolved that would benefit both the user as well as the computer architect.

Intra-computer standards

by TSE-YUN FENG
Wayne State University
Detroit, Michigan

The need of standards on many industrial products is quite easy to understand. Ideally, we would like to have various parts of a product interchangeable. From a user's point of view standards provide him with desirable convenience and reductions in product cost as well as costs for maintenance and repair. In some respect, even manufacturers stand to gain from standardization. Yet, the progress in standardization on various products has been slow. This is particularly true in the case of computer standards.

Since the introduction of the first electronic digital computer some thirty years ago the standards activities on computers have been relatively small. There are several factors that may contribute to this phenomenon. One is that until recently computer systems have been quite bulky involving many components and circuits that are proprietary or patented. The number of major companies manufacturing computers are relatively few and each of them has its own system of standard equipment. Also, the maturity of a product is usually a prerequisite for standardization, but the rapid advances in computer technology prevent the standardization in many areas. It is thus not surprising to find that much of the recent national standards effort has been mainly in the language area since they are relatively machine independent. Languages such as FORTRAN, APT, COBOL, PL/1, BASIC have been standardized by the American National Standards Institute (ANSI). In addition, there are also activities on character sets, and information processing vocabulary. Recently, IEEE Computer Society took the initiative in proposing and developing software standards. These projects are on Software Development, Software Quality Assurance, and Software Documentation.

On the hardware side, the standards activities have also been limited to those that are not closely related to the central components of computers. They are mostly on magnetic tapes, disc packs/cartridges, codes, character recognitions, and interface circuits. Recent advances in integrated circuits make it possible to have a large number of memory bits and their associated circuits implemented on one chip. A number of these chips can then be interconnected to form a larger memory. Furthermore, such large scale integration also permits designs for a small processor to be implemented on a chip. The microprocessor chips together with memory modules can be used to form larger computer systems. The impact of the integrated-circuit chips on future computer architecture is quite evident. Several standards projects on semiconductor memories and microprocessors have also been initiated by IEEE Computer Society with the participation of both manufacturers and users. On semiconductor memories, the projects involve Electrical Description of Semiconductor Memory Devices, Test Pattern for Testing Semiconductor Memories, and Thermal Properties of Memories and Other IC's. In addition, a number of new standards projects relating to semiconductor memories are being initiated. In the microprocessor area three new standards projects, Floating Point Format and Algorithms, Assembly Language Syntax and Lexicography, and Relocatable Object Module Formats are in progress.

It should be noted that there are also parallel efforts on computer standards by the federal government, the military, as well as Joint Electron Device Engineering Council (JEDEC), the International Purdue Workshop, etc.

Software standards—With hints of their relation to computer architecture

by H. HECHT
Consultant
Los Angeles, California

INTRODUCTION

Software standards can help the developer, the user, and regulatory agencies in facilitating communications, in extending software life, in broadening the applicability of programs, and in reducing the personnel and organizational reorientation required in transitioning from one project to another.

Communications are facilitated by use of standardized terminology, by use of standards for development methodology (e.g., structured programming), and by standardized test reporting to name just a few pertinent areas. Facilitating communications implies not only that misunderstandings are avoided but also that the software procurement cycle can be shortened and procurement costs reduced because both contracting parties may from prior experience know their obligations when a standard is invoked. Use of a standard also reduces the cost of software development because the allowance for coping with unfamiliar specifications can be reduced.

Software standards can extend the useful life of programs by facilitating adaptation to new versions of operating systems, by making it possible to transfer the program to a new computer, and by making maintenance and updating of the program itself a lot easier and cheaper. The broadening of a program's applicability is made possible by the features cited above plus uniformity among users of program format, test, and test reporting requirements that can be accomplished by standards.

Much time is required during the start-up phase of critical programs in order to train otherwise experienced analysts and programmers in specific contractually imposed design, coding, or documentation requirements. Allowances have to be made for errors in complying with unfamiliar requirements, and at times management may be reluctant to bid on a software development that is within its normal range of business interests simply because of uncertainty regarding a test or documentation requirement that had not previously been encountered. Software standards could reduce this wasted effort in transitioning from one project to another.

In view of these benefits one must ask why the few existing standards are not more widely employed and why there is not more effort at implementing software standards. Part of the answer lies in the newness of software engineering as distinct from programming for one's own use. The latter implies the translation of a defined sequence of operations into machine-readable form, an activity that was best managed in a local context and to which standards are about as applicable as they are to the writing of business letters. Software engineering recognizes that requirements analysis, test, validation, program maintenance and related tasks, in addition to programming proper, are necessary to provide the computing service that the user expects and needs. This broader activity involves the interaction of many groups, extends over a long period of time, and is in scope quite like a construction project. Hence, standards are appropriate to guide the activities.

But together with the recognition of the benefit of standards must also come the recognition that they involve costs. A standard for documentation may require a more detailed format than is essential for a given application, and a software quality assurance standard may impose access control that will be perceived as burdensome by personnel that arranged the mounting of their own test tapes as they saw fit. In the context of computer architecture it is appropriate to point out that just about every software standardization activity will increase memory and throughput requirements. For example, standards for test or test documentation may invoke analysis tools that slow down the execution of the primary program. So right at the outset let it be said that whatever can be done to increase the speed of computers and the size of the easily accessible memory will be welcome for the application of software standards.

In terms of scope, software standards can be divided into three broad categories: language standards, software engineering standards, and software implementation standards. Each of these classes will be separately discussed below. There is another important classification of standards by issuing agency: voluntary industry standards, semi-official standards (e.g., those promulgated by international agencies), federal standards, and military standards. This paper will be principally concerned with non-governmental standards.

Finally, the common use of the term standards encompasses some documents that are actually recommended practices, guidelines, or specifications. These documents

obviously have a lesser enforceability or more restricted applicability than true standards, but, in view of the rather limited effect of any software standards on computer architecture, these distinctions are not too important in the present context.

LANGUAGE STANDARDS

Standards promulgated by professional organizations are presently applicable only to High-Order Languages (HOLs).[1-8] As such, their effect on computer architecture is indirect; clever compiler designers, if necessary, can cope with almost any machine instruction set. Military agencies may be motivated to standardize the assembly level instructions for certain classes of computers, primarily those that process tactical software. Implementation of such standards would have a much more direct effect on architecture, but discussion of this event is beyond the scope of this paper which emphasizes voluntary compliance.

We should also be careful to point out that the effect HOLs have on computer architecture is to a large measure independent of the existence of language standards. Thus, the adoption of features such as general register organization and floating-point processors that are a boon to processing FORTRAN object code preceded the adoption of the ANSI FORTRAN standards. Standardization of HOLs may nevertheless be significant in this connection because it increases the portability of code and makes the benefit of architectural features that support HOLs more visible to the user. Since source code written in a standardized HOL can be executed on any computer for which a compiler written to that standard exists, it can become quite apparent to a user interested in such matters how both compile time and run time are affected by the computer organization. Hence, standardization of HOLs in general is a positive factor in promoting architectural features that support processing of HOL-derived code.

So far the discussion has dwelled on use of compilers for translating a program coded in a standard HOL for generating the instructions that ultimately are operated on by the computer. Another approach for handling HOL source code is through direct-execution machines. Considerable research in this field has been under way for some time but so far leading to full-scale development of only a few direct-execution computers.[9] Among many factors responsible for the slowness of this development may have been the proliferation of language "dialects", requiring translation or other special processing before existing source code could be processed on a direct-execution machine. HOL standardization may remove at least this factor among the obstacles to acceptance of architectures for direct execution.

Block-oriented languages, such as ALGOL, benefit particularly from provision of stack features in the computer. Further standardization of block-oriented languages may therefore become a factor in promoting stack architectures.[10]

The general tendency toward increased use of standardized HOLs (likely to be heightened by a recent DoD directive) will tend to benefit those computers that can efficiently process code derived from them. However, it must also be realized that going from assembly code to HOLs will require more memory and greater processing speed if the same computational capabilities are to be provided. Thus, the previously mentioned effect that standardization demands faster computers with larger memories is evident in the area of language standards.

SOFTWARE ENGINEERING STANDARDS

In the broader sense, dictionaries for information processing that have been available for some time[11] could be considered software engineering standards. Also, some Department of Defense acquisition management documents contain material related to software engineering standards.[12] But specific software engineering standards are only in the draft stage, e.g., a Military Standard for Tactical Software Development was circulated as a draft in June 1977. It is also interesting to note that the Federal Information Processing Index provides for software engineering subjects, e.g., operating procedures and operating systems, but that there are at present no entries under these headings.

Effectiveness of software procurement and development suffers, and in some cases the introduction of computers for critical tasks is being hampered, by this lack of standards. The IEEE Computer Society Subcommittee on Software Engineering Standards is now active in preparing three standards in this area: software development, software quality assurance, and software test documentation. A specialized terminology for software engineering has also been drafted by this committee.

The software development standard is expected to require a modular organization, some form of structure programming, and "readable code." These requirements do not easily translate into effects on machine architecture but they will in general result in an expansion of code over that generated without them and hence again will demand greater memory capacity and speed.

Standards to be drafted for the quality assurance area may, among other things, be concerned with controlling access to software and with recording of all executions of a program during test or certain other critical phases. In current practice compliance with such requirements can be monitored by making use of features of advanced operating systems. As a result of the standardization the requirements for such controls may become sufficiently common that it may be profitable to explore architectural features that can simplify the demands placed on the operating system. In the quality assurance area there is an existing Military Specification on Software Quality Assurance Programs that has no apparent impact on computer architecture.[13]

Test documentation standards will be concerned with areas such as reporting completeness of test, complete description of the test environment, and accurate recording of all changes to software or the environment over the usually rather extended period required for test of critical software programs. One of the methods for reporting completeness of test, but probably not the only one that would be acceptable under

such a standard, is the recording of all node exits taken during a series of test runs. In current practice this can be done by use of staic analyzers to locate the nodes, and subsequent "instrumentation" of the nodes such that passage during execution can be counted. Execution time of such an instrumented program can be orders of magnitude longer than that of the original code, and the need to insert and then to remove the instrumentation may impair validation of the test. This is one of the major obstacles to more widespread use of these software test tools, and architectural features could possibly be brought to bear to simplify instrumentation requirements and to reduce the execution time penalties.

STANDARDS FOR SOFTWARE DELIVERABLES

Software can be delivered to the user in a large number of ways: installed in a specified computer, as a listing, as card decks, as paper tape, and as magnetic tape to a number of formats. Within most of these there are further variations on character set, density, and other format variables. Physical dimensions of the deliverables and format features are, in many cases, covered by standards or trade practices. In most cases these affect the design of computer peripherals much more than computer architecture proper. As a matter of fact, there seems to be a tendency, through the use of microprocessors, to make peripherals "smarter" (i.e., to adapt themselves to format variations) and thus to remove the need for some of the conversion tasks that must now be handled by processing in the central computer.

Software documentation is an important deliverable that is covered by a number of voluntary standards.[14–15] In addition, this area is the subject of numerous Department of Defense specification and data item descriptions (DIDs). None of these documentation standards appears to have an immediate or even remote impact on computer architecture.

CONCLUSIONS

The imposition of software standards will, in several areas, require longer code (i.e., more storage) and slower execution (i.e., require a faster computer in order to handle a given task). Thus, software standardization imposes a requirement for more powerful computers. It would, however, be probably more correct to say that the capability of industry to provide more powerful computers permits standardization rather than the other way around.

The requirements for HOL processing, in particular the requirements of newer HOLs, may favor certain architectural features in the central processing unit, and the fact that these languages are standardized may impose a further urgency on the computer community to adopt architectural features that support these languages.

Software engineering standards may become accepted in the near future. These will require some code expansion, control of software access during critical test phases, and may lead to more widespread usage of automated test tools to quantify completeness of test. Requirements likely to be formalized by these standards are currently being met by software but hardware features to support the software or to supplant it may at some future time be worth investigating.

Standards for software deliverables primarily affect peripherals. Some unburdening of the central processing unit by "smart" peripherals may be in the offing. Standardization of output formats may further simplify the central processing requirements in servicing peripherals.

Standards for semiconductor memory

by J. REESE BROWN, JR.
Burroughs Corporation
Piscataway, New Jersey

INTRODUCTION

The concept of standardization and the advantages which it offered by-passed the semiconductor memory industry for the first five years of its existence. Standardization has never been easy to achieve in the modern electronics industry, but it has been doubly difficult for the fledgling semiconductor memory industry.

This difficulty can probably be attributed to the highly competitive nature of the industry combined with the high technology levels involved in the products. Each company had what they felt were advanced proprietary concepts, processes, and designs. This, they felt, would give them a competitive edge so they were reluctant to talk to the competition regarding standards, for fear that they might lose some of their commercial advantage.

The lack of standardization extended over a broad range of aspects of the industry. The language used by each company in describing its product was different from that used by its competitors, even when the products were intended to be interchangeable.

Beyond the lack of communications standards, there was the more fundamental problem that the product images and characteristics were not standardized. At one time there were over four different 1K dynamic MOS RAMS. The situation got worse with the advent of the 4K dynamic RAM. At least seven different noninterchangeable designs were announced, each described in a different language.

The first 4K devices to be introduced were in a 22 pin package. The twelve address bits were supplied in parallel. From a performance standpoint, the parts were generally compatible. However, the two companies which led the field chose to use different pinouts, making the parts incompatible. In addition, a third company introduced a part which was compatible with one of these except that the output was different. It had a low level constant current rather than a TLL compatible voltage out.

Following the original 22 pin devices, there were three different 18 and 16 pin devices introduced. The two 18 pin devices used different pin-outs and interface logic. The 16 pin design used a two clock, multiplexed address interface logic.

In addition to the gross differences of pin-out and logic, there were numerous cases of subtle differences in timing requirements and interface signal levels which created incompatibilities between parts.

Another aspect of Semiconductor Memory where we have been hampered by the lack of standards is related to device test. A critical aspect of testing is the test pattern used. This is the address and data sequence which when combined with the power supply voltages and interface voltages and timing, are used to determine if a device meets specifications or not. Often, in marginal devices, minor variations in the test pattern can make the difference between detecting a bad part or not. It is essential that we be able to communicate the exact details of these test patterns so that tests may be duplicated by vendors and customers.

Several years ago, a group of engineers representing both vendors and users recognized the problems which resulted from this lack of standards and set off to correct the situation. They formed a committee and then petitioned the IEEE Computer Standards Committee to sponsor their work. The group became formally recognized as the "Semiconductor Memory Standards" sub-committee. The membership is made up of representatives from device manufacturers, manufacturers of computers and related equipment, and memory test equipment manufacturers.

The group normally meets twice a year at the solid state circuits conference in February and at the semiconductor memory test symposium in October.

The sub-committee is made up of several task groups which meet more frequently to prepare drafts of standards to present to the sub-committee. At the present time there are three task groups working on standards. The first of these is working on standards related to the electrical description of Semiconductor Memory devices. The second group has addressed the problem of describing the test pattern used to test Semiconductor Memory devices. The third one, which is now being organized, will develop technical standards for describing and measuring the thermal properties of memories and other integrated circuits.

STANDARDS IN PROCESS

There are three standards currently in various stages of preparation. The first one is being developed by the device description task group: It is entitled "Proposed Standard for

Semiconductor Memory Data Sheet Generation". The intent of this standard is to provide a common language and format for the industry to use in describing the electrical and mechanical properties of Semiconductor Memory devices.

The document is divided into four sections. The first section title "Product Description" lists a series of different items of a general nature which should be included in the specification of any product. It also gives some definitions and logic conventions which are recommended to be used so that the data sheets and specifications can easily be understood by everyone.

Section two, "Product Specification" gives recommendations for the actual electrical and mechanical specifications of the device. In the various sections, ground rules, definitions, and conventions to be used are given. For example, it contains a statement which gives a common definition of the basis for generating the "Absolute Maximum Ratings" section. In the past, there was never a definition of what this means. Every company had its own ground rules for generating these numbers, or in some cases, no ground rules. As a result, the numbers are often arbitrarily chosen and therefore meaningless.

In other areas, definitions and conventions are given to standardize symbology and the presentation of the data. The section on timing specifications is one which has suffered from the largest differences from vendor to vendor and as a result, the greatest amount of confusion amongst the users. The timing specification of current dynamic MOS memory devices is extremely complex. There are typically seven different signals or groups of signals, each of which have up to four critical timing events. Each of these events must be specified with respect to at least one other signal and often with respect to three or four others. The result is a timing specification which often contains a table of over 30 parameters with either a minimum or a maximum value, and sometimes both. For this standard, the task group has invented a symbology and procedure for generating timing parameters to relate any timing event to any other timing event. The result is a uniform, nonambiguous "language" for the timing specification. A summary of the new symbol procedure is included in Appendix A.

In a similar, though less complex way, the voltage and current portions of the specification are covered. Preferred symbols are given for the different lines as a function of their use within the device.

The third section covers the area of use related information. It includes recommendations for the inclusion of information which will simplify the users task of applying the device. The items covered are: graphs showing the interaction between operating variables, current waveforms, bit maps, equivalent interface circuits, testing information, and application information.

The standard is concluded with a series of appendices which give: (1) a summary of input/output pin names, their symbolism and definitions, (2) a format and example of timing specification for a part using the conventions of the standard, and (3) a summary of the timing parameter symbol procedure.

The second standard being worked on is one relating to the description of test patterns for RAM Memory. The original intent of the task group was to accomplish two tasks. The first was to develop a language which could be used to uniquely define the address and data sequence used in a memory test pattern. The second was to use the results of the first task to stabilize the definition of some of the more commonly used patterns such as march, galpat and walking 1/0.

One of the original ground rules for the language development was that it should be machine independent and not rely on the readers knowledge of the programming language or architecture of any of the currently popular memory testers. The reason for this is the wide disparity between tester pattern generators used. Some work with an absolute address scheme and others use relative addressing. Some define data as a simple sequential string of bits, while others define data as a spacial function of the addresses, while at least one has the capability of doing both.

In its initial efforts, the task group attempted to apply one of the more widely understood high level programming languages, such as APL or Basic. As the standard went through successive drafts, the language evolved into one which tends to be closer to the language of some of the testers. It is undergoing further refinements to satisfy the objections of some of the more hardware oriented sub-committee members.

When the language is stabilized, the task group will then start to develop a repertoire of test patterns which are in common use in the industry. This is being done, not to give support to any patterns as more effective than others, but to improve communications so that when someone uses a pattern name, everyone knows exactly what he means.

The third standard is one which is concerned with the thermal resistance of an integrated circuit. In the past, the terms, symbols, and definitions for I.C. thermal resistance have not been standardized at all. Each vendor and user tends to have his own private set. In addition, some of the definitions used by device manufacturers have no real value to the user in the environment in which he uses the parts.

The work has progressed to the point of having a first draft which has been circulated to the task group for discussion. It will be at least late 1978 before it has been refined to the point where it is ready for presentation to the subcommittee.

The draft standard starts with a series of thermal resistance definitions. The list includes the traditional parameters $R_{\theta jc}$ and $R_{\theta ja}$, which are favored by the device manufacturers. It also contains several new ones which allow the user to predict or measure the I.C. junction temperatures under system operating conditions.

The definitions are followed by a section on test methods for measuring thermal resistance. It includes discussions on test fixtures, test devices, test instruments and procedures.

The end result of this effort will be an all inclusive standard which serves the needs of device designers, manufacturers, and users. At the present time, there is no applicable standard for anyone, only a variety of sometimes conflicting traditions.

The work of the sub-committee will continue until those

topics which are the proper province of the IEEE have been considered.

OTHER STANDARDS WORK

There is another class of standards which is badly needed by the industry but which is not properly handled by an organization like the IEEE. This is the standardization of the interface image and specifications of the memory devices themselves. It was this lack of standards which allowed four different 1K devices and seven different 4K devices to be introduced into the market. There is, however, a committee which has been formed, to address this problem. This committee was formed by JEDEC (Joint Electron Devices Engineering Council) as committee JC-42. This committee is made up of representatives of device manufacturers only, however, there is close communciation between the IEEE Semiconductor Memory Standards sub-committee and JC-42 so the users voice is well represented.

In addition to the work of JC-42, there are some additional standards work being pursued by other groups. The JEDEC committee JC-11 is preparing standards on the mechanical packages used to house memory devices. Some of the smaller "chip carrier" packages which are now being considered by this committee can have a long range effect on memory architecture. This can come about as a result of the increased packaging density which the use of these packages will allow. In addition, their use opens up the possibility of cost effective multi-chip packages with higher levels of complexity.

There are numerous standards being generated by the N. B. S. or through the MIL specification channels which relate to the Semiconductor Memory field. They are broad based standards which are intended to cover the general field of intergrated circuits. One of these is worth noting since it covers topics being considered in the IEEE thermal resistance standard. This work, done by G.E., has been published in the report RADC-TR-77-321, "Thermal Resistance of Microelectronic Packages."

This is an excellent piece of work which covers in a broad way definitions and test methods relating to package thermal resistance. The work of the IEEE committee is an expansion of this work to make it more broadly useful to the commerical users of integrated circuits.

CONCLUSION

The Semiconductor Memory industry has suffered for its lack of standards. The result has been a needless waste of resources, both by the vendors as well as the users. The progress of the industry has been retarded in ways which it is impossible to quantify. The task of making up this lack has now been undertaken by two separate groups: (1) an IEEE Committee working on standards related to communication and definitions, and (2) A JEDEC Committee working to standardize product definitions and images. The combined results of these committees will greatly assist the Semiconductor Memory industry to develop new, better products and the users to apply them more effectively.

APPENDIX A

SYMBOLS AND ABBREVIATIONS

This data sheet uses a new type of specification nomenclature that is derived from background work of several users and manufacturers of semiconductor memories. It should help to clarify signal and parameter symbols and definitions and make data sheet information more consistent.

ELECTRICAL PARAMETER ABBREVIATIONS

All abbreviations use upper case letters with no subscripts. The initial symbol is one of these four characters:

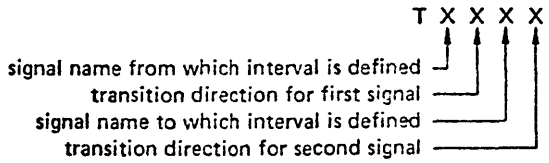
V (Voltage)
I (Current)
P (Power)
C (Capacitance)

The second letter specifies input (I) or output (O), and the third letter indicates the high (H), low (L) or off (Z) state of the pin during measurement. Examples:

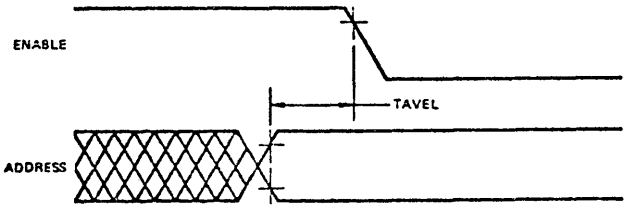
VOH = Output high voltage
IIL = Input low current
IOZ = Output off current (leakage)

TIMING PARAMETER ABBREVIATIONS

All timing abbreviations use upper case characters with no subscripts. The initial character is always T and is followed by four descriptors. These characters specify two signal points arranged in a 'from-to' sequence that define a timing interval. The two descriptors for each signal point specify the signal name and the signal transitions. Thus the format is:



Example:



The drawing shows the address setup time defined as TAVEL, Address Valid to Enable Low time.

The signal definitions used in this data sheet are:

A = Address
D = Data In
Q = Data Out
W = Write Enable
E = Chip Enable

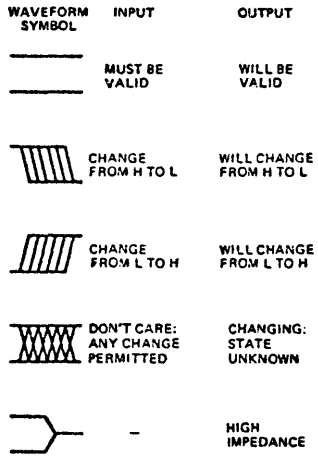
The transition definitions used in this data sheet are:

H = transition to high
L = transition to low
V = transition to valid
X = transition to invalid or don't care
Z = transition to off (high impedance)

TIMING LIMITS

The table of timing values shows either a minimum or a maximum limit for each parameter. Input requirements are specified from the external system point of view. Thus, address setup time is shown as a minimum since the system must supply at least that much time (even though most devices do not require it). On the other hand, responses from the memory are specified from the device point of view. Thus, the access time is shown as a maximum since the device never provides data later than that time.

WAVEFORMS



Microprocessor standards

by TOM PITTMAN
Itty Bitty Computers and Homebrew Computer Club
San Jose, California

and

ROBERT G. STEWART
Stewart Research Enterprises
Los Altos, California

Now that microprocessors have been with us for three or four years, we can stand back and observe some disadvantages of our free enterprise system, as well as obviously great advantages. The disadvantages tend to fall most heavily on the shoulders of the user, not the manufacturer. The proliferation of microprocessors with incompatible instruction sets, adds unnecessary chores to learning new mnemonics, and requires rewriting (at large expense) existing software. Another interesting situation can be seen in the case of the 8080 and the Z80 processors whose mnemonics differ for precisely the same instructions. The act of copyrighting mnemonics by microprocessor manufacturers places the problems in the user's laps in order to protect the proprietary interests of the manufacturer of the chip.

Whenever standards are proposed, two reactions are voiced, polarizing the opinions. On the one hand we hear general disdain: "Who needs them?" or "Standards impede progress." On the other hand we hear cheers: "What took so long?" or "Lack of standards impedes progress." The field of microprocessors is not immune to this division.

We will have standards in software as well as in hardware. Unlike the larger mainframe computers, where the entry costs are high enough to insure a virtual monopoly on software and interface standards by a single manufacturer, there are a half dozen or more significant contributors to microprocessor software for each chip type, and as yet none of their products are compatible with each other. There are hundreds of components designed for very few processors, and many of these cannot even coexist in the same system. Standards are inevitable because the users will not tolerate this chaos very much longer.

The absence of standards for the large, batch computers today is simply due to the fact that the manufacturers fight standardization. Plus compatible peripherals are a touchy example. It is not in the mainframe companies interest to foster a standard interface. This reluctance to standardize extends to software aspects which directly affect a user such as job control streams, editor commands, disk I/O calls, tape formats, internal data representation, ASCII vs. EBCDIC, and pairing of source and relocatable files. These differences are particularly vexing for someone who must use computer systems made by a number of different companies. If there were only one computer company, then standardization efforts would not be necessary. The interesting thing is that the present situation looks like it results from a condition where all the different computer companies believe that they are the only one! Note that most of the problem areas which would benefit from standardization would have relatively little or no impact on the computer architecture!

The fun aspects of the hobby or homebrew computer run headlong into the software and hardware idiosyncracies of the different manufacturers. For example, because the Port designations for the console and the console status flag's ready bits have not been standardized, the act of bringing

"We can't do business after all... my computer isn't speaking to your computer."

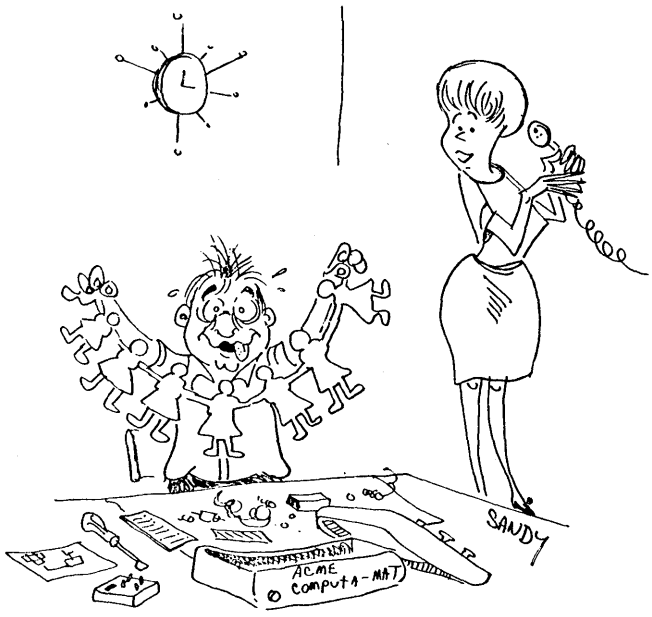
up a system is rendered much harder since a friend with a working system may not be able to substitute his proven software without first patching in the required changes. This patching can be quite difficult because the hardware may be flaky also.

Note that these types of problems are seldom serious to the manufacturer, but represent hurdles to the novice user that make him curse the people responsible for making life difficult for him. And typically those people are cloistered within companies and make arbitrary decisions without regard to the problems that result for users interfacing with hardware and software from a number of sources.

A veritable jungle has come into existence in the homebrew or personal computer hobby. Memory boards and DMA devices for the S-100 bus are an example. The manufacturers state that they are S-100 compatible, and indeed they are unto themselves. However memory boards from different manufacturers are, in some cases, not compatible with each other. The initial MITS description of the Altair or S-100 Bus did not nail down the timing of the bus. By this absence, the timing defined by Intel for the 8080 processor must intrinsically be recognized as the original timing standard for that bus. Later, other processors such as the Z-80 and the 2650, have been used on the bus, without having the same timing signals and relationship as the 8080, so that memory and DMA devices are not directly interchangeable.

Usually it is the user who takes the lumps in both cost and frustration because the manufacturer had stated the boards are bus compatible, when they actually were not because of their timing and control characteristics.

The IEEE Computer Society Microprocessor Standards Committee was formed in the summer of 1977 to try and resolve some of the obvious problems that have arisen in the use and applications of these marvelous chips called microprocessors. The veritable complete revolution in technique which the microprocessor has brought to the electrical engineering profession will be aided for years to come by a codification attempt at this time.



"I've got the Acme people on the line. They say they are sorry but your kit contained instructions for a KI-8 kit and you bought a KP-2 kit. They hope you have not been inconvenienced."

SOFTWARE STANDARDIZATION EFFORTS

The IEEE Computer Society has taken a bold step forward in forming a standards committee to deal with the most pressing of these issues. We have selected three specific areas of concern in the software area where immediate action can be of tremendous benefit in the microprocessor community:

1. *Floating point format and algorithms*—We expect to be soliciting comments on a first draft of a proposed standard by the time of NCC. In this standard we will be defining forms for both normal floating point operations and for extended range and/or precision. Overflow and underflow conditions will be specified, and minimal requirements of the algorithms implementing these operations will be defined.
2. *Assembly language syntax and lexicography*—There are major questions subject to compromise in this area. It is expected that this standard will define the assembler syntax for each of the more popular microprocessors, specifying both mnemonics and operand coding. By considering all of the processors at one time it is hoped that the similarities between processors will be reflected in the mnemonics and operand syntax, and that guidelines may be developed for the assignment of mnemonics to new microprocessors as they appear. In particular, it is hoped that assemblers supported by timesharing services will all accept the same source code for the same chips (this is not now that case), and that their reduced development costs in bringing up additional processors will make wider support for new CPUs more attractive.
3. *Relocatable object module formats*—This area, though of vital importance, seems to be moving the slowest. Again, the major thrust of our efforts is the specification of an adequate object module format for each of the major processor families.

Here also it is expected that the careful selection of functional and lexical characteristics will insure a uniformity across processor lines which will therefore also extend into future CPU design. Clearly the burdens placed on the relocating linker are somewhat arbitrary, so part of our work includes the analysis of the kinds and extent of the tasks which should be deferred to that phase of program translation. Obvious candidates for support are the output of macro assemblers (see standards effort #2 above) and of FORTRAN compilers. The requirements of other high level language compilers should also be considered, as well as the possibility of a proper subset (with reduced functions) for minimal operating systems.

One of the frequent objections we hear points to the dissimilarities between different microprocessors, with particular reference to the one-chip controllers. Since most of these are single-sourced and lack the multiple-manufacturer proliferation of software development tools seen in the 8-bit processors like the 8080 and the 6800, we have not been overly concerned about extending compatibility in these directions. However, most of the committee members have had extensive experience with several microprocessors, and our emphasis in each of three areas is focused on the similarities rather than the differences between the varieties of chips under consideration.

HARDWARE STANDARDIZATION EFFORTS

The initial hardware problems tackled by the Microprocessor Standards Committee are standardization of several of the existing and proposed busses, namely the S-100 bus, the Intel MDS Bus, National's Microbus, and the PI bus proposed by Pietsch and Khalsa. After the bus issues have crystallized, the Committee will look at problems in the Small Business and Hobby Computer area, such as interfacing and protocols, standards for memory peripherals, data formats, disk formats, etc.

The key issues that arise in standardizing the de facto busses are timing diagrams, DMA control, defining unused pins for future address, data space, and control extensions, and accommodating the higher clock rates of future processors. The proposed standards for the busses will be given at NCC and the audience will have the opportunity to make comments on them. They will also be able to make suggestions for future standards activity by the committee.

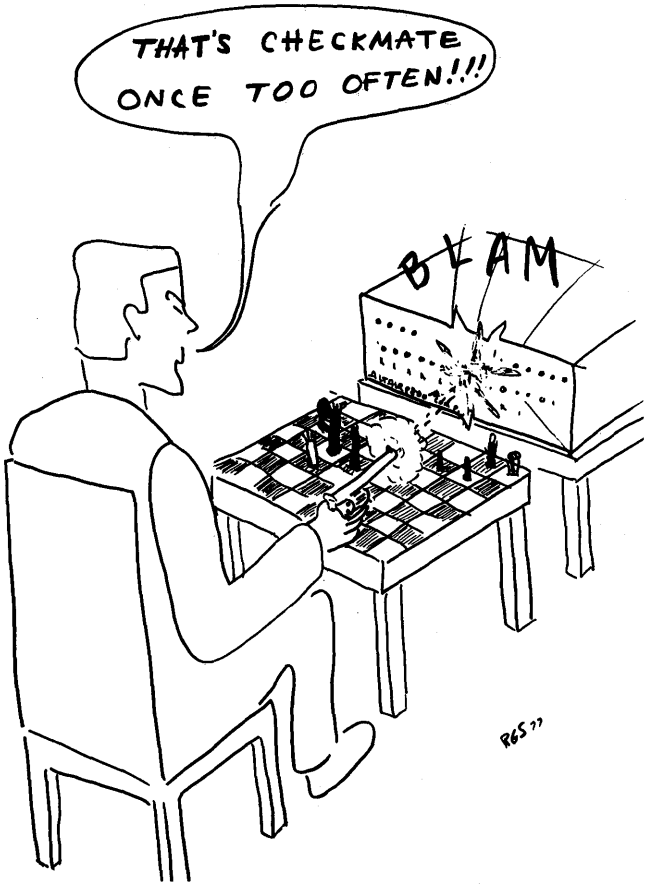
Of the existing de facto busses for microprocessors, the most widely used is the bus MITS used on its Altair 8800 computer announced by Ed Roberts in Popular Electronics magazine in February, 1975. (Many computer hobbyists regard that as the world's first digital computer.) The wide variety of plug-in boards that are available for the Altair of S-100, at competitive prices, have enabled the bus to serve the hobbyist and the small business market reasonably satisfactorily. The problems that have arisen with the S-100 bus are: (1) The use of positive true rather than negative true logic, (2) an overabundance of control and non-essential signals on the bus, (3) the use of separate data in and data out busses, (4) the use of microprocessors with different timing characteristics than the 8080, (5) different voltage power lines directly adjacent to each other, (6) one common AC and DC ground, and to some extent, (7) poorly designed boards which plug into the bus.

The efforts of the IEEE Computer Society Microprocessor Standards Committee to resolve some of the S-100 bus problems have been spearheaded by Howard Fullmer and George Morrow. The timing and DMA protocols adopted define processor-memory interactions in a manner which is more tolerant of non-8080 processors. All timing relationships are specified only with respect to the phase two ($\phi 2$) clock signal. Any device proclaiming itself to be a bus master, such as a DMA device as well as a processor must generate a set of 18 control signals as well as the address and data signals. Some DMA devices have failed to generate the full set of bus control signals and so have led to incompatibility problems with different memory boards which were relying on the presence of those signals. The 8224 system controller can be used by DMA devices and non-8080 processors to generate the control signals needed on the S-100 Bus. The adoption of standards for the bus will enhance its utility in the years to come and help preserve the investment which tens of thousands of hobbyists have made in their equipment.

The capability of the chip manufacturers to develop ROM chips to store specialized software also will act to force standards on higher level languages as they relate to microprocessors, development systems, operating systems, and the personal computing market. Such chips will provide BASIC, FORTRAN, PASCAL etc. interpreters and compilers at the selection of the user. Thus the advance in hardware technology acts to force upon us the standardization of relocatable code formats discussed earlier.

Packaging standardization for microprocessors has evolved to the predominant use of a 40 pin package. As longer word length processors are created, more pins may well be required unless extensive bus multiplexing is used. There is some tendency now to use pins on opposite diagonals for ground (pin 20) and power supply (pin 40); however, even that very limited pin-out standardization is not at all universal. Chip designers lay out the chip with all the logic capability they can, and only worry about the package pin-out at the end. If a pin-out standard is imposed for microprocessors, then the chip designer would have to consider the pin-out in the initial chip design, and may have to run traces for longer lengths than otherwise in order to reach the pads. This acts to reduce the available chip area for the device's logic functions. Thus there are significant semiconductor chip layout and utilization reasons to deter the formulation of a pin-out standard of μP packages.

A far more significant aspect of microprocessor architecture and design which would benefit from standardization right now is the "timing architecture," or precise sequence of signals that interface with external busses and support chips. In the practical sense of being able to use existing support chips and busses for a new or different microprocessor, the timing architecture is as (or more) important a conceptual issue as the register structure and logic capability. The dominant existing de facto busses have intrinsically been designed around the timing convention of the 8080. A timing standard for handshaking and control signals of microprocessors would be very useful in furthering the universality of busses, support chips, DMA devices, and controllers. Such a standard should have to be processor independent if at all possible. The work which our committee has undertaken on the S-100 bus timing is essentially committed to the same goals, and will probably be helpful in developing a standard timing architecture for microprocessors themselves. The committee has attempted to choose specific tasks which do not impact architecture in the usual sense, and the microprocessor manufacturers in Silicon Valley agree that our tasks would not.



The efforts by U.S. governmental agencies to impose standards on computers has resulted in the selection of a subset of existing architectures as being acceptable for future DOD procurement. Further, the instruction set of the AN/UYK 20 minicomputer is being established as the standard required instruction set for all future minicomputers. In addition, some governmental agency staffs active in standardization efforts believe that a standard bit pattern for the processor word is achievable for a given instruction. If such a requirement is imposed in the future, then the specific processor design and architecture will certainly be impacted. An instruction set standard can be dealt with by an assembler or cross-assembler; imposing a standard bit pattern in the word would require hardware or a chip design that would implement the standard. Whether the conventions that have been established by DOD for computers and minicomputers are forced downward on microprocessors remains to be seen.

The rapid changes in technology have led to multiple sources of software and hardware to create a system, as compared to a single source, bundled situation which has prevailed in the past. For the user to benefit from the remarkable advances in technological capability, it really is essential to formulate suitable software and hardware standards now.

Reflections in a pool of processors— An experience report on C.mmp/Hydra*

by WILLIAM A. WULF and SAMUEL P. HARBISON
Carnegie-Mellon University
Pittsburgh, Pennsylvania

INTRODUCTION

This paper is a frankly subjective reflection upon the successes and failures in a large research project—the construction of a multiprocessor computer, C.mmp, and its operating system, Hydra—by those most intimately involved in its design, construction, and use.

C.mmp and Hydra have now reached a sufficient level of maturity to establish themselves as useful and reliable computing resources at Carnegie-Mellon University. The user community has grown from primarily operating system implementors to include researchers in other operating systems and multiprocessors and casual or curious users interested in using the unique features of the system (e.g., the Algol 68 language, whose first implementation at CMU was on C.mmp.).

Some of the scientific results we originally hoped for have been published and are listed in the bibliography at the end of the paper. Other results will be published in the future as we observe the system under varied loads and over longer periods of time. In addition to these factual results, however, we have learned a number of things of a more subjective nature—things that we did right and, perhaps more importantly, things that we did wrong. We believe that many of these lessons are not unique to our project, and their presentation here will be valuable to the larger computer science community.

For those people unfamiliar with C.mmp and Hydra, we shall provide a brief overview of multiprocessor research at CMU, and some details about C.mmp, Hydra, and the goals we originally set for the research project. This information should serve as a general background against which our evaluation of the project can be cast. The interested reader will find more details in the bibliography.

Multiprocessor research at CMU

In late 1971 we at CMU decided to embark on a research program to explore multicomputer structures—especially those structures in which the several computers share a common address space. At the time it appeared to us that the economics of LSI technology would make multi-mini or multi-micro structures the architecture of choice for many medium- to large-scale applications. In addition to the economic arguments, there appeared to be many other advantages to such structures, including high availability, expansability, and so on.

Despite the fact that a number of multiprocessor computers had been built prior to 1971, relatively little of a scientific nature was known about them. Our goal was to explore a number of alternative multiprocessor designs, examining both the hardware and software issues, and to report on these explorations. To that end we undertook the design and construction of two multiprocessor systems, C.mmp and Cm*, and their associated software.

C.mmp, the subject of this paper, is a relatively straightforward multiprocessor. Begun in 1972, it connects 16 processors to a large shared memory (up to 32 megabytes) through a central crosspoint switch. The access time from any processor to any word of memory is identical. Cm*, started in 1975, replaces the crosspoint switch with a distributed, bus-oriented interconnection scheme between processor-memory pairs. In contrast to C.mmp, the access time from a Cm* processor to a word of memory can vary by an order of magnitude depending upon the particular processor and memory module involved. These two machines have quite different implications on the software which runs on them; between them we are able to explore many of the interesting issues of distributed processing.

C.mmp

C.mmp is a multiprocessor composed of 16 PDP-11's, 16 independent memory banks, a crosspoint switch which permits any processor to access any memory, and a typical complement of I/O equipment. A path through the switch is independently established for each memory request and up to 16 paths may exist simultaneously. An independent bus, the IP-bus, carries control signals from one processor to another; no data is carried by this bus. Collectively the 16 processors execute about 6 million instructions per second;

* The research described here was supported by the Defense Advanced Research Projects Agency (Contract: F44620-73-C-0074, monitored by the Air Force Office of Scientific Research). The views expressed are those of the authors.

the total memory bandwidth is about 500 million bits per second. In short, despite the fact that it is built from minicomputers, C.mmp is a large-scale machine.

The current configuration of C.mmp includes 5 PDP-11/20 processors (5 usec/instruction), 11 PDP-11/40 processors (2.5 usec/instruction), and 3 megabytes of shared memory (650 nsec core and 300 nsec semiconductor). All of the 11/40 processors have been modified to include writable microstores; thus we are able to tailor their instruction sets to specific applications. The cost of this configuration is roughly $600,000, of which $300,000 is the cost of processors, $200,000 is memory, and $100,000 is the switch, IP-bus and other special equipment. Of course, there is an additional cost associated with I/O devices.

Hydra

Hydra is the "kernel" of the operating system for C.mmp; it is not intended to provide most of the familiar features of an operating system (e.g., it does not provide files, a command language, or even a scheduler). Rather, Hydra provides an environment in which it is (intended to be) easy to write user-level programs that supply these familiar facilities. Hydra was designed in this kernal fashion in order to permit (and encourage) experimentation with features and policies appropriate to multiprocessors.

Hydra, which was a research project in its own right, uses a capability-based protection structure, a scheme in which only the possession of the appropriate kind of reference to an object (e.g., a file) grants access to that object. In order to allow user-level definition of operating system facilities, Hydra extends the basic capability scheme with the ability to define new types of objects and (protected) operations on these object types. Thus it is possible for a user to define new types of files, processes, message buffers, or whatever. These newly defined types share an equal status with those that already exist—which is another way of saying that Hydra attempts to preempt as few decisions as possible, thus allowing the users to tailor the system to their needs.

Software already built on top of Hydra in this manner includes file systems, directory systems, schedulers, and language processors (for Algol 68, L*, and a flexible command language).

Project goals

Two general goals influenced both the hardware and the software design from the outset. The C.mmp/Hydra system was envisioned as both *symmetric* and *general purpose*. By *symmetric* we mean that replicated components, such as processors, are treated as an anonymous pool; no one of them is special in any sense. By *general purpose* we simply mean that we did not intend to cater to *only* those programs which need a multiprocessor; the multiprocessor character of the machine is used to improve throughput across a set of independent jobs as well as to multiprocess single jobs. Both the hardware and software were designed with these goals in mind.

The *symmetry* goal is manifest in a number of ways. At the hardware level, for example, an interprocessor interrupt mechanism was designed so that every processor could interrupt every other processor (including itself) with equal ease. At the software level there is no "master-slave" relation among the processors—any processor may execute any part of the operating system at any time (subject, of course, to mutual exclusion in accessing shared data structures). At the user level, a job may execute on any processor, and indeed may switch from one processor to another many times during its execution.

The impact of the *general purpose* assumption is more subtle; it implies that we have to provide a broader range of software than would be expected if our focus had been more narrow. It also implies that optimizations to a specialized problem domain should not be made in the operating system. Some of the specific effects of this goal will be found later in the evaluations.

Performance evaluation tools

Many of our evaluations of C.mmp are based on data obtained from a number of tools designed to measure system performance. Although not one of our greatest successes, we think these tools are important enough to present here. We have three measurement tools: a script driver, a hardware monitor, and a kernel tracer.

The Script Driver is a program which can place a measured load on the system by simulating a number of users at terminals performing various tasks. This known load can make the interpretation of performance measurements much easier.

The Hardware Monitor is a device built at CMU which can monitor in real time the signals on a PDP-11's bus. The Monitor is very useful in measuring the activity of a single C.mmp processor, and for recording the activity of small portions of the operating system. It is less effective in measuring total system performance.

The Kernel Tracer, the most commonly used tool, is built into the Hydra kernel. It allows selected operating system events (e.g., blocking on semaphores, context swaps) to be recorded while applications are running. The accumulated data can be processed off-line to give a detailed record of what was happening on each processor. Naturally, the use of the tracer slows down the entire system, but this obvious point doesn't really seem to matter in practice.

The importance of these tools should not be underestimated. In any system as complex as an operating system, design decisions are often based on intuitive assumptions of performance tradeoffs. Without accurate measurements, these design assumptions cannot be verified. Certainly we found that some of our assumptions were wrong, causing us to redesign several parts of Hydra.

Format of the paper

The body of this paper is a highly edited report of a meeting called specifically to evaluate the C.mmp/Hydra

project. The attendees were representatives of the various groups involved in the design, implementation, and use of C.mmp and Hydra; hardware designers, operating system implementors, those doing performance evaluation, and four major users. In all, sixteen persons attended, the maximum number we felt could interact productively.

The purpose of the meeting was to solicit the opinions of the participants concerning the nature of our successes and failures. We had also solicited written opinions from a wider group—in fact, just about everyone who has had anything to do with C.mmp and Hydra. The participants knew, of course, that the results would be reported in this paper.

The meeting and written responses produced over a hundred distinct comments. To organize these in a coherent fashion we asked the participants to decide upon our five greatest successes and five greatest failures. With some exceptions the comments have been organized under these headings; the participants' comments have been indented to separate them from background information and summary comments.

Any paper that sets out to reflect upon the successes and failures of a research project is potentially self-serving. We were extremely conscious of that danger and have attempted, through the format of the meeting and the editing of its transcript, to construct the paper in a manner which minimizes this effect. Either our initial fear of being self-serving was groundless, or the format chosen worked extremely well. We shall let the readers judge for themselves, but we feel that the result has been a reasonably objective, well-balanced view of the C.mmp/Hydra project.

OUR GREATEST SUCCESSES AND FAILURES

We shall begin this report with what, in fact, happened last at the meeting—a listing of our most notable accomplishments and mistakes. This list was created after all opinions had been expressed, thus the participants had the opportunity to hear the opinions of the others before deciding upon the content of the list. To keep the discussion crisp we arbitrarily chose to limit each list to five items. Surprisingly (to the editors at least), despite the differing interests of the participants there was essentially complete agreement on the items to be included on each list.

Our notable accomplishments:

- We constructed a cost-effective, symmetric multiprocessor.
- We provided, in Hydra, a capability-based protection system which allows the construction of operating system facilities as normal user programs.
- We were able to distribute the Hydra kernel symmetrically over all processors.
- We provided successful mechanisms for the detection of, and recovery from, software and hardware errors.
- We used an effective methodology for constructing the Hydra kernel.

Our notable disappointments:

- The hardware is less reliable than we would like.
- The small address of the PDP-11 has a large negative impact on program structure and performance.
- We are unable to partition C.mmp into disjoint systems.
- We did not put enough human-engineering into the software interface to the user.
- We did not give enough attention to project management.

Neither our successes nor failures are, of course, unqualified, and the story behind each is littered with smaller successes and mistakes. Moreover, there are dependencies between the things that went well and those that didn't; the fact that we have a running 16-processor system must be tempered, for example, by a poorer-than-expected reliability record. The reliability record, on the other hand, led us to greater concern for software structures that detect and survive hardware malfunction—and we count those structures among our most important accomplishments. For all these reasons, while we have used the success/failure list to organize the paper, one should not expect all the points listed under a "success" to be positive in nature. On the contrary, we believe it important to expose the contributing events, both positive and negative, as well as the major points listed here.

With that introduction then, here is the report of the meeting.

THE SUCCESSES

A cost-effective multiprocessor

C.mmp's design goals included speed, simplicity, and the use of as many commercially-available components as possible. Because C.mmp is a unique computer some critical parts had to be designed and built especially for the project. While this was a burden, it did give us maximum freedom in the design of these critical components, including the crosspoint switch, the IP-bus, and the processor modifications for memory relocation. These were all built by the CMU Computer Science Department Engineering Laboratory.

- The basic design goals have been justified by experience, with speed having been the least important emphasis.
- CMU-built hardware is not a large proportion of the total system cost.
- The crosspoint switch is very reliable, and fast enough.
- The use of immediately available components was a major factor in getting C.mmp built as fast as we did, but it limited us in taking advantage of technology which developed in succeeding years.

We were especially happy about the evaluation of the crosspoint switch, which many people thought would be C.mmp's Achilles' heel. In retrospect we think we were too concerned about raw speed in the design of the switch and

memory; as it turns out, most applications are sped up by decomposing their algorithms to use the multiprocessor structure, not by executing on a processor with short memory access times.

The comments at the meeting did reflect some specific complaints about the hardware, several of which we later decided were significant enough to be listed as some of our major disappointments. Many of these stemmed from our choice of a processor for C.mmp. In 1971, only the PDP-11/20 minicomputer met our requirements. In 1974 we decided to take advantage of technology advances and use the new, faster PDP-11/40 processors to complete C.mmp. One feature of the PDP-11 architecture which might be expected to impact the goal of symmetry for C.mmp is the close association of an I/O device with exactly one processor.

The PDP-11 processors required more modifications than we expected to ensure the security of the operating system.

The PDP-11's 16-bit address is too small for many interesting applications.

Having to supporting two PDP-11 models complicated the development of the processor modifications and the operating system. It would have been better to have had a single processor model, regardless of its speed.

Having I/O devices bound to particular processors made it difficult to move a device from a malfunctioning processor to a good one, but device utilization was not otherwise sacrificed.

Perhaps more than anything else, our experience with the PDP-11 has given us a much clearer idea about what features are really important in choosing a processor, and which are not. Our consensus is that speed is not very important, for reasons already cited in conjunction with the crosspoint switch. Reliability is very important, but we found that much can be done in software to increase the overall system reliability, as long as the hardware has some basic error-detection mechanisms. (Our own approach to this is described later.) The address size is important because if it is too small for the expected applications, the ensuing problems cannot be completely overcome by software. The PDP-11 I/O architecture is an example of a feature that turned out to be unimportant because it could be completely hidden from users by software.

At a higher level, users of C.mmp seemed satisfied with the overall system performance.

Our ability to support multiprocess algorithms is well established by the performance of the many applications on C.mmp.

We have successfully supported user processes that require real-time response, although this was not one of our major goals.

At the end of the paper we will give some performance figures for an application which runs on several CMU computers, including C.mmp.

Most often cited criticisms of the system were:

Interaction with operating system facilities, in or out of the kernel, is accompanied by a high overhead.

The most serious obstacle to rapid execution of large systems is the limitation imposed on programming by the small PDP-11 address.

Memory contention significantly degrades performance when many processes are accessing the same memory page. This is usually caused by the processes sharing the same code pages.

Memory contention is very serious when using high-performance I/O devices which depend on rapid access to memory during transfers.

The performance bottlenecks are due to a combination of avoidable and unavoidable factors. We were initially distressed at the high operating system overhead (it takes about 500 microseconds to enter and exit the kernel), but we attribute most of it to a lack of experience with the fairly complex features we wished to implement. We are confident that the overhead is not an inevitable result of our protection mechanisms, nor is it due to the hardware design.

Memory contention, caused by several processors trying to access the same memory simultaneously, was a performance concern from the outset of the project. Our simulation studies indicated that its effect would be minimal, but in practice several circumstances conspired to make the problem significant. First, typical large multiprocess applications tend to share the same code among all processes, and this greatly increases the probability of accesses to the same memory. Second, the installation of per-processor caches, which were to handle this code-reference problem, has been delayed due to various resource shortages. Finally, we found that devices such as our disks and drums could not tolerate the long memory access times characteristic of periods of high contention. A software solution to this problem had to be implemented.

The small address problem is serious for large applications which cannot fit within the 64K address space on the PDP-11. Although we could not have avoided this problem, we were guilty of underestimating its significance for the applications which were to run on C.mmp. The problem is considered in more detail later in this paper.

Protected subsystems

In Hydra, the construction of operating system facilities outside the kernel is centered around an abstraction called a *protected subsystem*. A subsystem is, in its basic form, a new object type combined with a set of procedures which operate on objects of that type.

Our experience derives from over twenty working subsystems implementing schedulers (*Policy Modules* in Hydra terminology), files, directories, an I/O device allocator, and a host of other traditional operating system facilities. As

software development continued by diverse users, we were curious to see whether all the required software could be built within the subsystem abstraction, whether such development could be done easily and quickly, and whether the resulting facilities could be easily merged into the user environment.

> The protected subsystems abstraction is very powerful in designing operating system software in a capability environment.
>
> It is easy to design subsystems which are easy to use and which are protected from any interference from software outside the subsystem.
>
> The subsystem structure makes it easy to provide several coexisting and competing facilities.
>
> The subsystem structure is useful for isolating facilities under development or being debugged.
>
> New subsystems are easily incorporated into the standard system.

We think the subsystem concept in Hydra is as useful as the closely-related notion of extended data types has been in the field of programming languages. Part of the original motivation for the subsystem concept was our desire to allow alternate solutions to problems which we could not foresee in a multiprocessor environment. However, we found that subsystems are also very useful in debugging versions of "standard" systems without interfering with users.

Many people at the meeting were critical of the failure to follow up the subsystem design with the software tools which would encourage building subsystems in this new environment.

> Subsystem construction still suffers from being ad hoc, there being inadequate software support for managing the programs, data structures, and documentation which comprise the subsystem.
>
> The development of system software (subsystems) by many different people makes it more difficult to impose any standardization.
>
> Subsystems are less likely to be successful when they attempt to implement traditional (non-capability) systems in traditional ways.

These problems are the result of our not giving the user environment outside the kernel as much attention as we gave the Hydra kernel itself. We consider it one of our worst mistakes and will discuss it more later in the paper.

Scheduling is an example of a traditional operating system function which, in Hydra, is partially implemented outside the kernel by a subsystem called the Policy Module (PM). We thought that providing scheduling policy outside the kernel would allow us to experiment with different specialized strategies for scheduling cooperating processes.

The first Policy Module is a distinguished subsystem for several reasons. First, it was one of the first subsystems built outside the kernel and exhibits many of the mistakes of any first attempt. Second, it is a particularly nice example of our ability to build operating system facilities outside the kernel. Finally, it interacts very closely with the kernel, so the efficiency of the kernel interface is emphasized.

The first Policy Module was operational from 1974 through May, 1977. Our basic evaluation at the meeting was that

> The first Policy Module adequately demonstrated that traditional policy decisions could be made outside the kernel.

In spite of this, many people noted flaws in the implementation which were glossed over in our rush to see if the PM would work.

> Insufficient attention was paid to reliability and throughput in the Policy Module.
>
> The PM-kernel interface turned out to be more complex than we had anticipated.
>
> We included things in the kernel facilities which logically belonged outside; this acted to complicate the kernel interface. [*For efficiency reasons, we implemented in the kernel some facilities which should have been outside according to our philosophy.*

Hence,

> The construction of Policy Modules was not as easy as we had imagined before we actually tried it.

Because we expected a PM to incorporate specific knowledge about the processes it was scheduling, we anticipated having many PM's simultaneously scheduling different sets of processes. Indeed, having several PM's run at the same time was no problem, but again the performance left something to be desired.

> To support multiple Policy Modules, more facilities are needed in the kernel to ensure a fair allocation of processor and memory resources to each Policy Module.

We began to build a second version of the Policy Module almost as soon as the deficiencies in the first were recognized. This design proceeded in parallel with performance improvements to the first PM, and in fact we were running both PM's simultaneously for a short time.

The distributed operating system

Hydra was designed with no master-slave relationship among processors. With the exception of the lowest level of I/O device support, all system tasks may run on any and all processors. An immediate result of this is that we expected

a high degree of parallelism in Hydra and the corresponding need for effective synchronization methods.

There are two notable aspects to our approach to synchronization. First, we decided to synchronize on data rather than code. Every data structure which can be accessed by more than one processor is provided with a lock or semaphore which is used to ensure mutual exclusion.

Second, we provided a range of synchronization primitives, from very fast "locks" to much slower "semaphores." The tradeoff here is the overhead needed to P or V the lock or semaphore against the resources which will be tied up by a process waiting to pass the lock or semaphore. Small data structures which are locked for short periods of time (order 300 microseconds) use locks, which involve a very small overhead (approximately four instructions) when the process does not block. Large data structures, or data structures whose processing may be interrupted for long periods of time (as when waiting for I/O) use semaphores, which tie up fewer resources when blocking is necessary.

The simple, symmetric hardware has permitted a much simpler operating system design.

Hydra hides the processor-device correspondence so well that most of Hydra, and all the software at the user level, is unaware of the actual location of I/O devices.

The symmetric distribution of the operating system has been an unqualified success. We are able to achieve a high degree of parallelism within Hydra, and the system is insensitive about the number of processors available.

The use of asynchronous processes ("demons") to implement system functions resulted in simpler designs and improved performance.

In providing synchronization within the kernel, we believe we profited by locking data structures rather than code.

Our decision to provide several types of synchronization mechanisms gave us much design flexibility.

The natural synchronization primitives and our conscious and constant commitment to a high degree of parallelism has resulted in our encountering few software bugs caused by inadequate synchronization.

We have found that the use of demons to absorb much of the system work load outside the normal computational stream has simplified much of Hydra's design. We might not have used this technique if we did not have so much confidence in our synchronization techniques and our ability to achieve a high degree of parallelism.

Coverage of hardware and software errors

There are times when clouds do have silver linings. From the earliest days of the project we had to contend with unreliable hardware and our own software mistakes; moreover, we could not afford a 24 hour/day operator to reload the system after each crash. Thus we were forced to consider the general problems of software detection and recovery from errors—whether they be hardware or software induced.

When an error is detected by Hydra, we try to answer a number of questions. What was the exact error? Can we tell if it is due to a hardware or software malfunction? If hardware, is the problem repeatable or transient? Have any critical data structures been damaged? If so, can the damage be repaired? Can we eliminate a piece of malfunctioning (or just suspicious) hardware and still run? In all cases, our aim is to keep the system running with as much functionality as possible.

Our probability of detecting an error soon after it has occurred is increased by building error-detection mechanisms into the hardware and software. The CMU-built memory relocation units implement parity checking on every memory byte and on the address bus through the crosspoint switch. Software modules employ redundant representation and other techniques to try to limit the propagation of errors not detected by the hardware.

Recovery mechanisms invoked by the detection of any error employ a "suspect-monitor" paradigm to ensure that a failure in the recovery processor may be detected cleanly. Two processors are always involved; one, the *suspect,* attempts to record the system state at the time of the error; the other, the *monitor,* watches the suspect and assumes control if the suspect is unable to finish. The suspect is always the processor on which the error occurred. The monitor is selected at random from all other processors. There are a number of steps which can be taken during a recovery action depending on the type of error, including removing processors or memories from the system and producing extensive crash dumps for later off-line analysis.

The fault tolerance built into some kernel modules resulted in making them among the most reliable in the system—more reliable than other modules coded by the same programmer without using such techniques.

The software facilities for detecting software and hardware errors and restarting the system automatically have been a big success.

Similar facilities in user software are beginning to be developed and show much promise in improving overall system reliability.

Even though we are proud of our current error-handling mechanisms, we know that system needs more work in this area, particularly in the area of supplying policies to determine which mechanisms should be invoked for different types of errors. While it is true that we can recover from virtually any error by initiating an automatic reloading of the operating system, this is a drastic action we would like to use only in the case of truly catastrophic errors. Unfortunately, the difficulty in pinpointing the exact location of some hardware errors and the difficulty in verifying the consistency of the complex capability data structure has resulted in our classifying almost all errors as "cata-

strophic" in this sense. We are in the midst of redesigning both hardware and software to correct these deficiencies.

Software development methodology

Our initial goals for the Hydra implementation did not explicitly include the notion of exploring a software engineering methodology. Nevertheless, we used a method based on Parnas' "modular decomposition"* and it worked quite well; indeed many of us believe that without it the project would not have succeeded.

The methodology used caused us to divide the units of work (programming tasks) along the lines of the major data structures in the system. A module (and hence a programmer) was responsible for the representation of, and all operations on, a data structure. No one other than the responsible programmer had access to knowledge concerning the implementation details.

Because methodology *per se* was not our major goal we were not fanatical about enforcing the methodology, and were often less precise about the specifications than we might have been. Both the positive and negative aspects of this informal approach are reflected in the following remarks:

> We believe that it is a measure of the success of the modular implementation of the kernel that one full-time programmer can maintain this program which comprises 2000 (listing) pages of source code.
>
> The independent implementation of the modules in Hydra resulted in a lack of any uniform coding style and in some duplicated effort in interfacing to the underlying hardware. The effect was not very serious since all the implementors were highly talented, exhibiting differences in style rather than quality.
>
> Because modules were implemented independently, no one initially had a detailed knowledge of the entire system. This made debugging more difficult and resulted in a difficult transition when Hydra began to be maintained by a single programmer who was not part of the original implementation team.
>
> Coding of the kernel began quickly after the initial design. Some think too quickly.
>
> Loose management coupled with the modularization technique worked well except in promoting a standardization of coding styles.
>
> Information hiding as a modularization technique resulted in coding situations in which information necessary to make a decision was not available.
>
> As Hydra developed and was modified, the original, clean modularization began to break down as new features were added and performance bottlenecks removed.

* Parnas, "On the Criteria to be Used in Decomposing Systems into Modules," *CACM*, 15, 12, pp. 1053-1058, 1972.

We still think the modular decomposition methodology is extremely good for structuring large systems. In our experience, breakdown of the modular structure occurs mainly when programmers in the midst of debugging adapt "quick and dirty" solutions which do not preserve modularity.

All but a very small part of Hydra is written in a high-level implementation language, Bliss-11. There seems to be no question that it was possible, indeed advantageous, to write the kernel in Bliss, but there were problems. The Bliss-11 compiler was developed only shortly before the kernel was begun and was an independent research project (investigating compiler optimization techniques). There was some initial friction between the two groups, but both appear to have benefited in the long run.

> The Bliss-11 compiler was designed to compile a slightly modified version of the Bliss-10 language into very compact PDP-11 code. This it does.
>
> The implementors of the Hydra kernel were, and continue to be, a major influence on the addition of new features to Bliss-11.
>
> The facilities of the Bliss-11 language and compiler had a significant influence on the coding of Hydra.
>
> Some of us believe that Hydra could not have been written in this environment without a language of Bliss's caliber.
>
> Bliss-11 preceded Hydra by too short a time. The unreliability of the compiler during its first year of use hindered kernel development.
>
> Compatibility between Bliss-11 and Hydra was a problem. Changes in Bliss-11 sometimes had unfortunate consequences on Hydra code.

We think these comments reflect the close interdependence between a large programming project (Hydra) and the software engineering tools it uses (Bliss-11). Bliss was in a real sense critical to Hydra's development. The need to debug both Bliss and Hydra simultaneously was a necessary burden.

A common measure, albeit a crude one, of a methodology is the productivity of the programmers which used the methodology. By that measure our development strategy worked very well; the average productivity has been about 20 instructions per man-day for kernel code (the typical industrial average for similar code is 5-7 instructions per man-day).

THE FAILURES

Hardware reliability

Hardware (un)reliability was our largest day-to-day disappointment at the time the evaluation meeting took place. The aggregate mean-time-between-failure (MTBF) of C.mmp/Hydra fluctuated between two to six hours, where a failure is defined to be any situation which triggers the recovery actions described earlier. About two-thirds of the failures were directly attributable to hardware problems.

There is insufficient fault detection built into the hardware.

We found the PDP-11 UNIBUS to be especially noisy and error-prone.

Our paging drums were chosen for their predicted performance, but their reliability was so poor that performance was often a moot point.

The crosspoint switch design is too trusting of other components; it can be hung by malfunctioning memories or processors. [*This almost never happens, but when it does automatic recovery is impossible.*]

We made a serious error in not writing good diagnostics for the hardware. The software developers should have written such programs for the hardware.

In our experience, diagnostics written by the hardware group often did not test components under the type of load generated by Hydra, resulting in much finger-pointing between groups. Faulty hardware is often kept in the user system because only Hydra can provoke and pinpoint errors.

Several components of the system have gone through several development cycles, mostly to improve the handling of exceptional conditions, but we are basically limited by the capabilities of the PDP-11 and its UNIBUS. There appear to be two flaws in many of the off-the-shelf components. One of these was mentioned during the meeting: the lack of mutual suspicion. There are a number of ways in which the entire system can be made to fail if one inessential component does not operate according to specifications. The other flaw was not mentioned: the failure to *contain* errors. Once an error has been detected the goal should be to make absolutely sure that the damage won't spread. Many of the standard components, unfortunately, will "complete" an operation even when an error is known to exist; in completing the operation they destroy data, thus making the error unrecoverable.

There is some good news to report, however. Following the meeting, increased emphasis was given to hardware maintenance. As this paper is written (January 1978) our MTBF has increased to about ten hours and many of the hardware problems seem to be settling out.

The small address space problem

The PDP-11 is a 16-bit minicomputer; of particular interest is the fact that this restricts all addresses generated by a user program to be 16 bits long. These 16 bits can be used to address no more than 64K bytes of memory. We refer to this limitation as the "small address problem", or SAP.

Although we were initially aware that the operating system would have to provide some sort of facility for allowing a user to address more than this amount of memory, we did not appreciate how restrictive the 16-bit limitation would be or to what extent circumventing it would affect performance. Our initial impression was that the 16-bit limitation would be offset by the ability to create multiprocess programs—that the typical program organization would be a larger number of processes, each addressing a smaller amount of memory. That impression turned out to be false, as is reflected in some of the comments made at the meeting:

Our initial prediction that programs would be implemented as small subsystems using less than 64K was wrong.

Multiprocess algorithms do not always produce small programs.

Even though programmers are writing programs which execute on PDP-11's, their tasks are CDC 6600-size.

There is nothing good to say about this problem other than that we were pretty much forced into it.

To circumvent this problem, Hydra provides a facility, supported by the hardware, to divide the address space into 8 pieces, each of which is called a "page." The user is permitted to have an indefinitely large number of pages, but to address only 8 of them at any instant. Operating system facilities are provided to allow the user to dynamically designate which of his pages are to be addressable; he does this by associating a page with one of the 8 "relocation registers" maintained by the hardware. Thus, except that the cost of loading is larger, the addressing scheme is very similar to the use of "base registers" on 360-370 style machines. We have found this facility, however, to be less than ideal.

Page boundaries are absolute, and the programmer must always be aware of them.

The problem is in addressing data. There are easy solutions to addressing code segments.

More relocation registers and a smaller page size would reduce but not eliminate the problem.

We believe the problem would exist even if making pages addressable required no overhead.

Because of the performance penalties associated with managing the address space, the inconvenience cannot be hidden from the user through a high-level language:

L*'s ability to allow access to large amounts of memory has been hindered by the short PDP-11 address. [*L* is a list processing language used for the implementation of large systems.*]

It must be emphasized that not *all* programs are affected by the small address space problem:

In practice, most subsystems have no problem fitting into 64K.

Our failure on the small address problem was really one of misappreciating the way in which the machine would

actually be used. The remark above to the effect that many tasks are 6600-size is a telling one. The machine is comparable in size to a 6600 and people want to use it that way. Big problems often imply big data and we failed to appreciate that during the initial design.

The partitionable system

When we first considered the possibility of building a multiprocessor in 1971, the ability to partition it into several disjoint subsystems was on our list of advantages for such architectures. While we are able to partition processors and memory, we are not able to run Hydra in more than one partition.

C.mmp can be partitioned in such a way that some processors and memories can undergo maintenance and run stand-alone diagnostics without interfering with the larger partition running the operating system.

The primary obstacle to running the operating system in two partitions is the money required to provide each partition with an adequate complement of I/O devices and memory.

We do not know how to provide meaningful communication between the capability structures of the two operating systems.

The principal effect of the failure to meet this goal has been that we must allocate disjoint time for users, hardware maintenance, and operating system testing. At present 28 hours each week are reserved for maintenance. This partitioning has been very inconvenient for all concerned, and has certainly impeded progress on several occasions. Yet it seems clear that we have been unwilling to spend the money necessary to solve the problem—thus it seems safe to conclude that the inconvenience has not been debilitating.

(The lack of) human engineering

As we have mentioned in several contexts previously, the human interface to the C.mmp/Hydra system is not well designed. To some extent this resulted from the novelty of the underlying system structure (we couldn't anticipate some of the kinds of facilities that would be needed by users of either a capability-based or a multiprocessor system). To a large extent, however, the failure seems to have been one of having concentrated on the new, innovative aspects of the system and ignoring more mundane issues.

There is a lack of human engineering in the operating system software which interacts directly with a user sitting at a terminal.

It is difficult to pick up the minimal knowledge needed to know how to do useful things at a terminal.

New users tend to have bad first impressions of the system.

We did not realize how much work was required to make a smooth user interface and so did not allocate enough resources for it.

We suspect the user environment would have received more work had the kernel implementors had to use it during their software development. (All kernel development and maintenance has been done on the PDP-10 computer, which has the Bliss-11 compiler and a linker for C.mmp.)

One particular aspect of the human interface is especially interesting—the command language. It seems to be an almost universal phenomenon that people don't like whatever command language they have used in the past. We were no exception. Thus, rather than modeling our command language on any existing one, we chose to strike out in another direction. In particular, we chose to make the command language a (modest) interactive programming language—with declarations of variables, assignments, conditional and looping control constructs, macros, and so on. The power of this approach seems unquestionable, as is reflected by the following remarks. The remarkable thing (to the editors) is the lack of negative remarks during the meeting; the command language usually comes under heavy attack on other occasions.

The Command Language is much more flexible and powerful than the command scanners found on most systems.

The concept of the Command Language as a programming language was good.

The Command Language user on C.mmp is unique in having complete access to the Hydra environment. Subsystems can almost be implemented directly in the Command Language.

Error reporting by the Command Language is poor.

Another aspect of the human interface is the (lack of a) spectrum of programming languages:

C.mmp lacks the wide range of languages available on conventional systems.

The L* system provides its users with a complete environment compatible with that provided on the PDP-10 by its version of L*.

The L* environment does not seem conducive to the construction of subsystems.

The Algol 68 implementation on C.mmp gives users access to the multiprocess capabilities of C.mmp, but does not yet provide access to capabilities or the Hydra protection environment.

The fact that most subsystem development takes place partially on C.mmp and partially on the PDP-10's (which

have Bliss-11 compilers) is not a severe hindrance now that smooth communication facilities exist between the machines.

It is interesting (to the editors) that the word "baroque" was not used during the meeting; in other contexts it often is. Several features of Hydra and its subsystems do exhibit "second-system-itis". There are things which are more general, and more complicated, than necessary.

Project management

The C.mmp/Hydra project was not a large project by most standards; there were never more than about 15 people, mostly students, working on the project at any one time. Nevertheless we made a number of errors which can only be classified as failures in the management of the project; taken together, these errors constitute one of our largest failures.

Among our errors is a classic! Because the hardware and Hydra structures were new and exciting, we tended to focus on them to the exclusion of the more mundane things which also determine the ultimate utility of any system. This point recurred in many of the points raised at the meeting:

The manpower allocated to the Policy Module was inadequate. In fact this was true of all software outside the kernel.

The failure to stress reliability and performance in the first PM was a mistake.

The user environment was ignored at first because of our natural preoccupation with the Hydra kernel and the research problems it embodied.

We underestimated how much work would be involved in constructing the user environment.

We have a much better idea now about the proper structure (or at least an adequate one) of the user environment than we did when we began building the first subsystems. Implementing basic concepts such as "jobs" and "terminals" in nonpriviledged software has subtle design and reliability implications which we are just now appreciating.

The management style used throughout the project was informal. There were very few memos, formal design reviews, or the other mechanisms of tight management control. In most ways this felt appropriate to the academic environment and the high caliber of the individuals involved. It led to a number of problems, however, and the consensus of the meeting was that the management had been too loose. This is especially evident in the comments relating to a lack of formal specifications and the lack of uniform documentation and coding standards.

The fact that the Hydra implementors did not have to use C.mmp for software development contributed to the neglect of the user environment.

The lack of detailed hardware specifications hindered the parallel development of hardware and software but not the end result.

Software was occasionally developed which took advantage of unspecified "features" of the hardware, making them difficult to change.

Loose management coupled with the modularization technique worked well except in forcing standardization of coding styles.

We should not have depended on graduate students for complete software development for so long. Graduate students cannot keep deadlines reliably and are not tied to the project. [*Furthermore, we feel that Ph.D. students should not spend an inordinate amount of time doing the standard programming chores which characterize any attempt to bring up a complete operating system.*]

Another class of management errors relates to what might be termed "public relations." Being academics, we instinctively react somewhat negatively to the "attention-getting" aspect of PR, forgetting that its "information-providing" function is absolutely necessary. In a number of ways we failed to make information available publicly.

Our problem is basically public relations—performance measurements indicate we have a winner on our hands.

The lack of a smooth user environment was a deterrent to new users which could form the foundation of a happy and vocal user community.

Since Hydra was not easily accessible to people outside the department, we could not adopt a "try it and see" attitude.

Documentation is needed to encourage use internally and generate credibility externally.

A DATA SAMPLER

The previous section concludes our report of the meeting. Since the body of the report contains many subjective and unsubstantiated comments, we decided to include a few examples of the kinds of data on which these comments are based. We have chosen two examples: (1) a study of the effect of the small address problem on a specific user program, and (2) a study of the contention for locks in the Hydra kernel.

A study of the small address problem

The program used in this study of the SAP is HARPY. HARPY is a speech-understanding system which has been implemented on all of the departments major computers: C.mmp, a stand-alone PDP-11 running under UNIX, and the PDP-10 (both KA10, circa 1967, and KL10, circa 1976, processors are available in the department). Since HARPY ex-

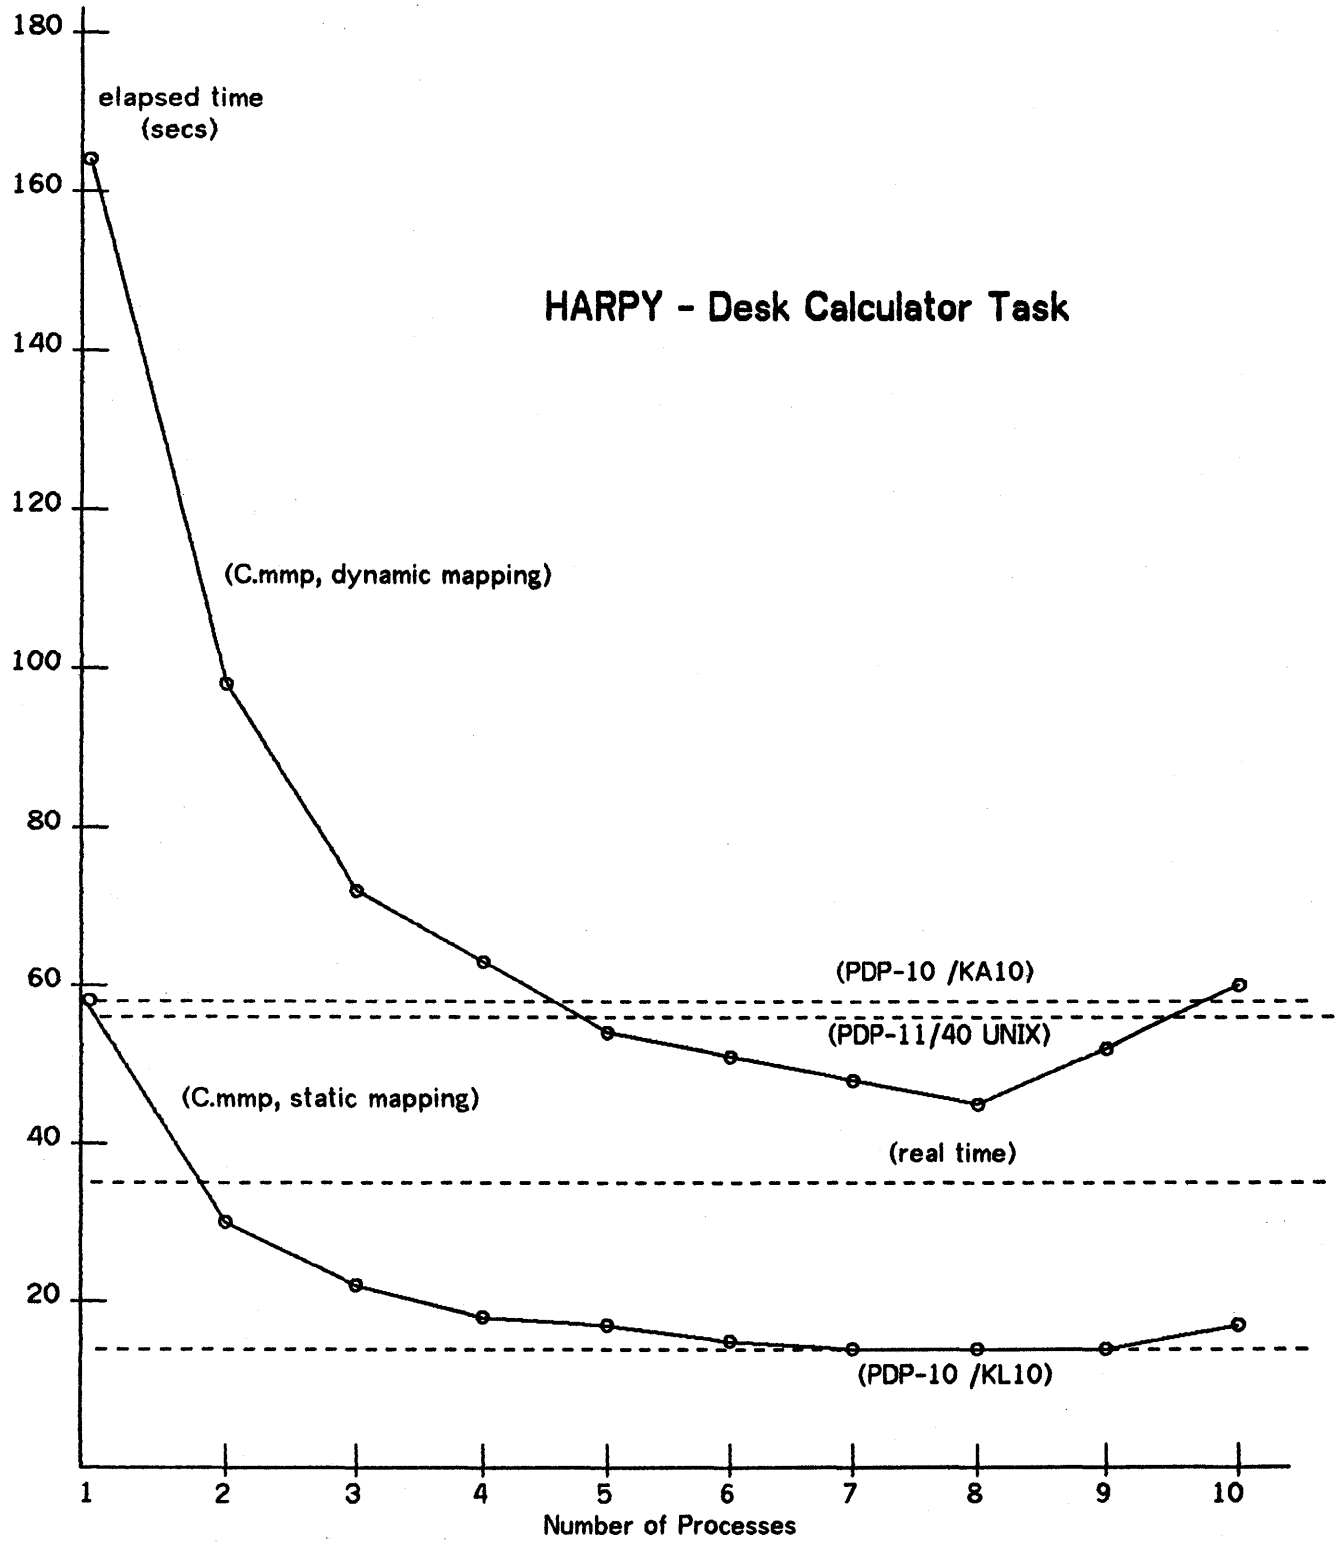

Figure 1—A look at the small address problem

ists on all these machines, it makes a convenient benchmark. (We should point out that HARPY is not necessarily the best application for C.mmp, nor are the HARPY implementations on C.mmp known to be optimal.)

Figure 1 summarizes the data obtained from a series of experiments with HARPY working on a rather small task, namely a voice-input desk calculator that has a 37 word vocabulary.

The horizontal dashed lines represent the performance of single-process implementations of HARPY on the departments uniprocessors. The solid curves represent the performance of two implementations on C.mmp, both of which can utilize any number of processes.

The two HARPY versions on C.mmp differ in their assumptions about the addressability of data. The "static mapping" version knows that all of its data is always addressable, while the "dynamic mapping" version expects to have to do some mapping of relocation registers in order to address the data. In this second version, it must be realized that, in fact, all the data is addressable, and thus no operating system overhead is involved. (The overhead is HARPY checking to see if relocation is necessary—it never is.)

This type of data dramatically illustrates the effect of the SAP on performance—it costs nearly a factor of three in this example. The effect on programming difficulty is at least as great, but is not so easy to illustrate.

Note that the one-process, static mapping version of HARPY runs very nearly as fast as the version running under UNIX, even though the C.mmp version has all the necessary mechanisms for multiprocessing. We think this indicates that the synchronization primitives (spinlocks in shared memory) do not contribute much overhead in this application.

Also note that little improvement in performance is seen beyond three or four processes. This is simply due to a lack of work to do—the small vocabulary simply isn't complicated enough to keep the processors busy. On larger vocabularies we typically see noticeable improvement out to eight processes. The upturn in the curves towards the end is due to the fact that all the faster PDP-11/40 processors are in use. As soon as one PDP-11/20 is used, the whole assemblage of processes slows down. This is because the particular decomposition of the algorithm limits the speed to that of the slowest process.

A study of kernel lock contention

One of the largest potential bottlenecks in a distributed operating system is contention for locks on shared data structures. The hardware monitor has been used to study this; the types of results obtained are shown in Figure 2.

In this study, three programs with seemingly different demands on the system were run while the hardware monitor measured the activity on one processor. The data is illustrative only, since no claim is made that the programs in any way represented a "typical" system load.

The principle result is that it seems we spend consistently less than 1 percent of the time blocked on locks. We do not yet have any measurement of the time lost due to blocking on semaphores.

Static	Program 1	2	3
Total time of measurement (millis)	17393	32924	20255
Number of different locks detected	53	79	181
Average time inside a critical section (micros)	279	378	279
Total number of lock operations	2955	504	4360
Percent of locks which blocked	5.5	11.7	6.1
Percent of time spent in kernel code	61.8	16.9	37.7
Percent of time spent in blocked state	.29	.83	.74

Figure 2—A study of kernel lock contention

CONCLUSIONS

The C.mmp/Hydra project has reached the point at which many of its most interesting and important results will emerge. With a growing user community, increasing reliability and a smoother user interface, we are in a position to gether data on various aspects of system performance under real loads. This data will augment that already collected on isolated algorithms to provide a comprehensive picture of C.mmp/Hydra performance. Along the way to constructing the current system we managed, in our opinion, to do some things well and some things not so well. This paper has been our attempt to report those opinions in the hope that others may benefit from our experiences.

ACKNOWLEDGMENTS

A large fraction of the faculty and staff of the Computer Science Department at CMU have been involved with C.mmp and Hydra over the past five years—as designer/implementors, as users, or as constructive critics. We are deeply indebted to all of them. We are especially indebted, however, to those who participated in the meeting that is reported here:

Hardware:	Bill Broadley, Jim Teter
Hydra:	Sam Harbison, Dave Jefferson, Roy Levin, Hank Mashburn, Fred Pollack
Non-kernel OS:	Bill Corwin, Rick Gumpertz
Performance Evaluation:	Sam Fuller
Major Users:	Anita Jones, Bruce Leverett, Pete Oleinick, George Robertson
Others:	Joe Newcomer, Bill Wulf

We would also like to thank Guy Almes, Peter Schwarz, and the NCC '78 referees for their helpful suggestions for this paper.

C.mmp/Hydra BIBLIOGRAPHY

This bibliography includes references to papers, articles, and theses related to the design, development, and measurement of C.mmp and Hydra. There are numerous internal documents and memos which are not included.

A design methodology for user oriented computer systems

by C. V. RAMAMOORTHY and G. S. HO
University of California
Berkeley, California

INTRODUCTION

A user oriented computer system is a computer system specifically designed to meet the users' requirements. With the advances in solid state technology and the emergence of microprocessors, system designers are able to design specialized systems to satisfy the users' requirements. This trend has led to an era of user oriented design. However, current approaches to the design of computer systems and their evaluation, unfortunately, are based primarily on experience and intuition. The specification, design, implementation, and evaluation of large embedded computer systems, such as the air traffic control systems, the patient monitoring systems and the ballistic missile defense systems (BMD), are very expensive, difficult to test adequately, slow to deploy, and difficult to adapt to changing requirements.[1] The major cause of these problems is the largeness of the systems. The activities of the systems are so varied and so complex that they are beyond the grasp of a single individual. For example, the BMD systems include, besides the data processing subsystem, the radar and missile subsystems. Each of these subsystems requires special expertise to design, implement, and enhance its operations. As a result, each subsystem is usually developed and maintained by a group of experts who have little knowledge of the other subsystems. This produces great difficulties in synchronizing and optimizing the development process. One common problem has been that some final decisions on primitives (essential system characteristics) are made in one subsystem, generally without considering the overall system requirements. These early commitments bias the development process and force and restrict the choices of the other primitives to accommodate them, which, in turn, impose undue constraints on design freedom and reduce the flexibility during integrating and interfacing the system. As a result, the development process is more expensive and time consuming than it should be, and the design that is obtained is usually far from optimum.

Another problem faced in the development of large computer systems is the ever changing system environment. When the system application changes or the technology changes, the system has to be modified to adapt to the changes. However, more too often, systems are designed without taking into account the provision for future changes. When the system evolves, the changes are incorporated into the system in a very disorganized manner. As a result, the unstructureness (or the entropy) of the system increases enormously[2] and leads to a regenerative, highly non-linear, increase in the effort and cost of system maintenance.[3] In addition to this, the reliability and the integrity of the system are also jeopardized greatly.

In large scale critical real time systems, such as the nuclear reactor control systems, the development process is further complicated by the real time constraints and the criticalities of the systems. These systems must perform all the required functions correctly within the given time limits, otherwise a large penalty has to be paid (for example, large loss of life due to a nuclear explosion). However, these systems cannot be tested in its real operational environments. As a result, system validation has to rely heavily on analysis and simulation. Due to the high complexity of the systems, exhaustive testing will be impossible. The only solution is to design the system in an orderly way so that both validation and testing can be done efficiently.

In this paper, a systematic design and development methodology for user-oriented data processing systems (DPS's) is presented. The methodology will provide guidelines for the systematic design and construction of DPS's so that the users' requirements are satisfied if there exists a feasible design under the given constraints. However, it must be emphasized that it does not mean the whole design process can be automated. The engineering decisions will often be very complex and dependent on the experience of the designers. The design methodology will provide design laws and analysis tools to help the designers in making design decisions, trade-offs and predicting the consequences. By following the guidelines given by the design methodology, the very complex design process will be simplified and we will be able to develop reliable, effective, modifiable systems with low costs and lead times.

Characteristics of the methodology

The philosophy behind the methodology is based on hierarchical modelling of a DPS. The objective of establishing

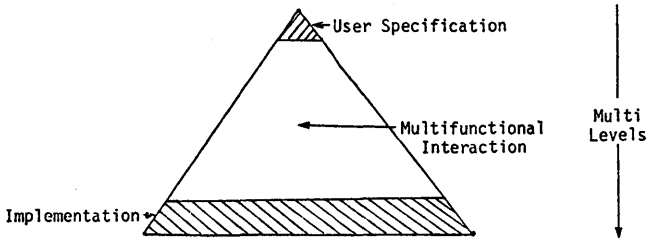

Figure 1—Hierarchical design

the hierarchy is to map the overall system requirements successively into lower levels of finer detail. At the top level in the hierarchy, the requirements described are abstract and the coupling between various attributes and associated functions may be loose. As we proceed down the levels, the characteristics of various functions and the attributes are elaborated and become more specific, Figure 1. The use of abstraction at the top level allows a designer to initially express the system requirements in a very general manner and with little regard to the details of the design and implementation. These initial system requirements are then refined in a step by step manner by gradually introducing more and more details (e.g., constraints and attributes) of the system. This combination of abstraction and stepwise refinement enables the designer to overcome the problem of complexity inherent in the construction of a complex DPS by allowing him to concentrate on the relevant aspects of his design incrementally at any given time, without worrying about other details. By this hierarchical approach, the assumptions and decisions made throughout the design process can be traced systematically and any revisions or modifications of the design as a result of the design development can easily be incorporated. In summary, the design methodology will:

(1) guarantee that the architecture (statement of need, system objectives, and constraints) of the problem will be preserved.
(2) support orderly evolution of the system satisfying the constraints such as performance, reliability, etc. without major revisions.
(3) provide formal (mathematically rigorous) basis for the approach allowing precise evaluation of completeness, consistency and correctness of requirements at any level of definition.
(4) represent effectively and efficiently the decision making constraints of a DPS by a specification language.
(5) provide design attributes and documentation for evolution (growth and modification) so that changes can be made without reconsidering the whole design process.

Overview of the methodology

The design methodology proposed here can be broken down into four successive phases, Figure 2:

(1) requirement and specification phase
(2) design phase
(3) implementation phase
(4) evaluation and validation phase

The requirement and specification phase starts with some (possibly incomplete, vague, and informal) users' require-

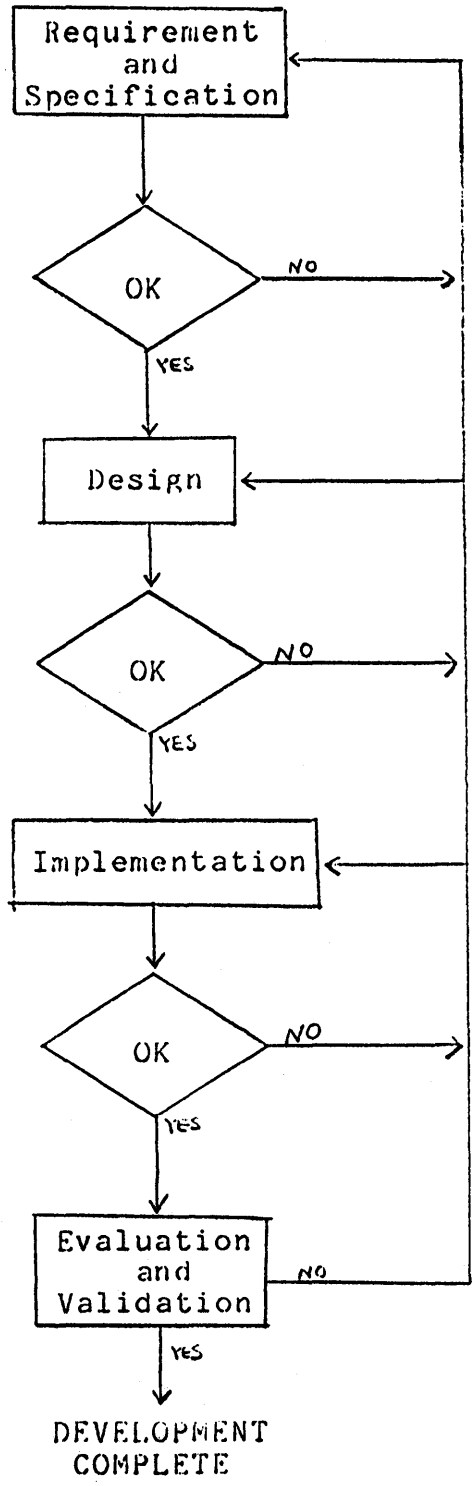

Figure 2—Proposed design methodology

ments that approximate the desired system, and finishes when the modified and elaborated requirements have been formally encoded and tested to the satisfaction of the system engineers and the "customers". This is the most difficult but also the most important step in the development process. Experience has shown that many design failures are due to either ill-defined (inconsistent and unclear) requirements or misinterpretation of the original problem statement. These account for up to 85 percent of requirement errors.[4,5] In order to avoid the above mistakes, the concept of a closed system is used. The users and their environment are considered together during the requirement and specification process. Requirement elaboration is done jointly in the environment and system models. By doing this, more complete and consistent requirements can be produced.

The design phase starts with the requirement specifications and finishes when the system specifications are produced. The objective is to organize and optimize the system in a well formed structure. It involves a hierarchy of decompositions and partitioning of the system into subsystems. Decomposition is the process of dividing the system into several levels of components and subcomponents, and partitioning is the process of grouping these components and subcomponents into subsystems so to minimize the amount of interactions and to satisfy the performance and reliability constraints of the system. After each decomposition and partition step, the subsystems are verified to be consistent to the original system. Any discrepencies and mismatches are corrected before they can propagate into the next level. After the design process, the system functions will be well specified and will be ready for implementation.

The implementation phase takes the system specification and develops the system architecture. It then maps the system functions into either hardware or software functions. It is only at this step that physical constraints and technology come into consideration.

The final step is the evaluation and validation of the system. This phase uses the bottom up validation approach. It takes the final design and ensures that the system meets the original requirements. This step uses both analytical modelling and simulation. Mistakes or unfulfilled requirements are traced back to the source of the error. The system is then redesigned from that point. Since the system is broken down hierarchically, only the subsystems affected by the error and therefore only those that are stemming from the error point have to be redesigned.

It should be mentioned that the development process is not a straight top down process. Tests and checks are conducted throughout the development process. Whenever errors are found, the design is backed up to the previous level. Therefore there is a feed-back path from each development process back to the previous one as indicated in Figure 2.

DESIGN METHODOLOGY

The design methodology is aimed at satisfying a broad spectrum of data processing applications including real time applications. Its primary objective is to develop reliable, effective, modifiable systems with low cost and lead time. In the following sections, the requirement and specification phase and the design phase of the methodology will be discussed in detail. The implementation and validation phases are too technology and architecture dependent and are beyond the scope of this paper.

REQUIREMENT AND SPECIFICATION PHASE

The requirement and specification phase starts with informally specified users' needs and elaborates on them to generate the formal system requirement specifications. These specifications are used for two purposes: (1) as a problem definition for the design process, (2) as a means against which an implementation can be validated. The success in the development of the data processing system greatly depends on the correct interpretation of the requirements in the specification phase. However, these requirement specifications usually suffer from many ills: they are often designs rather than a statement of need; they are usually incomplete and are expressed in an ambiguous language (English); they are difficult to verify and hence are often incorrect, conflictive within themselves (inconsistencies); they are difficult to test and if one wants to modify them, it is difficult to locate and accurately modify all affected areas. In order to rectify the above problems, a systematic procedure is used to generate correct, consistent, complete, traceable, design free and feasible requirements. Formal definitions of the above terms can be found in Reference 6.

In this methodology, the requirement and specification phase consists of four major steps, Figure 3: (i) requirement elaboration, (ii) requirement specification and attribute formulation, (iii) process definition, and (iv) verification of requirements.

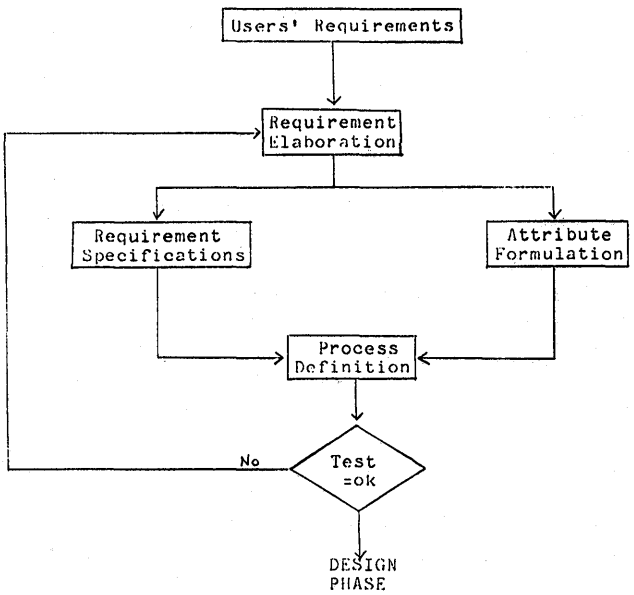

Figure 3—Requirement and specification phase

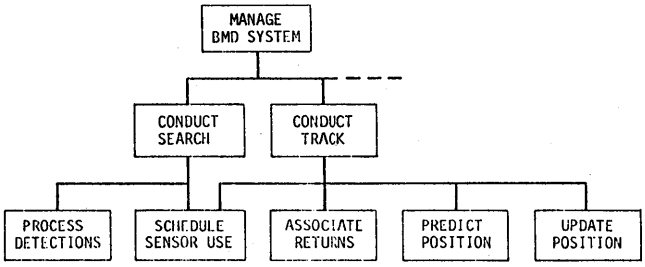

Figure 4—Functional decomposition of BMD management system

Requirement elaboration

The requirement elaboration step can be considered as a problem understanding stage. The requirement engineers investigate in great detail the users' needs and develop clear and precise requirements of the system. In this step, the closed system approach is chosen. In a closed system, the designed system and its external environment are considered as a single entity. All activities in the closed system are investigated in a homogeneous way. After the requirement engineers have fully understood the operations of the closed system, the data processing requirements and the attributes of the computer system can be derived from the behavior of the computer system. These overall system requirements can then be decomposed into finer detail according to their functional, logical or precedence relationships. For example, the BMD management system can be decomposed functionally as shown in Figure 4. Test experiments can also be generated from the behavior of the environment to verify the proper operation of the designed system. In this way, more complete and consistent requirements can be generated.

Requirement specification and attribute formulation

From the required behavior of the system, the users' original objectives can be formally expressed in the system requirements and system attributes.[1] The system requirements are the objectives and constraints which the system must satisfy. Any system which meets the requirements is a candidate solution to the users' problem. Attributes, on the other hand, specify either options or evaluation criteria for qualitative comparisons of competing systems that meet the system requirements. They are used to specify the preferences of the users. The generation of these system requirements and attributes is the requirement specification and attribute formulation step. As pointed out previously, one of the greatest problems in requirement specifications is the misinterpretation of the original system requirements. A plausible solution is to use dual specification teams to develop the system specifications from the requirements independently as in the development of critical real-time software for nuclear power plants.[7] The two specifications are then compared and discrepancies are resolved to the satisfaction of both teams. By this dual specification approach, most of the errors due to ambiguities and misinterpretations can be corrected before they can propagate into the next phase.

Requirement specification

The system requirements can be broken down into two categories: (i) functional requirements, and (ii) performance requirements.

Functional requirements specify the input (stimulus) and output (response) relations of the system. These input to output mappings can be expressed vigorously in mathematical formulas[8] or less formally in a specification language.[9,10] Mathematical formulation defines explicitly the ranges of input and output domains and exhibits the required system functions by tabulation or a set of mathematical expressions. This allows formal consistency and correctness proofs of the system. However, this method is greatly limited by the ability of the requirement engineers in formulating the mathematical functions. In real-world situations, the problems are usually so complex that pure mathematical formulation is impossible. Therefore in this methodology, the approach of using a specification language is chosen.

A specification language is a syntactically and semantically well defined language possibly intermixed with mathematical equations. Its whole purpose is to provide an efficient and effective medium for defining the functional requirements. Several specification languages have been developed previously.[5,9–12] This paper does not intend to develop a new specification language. We will choose a specification language and express the functional requirements in it. In choosing the specification language, the constructability and comprehensibility of the language must be evaluated carefully. The specification language must be able to express the functional requirements efficiently and be easily understood by the customers and the requirement engineers. It must be able to specify the system requirements unambiguously and provide capabilities of performance specifications in the case of real time system. The language should be amenable to both static (hierarchical relationship, data definition, etc.) and dynamic (control flow and data flow) analyses. Finally, it should be backed up by a specification data base management system and powerful graphical supports to provide easy and efficient accesses to the designed system.

Performance requirements specify the functional effectiveness of the system. They include the input and output rates, response time, accuracy etc. There is essentially no notion of completeness as far as performance requirements are concerned. The requirement engineers have to work closely with the users to ensure that all the important performance aspects of the system are captured in the specifications. At this point, it can be noted that there are still some uncertainties and vagueness in the methodology. However, these are unavoidable as design in general is a wicked problem.[13] There is no stopping rule and definite test to the solution of a wicked problem. One stops only because one has run out of resources, patience, etc. Therefore, the best

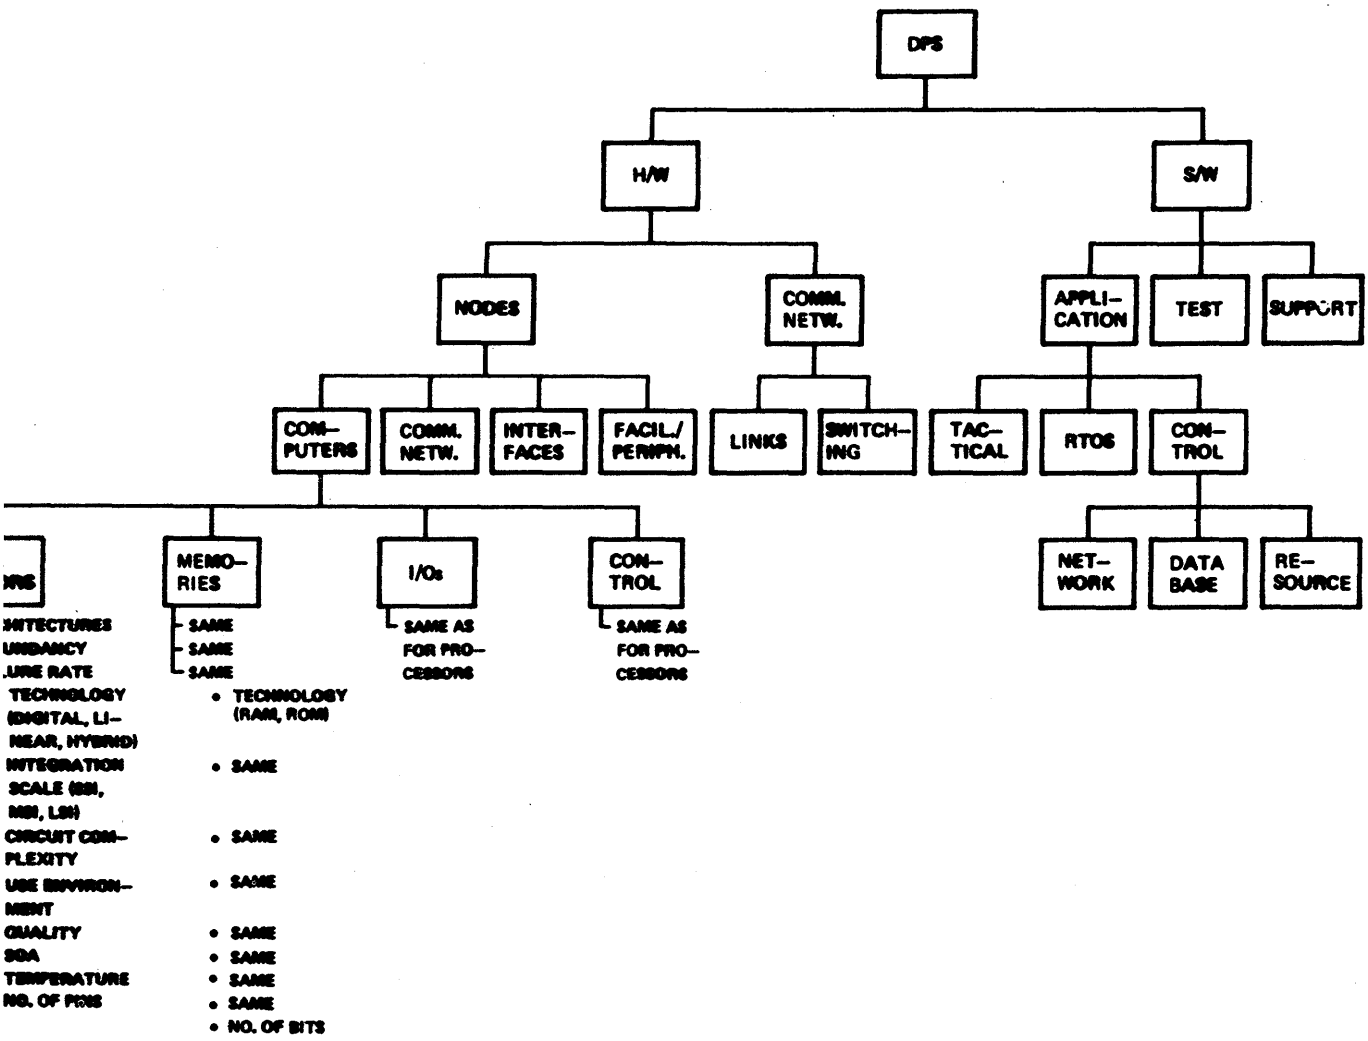

Figure 5—Reliability payoff tree

we can do is try to provide guidelines in the development process to improve the quality of the product.

Attribute formulation

Attributes represent the customers' preference on the designed system, e.g., cost, reliability, availability, flexibility, expandability, reconfigurability etc. They are the evaluation criteria used to determine which characteristics make one system desirable over another system even though they may both meet the requirements. Usually, the system attributes are interdependent on each other and they may compete and interact with each other. In order to clearly specify the preferences of the customers, the system attributes are weighted or ranked according to the customers' preferences. They are then expressed in a utility function[14,15] or in a payoff tree.[16] Utility function has been used extensively in economics and in business management. It measures formally the degree of satisfaction of the customers in terms of the utility of the system. Once the utility function of a system has been formulated, the optimal system configuration can be determined by optimizing its utility. However, due to the inherent complexity of a large computer system and the high interdependency of its attributes, the formulation of its utility function can be very difficult. In such cases, the less formal approach of using payoff tree is preferred. It involves first generating the payoff trees of the system attributes. For example, the reliability payoff tree is shown in Figure 5. The payoff measure interrelationship can then be generated, Figure 6. These payoff trees show clearly to the designers the tradeoffs involved in the attributes. Based on these payoff trees, trade-off decisions in later stages of the development process can be facilitated. This approach is being used in the development of the BMD system.

Process definition

The process definition step accepts inputs from the requirement specification and attribute formulation step and

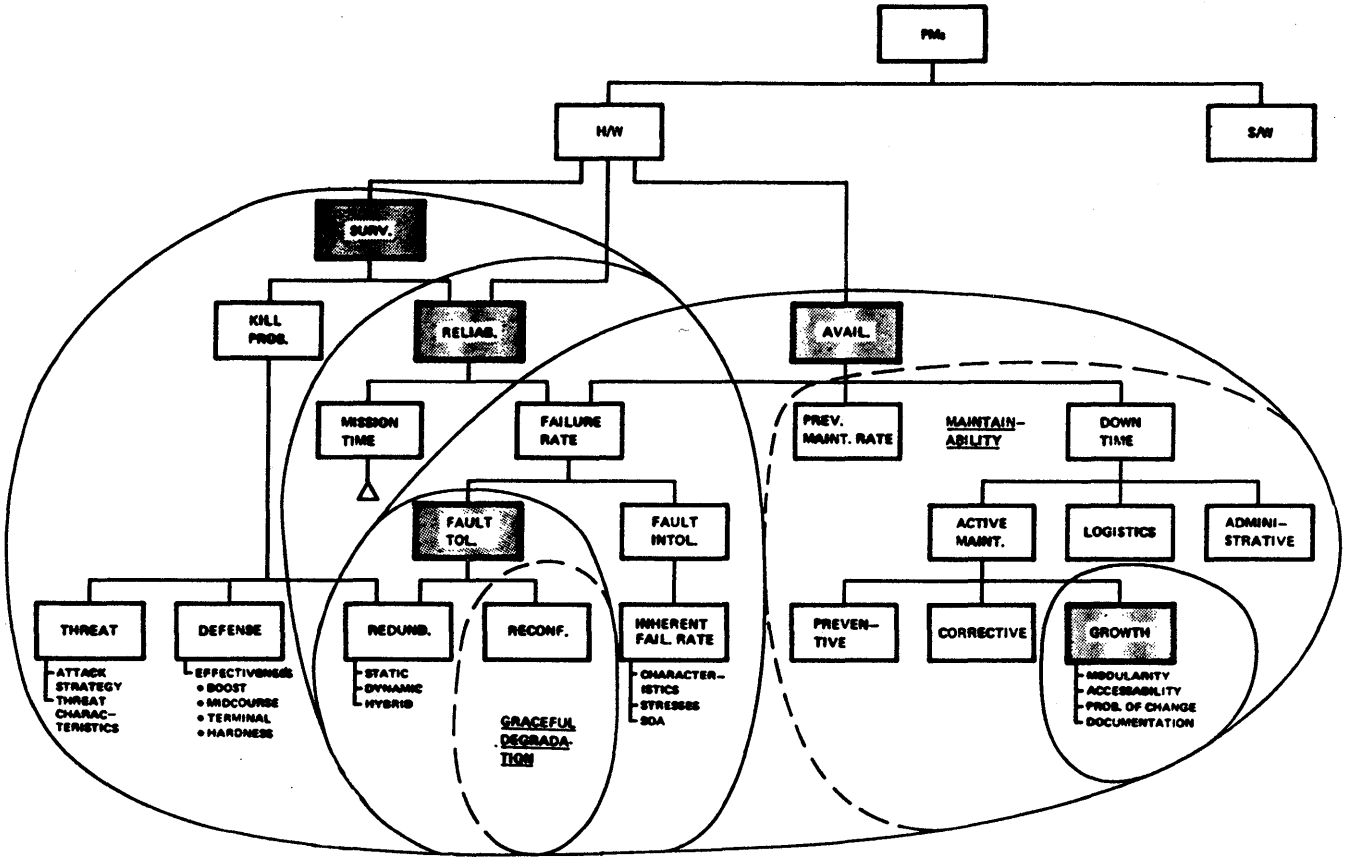

Figure 6—Payoff measure relationships (Note: Taken from Reference 16.)

identifies major functions to be performed. First the input stimulus and the required responses are characterized. This involves stating the form of the input and output signals. They may be mechanical, electrical, optical, etc. From this, the required I/O processes can be defined. For example, in an air traffic control system, it contains the radar control process, the graphic display process and the interactive I/O process.

In parallel to the formulation of the I/O processes, the functional requirements can be decomposed into data processing requirements, communication requirements, precedence constraints, etc. Similarly, the performance requirements can be decomposed into resource requirements, scheduling requirements, etc. Based on these requirements and the attributes defined previously, the information flow and control flow of the system can be modelled and analyzed to identify the major operations to be performed and their locations of occurrence. From these analyses, the system processes required to perform the above functions can be defined. These process definitions state precisely the function of the processes, the resources required by the processes, and the interaction between the processes. At this stage, the virtual system is formed and is ready for verification. For example, in the formulation of a tangent function, it can be decomposed functionally into a sine function, a cosine function and a division operation, Figure 7a. The attributes of the function (like accuracy, delay, output range, cost, etc.) can then be extended to become the attributes of the component functions, Figure 7b. In this manner, the virtual system is formed.

Verification of requirements

In this step, the processes of the virtual system is verified to meet the original users' requirements. As the system is developed hierarchically, the specifications of one level are the requirements of the next level. To verify the correctness of the virtual system, we only have to verify the consistency between the specifications and requirements between consecutive levels. This simplifies the verification process a lot and if an analysable specification language is used, the consistency can be verified automatically. In addition to this, test experiments generated automatically[17] or formulated from the environment in the requirement elaboration step can be used to check the quality of the virtual system. If the tests are not acceptable, necessary changes are incorporated into the requirement specifications. The affected processes will be updated and the corrected system will be tested again.

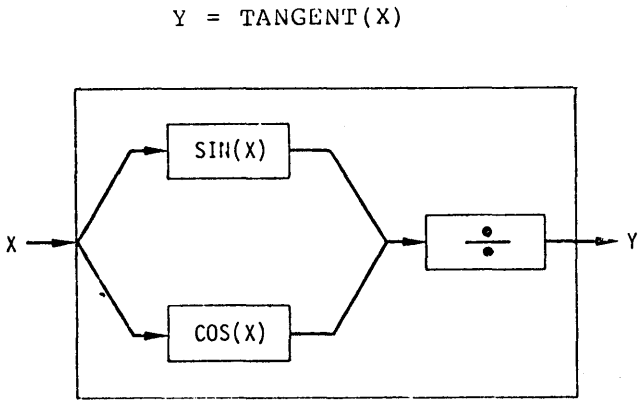

Figure 7a—Functional Decomposition

DESIGN PHASE

The design phase starts with the defined processes which are the output of the requirement and specification phase. The major steps involved in the design phase are process decomposition and partitioning, functional specification and finally verification, Figure 8. Basically, the design phase requires a provision to trace the system requirements through all levels of design, and a means of assessing trade-offs at the functional level and comparing design alternatives.

In the process partitioning phase the designer will decompose the system into a network of interacting tasks. The motivation for such partitioning is to increase modularity and testability and to decrease the interferences between processes.[18] This partitioning is based on the philosophy of hierarchical decomposition of the system into progressively more detailed networks of processes at different levels of abstraction. The hierarchical approach permits partial ordering and allows the designer to isolate interacting and non-interacting parts. The partitioning criteria and approaches depend on the level at which the partitioning is carried out and upon the nature of the logical aspects involved, for example functional decomposition, algorithmic decomposition and attributes decomposition. Several techniques can be adopted to perform partitioning at various levels. Our approach to this problem of partitioning is discussed in the following subsections.

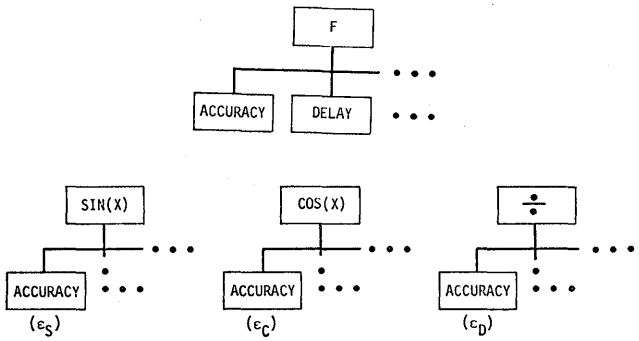

Figure 7b—Attribute decomposition

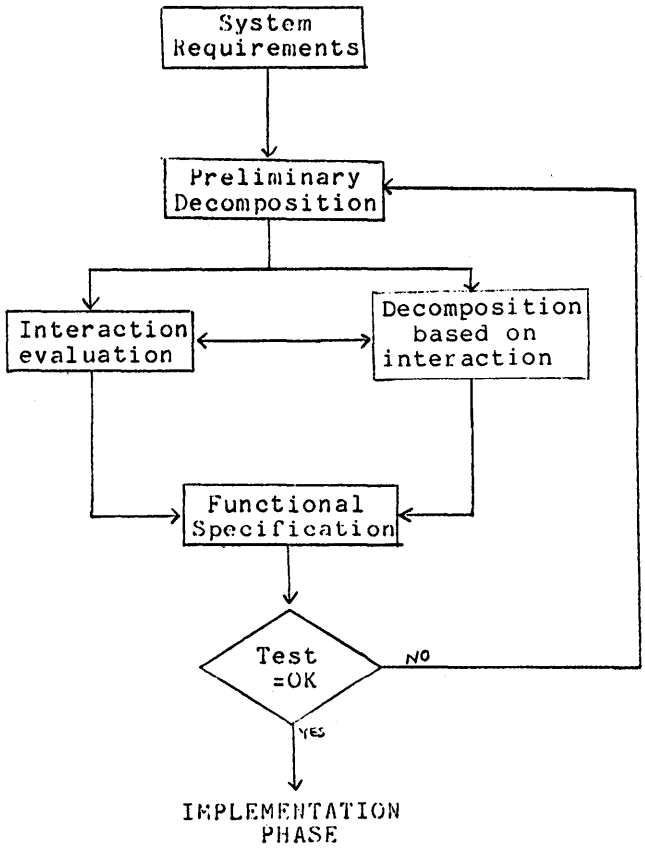

Figure 8—Design phase

Decomposition and partitioning

After the requirement process, a well defined, complete, consistent, unambiguous and testable set of system process specifications are produced. These system process specifications insure that the system behavior will be satisfactory to the customer and that the required system can plausibly be designed and implemented. Usually the specified system at this stage is so complex that it is very difficult if not impossible for the hardware designers to start implementing the system. In order for the design process to be manageable, it must be decomposed in such a way that most decisions can be made locally, based on data available within a local area of the developing system specifications.

The decomposition process can be accomplished by identifying the tightly coupled processes of the system and factoring the system into subsystems with respect to this criterion. The remaining steps of the development process can then independently (or nearly so) elaborate the design of each subsystem, maintaining the inter-subsystem interactions as design invariances. However, the decomposition must be carried out very carefully satisfying the following criteria:

(1) The decomposed system must be well-defined—they are consistent, complete, unambiguous and testable.
(2) The decomposed system must be capable of being integrated.

(3) The decomposed system must meet the resource allocation requirements, reliability requirements, performance requirements, etc.
(4) The decomposed system must satisfy the parametric logical specifications such that minor changes in the requirements would not require a redesign of the whole system.
(5) The decomposed system must be expandable so that future growth of the system can be easily incorporated.

In accomplishing the above criteria, a decomposition procedure will be used to guide the designer to generate a satisfactory decomposition of the system. The objective here is not to produce an optimal solution, but to develop a set of tools to help him to make his decisions. Most of the steps in the decomposition process will be automated to relieve the designer from tedious computations. However, some tradeoff decisions require human experience and interaction, and must be made by the designer. As a result, a close interaction of the designer in the decomposition process is required.

Preliminary decomposition

A large system will have many processes that are only loosely coupled, for example, the communication process and the data processing process. These loose subsets of tightly coupled processes can easily be identified by the designer and can be used to partition the system into subsystems. Thus, the whole system is decomposed into smaller subsystems, each representing some aspects of the original system from a different point of view. The number of such decomposed subsystems is application-dependent and sensitive to the identification of loosely coupled subsets of processes. By this preliminary decomposition, the system is decomposed into a structure according to its requirements and is ready for further analyses.

Decomposition based on interaction

The objective of interaction decomposition is to reduce the amount of interactions between subsystems. This in turn reduces the complexity of the interfaces and the amount of communication between subsystems. The interaction decomposition process can be divided into two cooperating steps: (i) decision process which requires direct interaction from the designer, and (ii) solution finding process which can be highly automated, Figure 9. In the decision process, the designer looks at the requirement specifications and assigns weights to the interaction between processes. These weights will be a function of communication cost, amount of traffic flow, degree of synchronization, ranking of the attributes, etc. By using this weighting function, tightly coupled processes will be assigned a high weight. Processes that should be in different modules (for example, due to reliability requirement) are assigned a very low weight. With

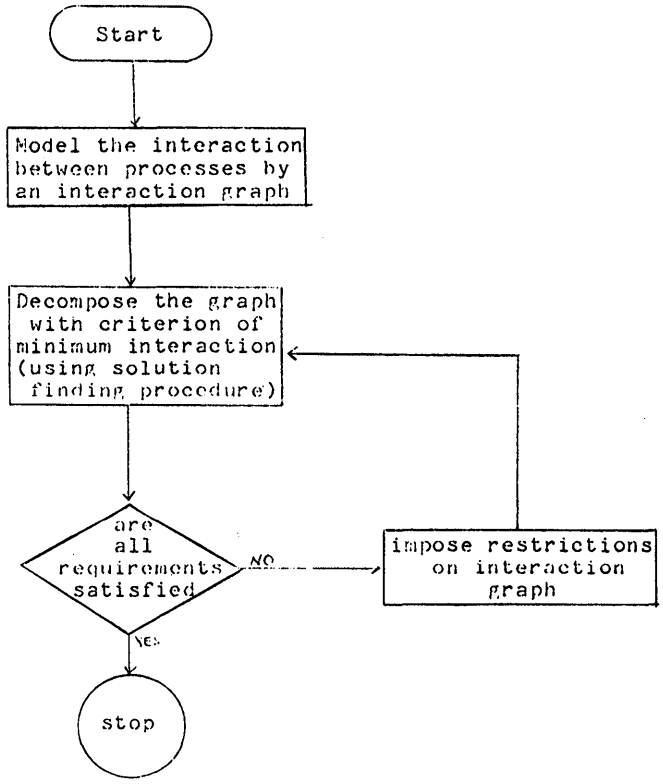

Figure 9—Decomposition based on interaction

this weight assigning function, we will then model the system by an interaction graph, Figure 10. In the interaction graph, nodes represent processes and the weight assigned to each arc corresponds to the amount of interaction of the two processes connected by the arc. In this way, the system can then be decomposed into subsystems automatically by the solution finding process. After the decomposition, the decomposed system is then checked by the designer to determine whether all the requirements are satisfied. The discrepancies are identified and the required changes are imposed onto the interaction graph which is analyzed by the solution finding step again. These two steps are iterated until all the specifications are met.

Solution finding procedure: In this step, the system which is represented by an interaction graph is partitioned into loosely coupled subsystems such that the system requirements are satisfied. First, the interaction cut-tree will be generated from the interaction graph by using the max. flow

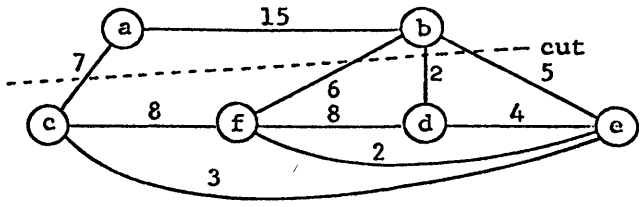

Figure 10—Interaction graph

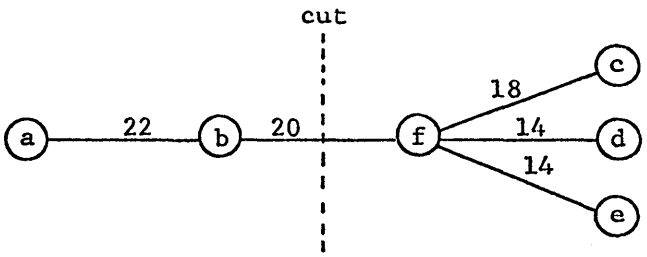

Figure 11—Interaction cut-tree

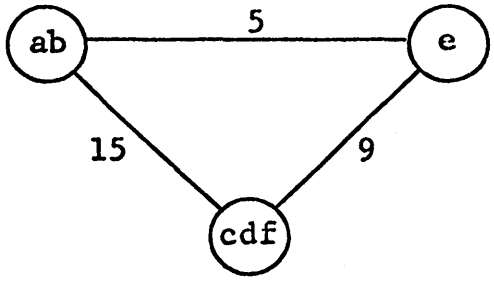

Figure 12—Decomposed system

min. cut algorithm.[19] It involves choosing two nodes arbitrarily in the interaction graph and finding the minimum cut set of the two nodes by the max. flow min. cut algorithm. This minimum cut divides the interaction graph into two subgraphs. Two other nodes are then chosen arbitrarily in one subgraph and the above procedure is repeated (with the other subgraphs being considered as macro nodes) until the interaction cut tree is generated. By this transformation, the interaction requirements between processes are represented very clearly by the interaction cut-tree, Figure 11. The minimal cut-set separating two nodes in the interaction graph is one to one corresponding to the minimal cut-set of the same two nodes in the interaction cut-tree. In addition to this, the values of the corresponding cut-sets in the two graphs are equal. For example, the minimal cut-set separating nodes a and f partitions the interaction graph and the interaction cut-tree identically into two subgraphs, {a,b} and {c,d,e,f}. The two cut sets both have values equal to 22. As a result, the decomposition can be performed on the interaction cut-tree rather than the interaction graph. This simplifies the computation greatly and displays clearly to the designer the condition of the system. The minimum cut can be identified easily in the cut-tree as it is the minimum weighted arc in the unique path connecting the two nodes.

After the interaction cut-tree has been generated, the system can be partitioned into loosely coupled subsystems such that the total weight of all the arcs in the cut-set is minimum. In addition to this, the partition should preserve the special configuration imposed by the requirements specified by the designer. For example, because of resource requirements, processes a and f, process a and d, and processes e and f have to be in different modules. In order for a and d to be on different modules, either arc (a,b), (b,f) or (f,d) has to be cut in the cut-tree. These requirements are then expressed in a table as shown in Table I.

The decomposition can now be achieved by finding the set of arcs in Table 1 such that each row in the table contains at least one cross in the arcs chosen. This can be solved by the set covering algorithm.[20] In our example, arcs (b,f) and (e,f) are chosen such that the interactions between subsystems are minimized, Figure 12. In general, this method will give a solution very close to the optimal solution and the computation complexity is very low when compared with that of generating the optimal solution.

TABLE I.—Constraint Table

arcs separating	(a,b)	(b,f)	(c,f)	(d,f)	(e,f)
a,f	X	X			
a,d	X	X		X	
e,f					X

Functional specification

The next major step in the design phase is functional specification of the partitioned processes. This functional specification is different from the process specification described in the requirement specification phase. The objective of the process specification is to define the interactions of the processes for the decomposition step. The objective of the functional specification here is to define the characteristics of the functions so as to enable optimization in the functions to processors mapping.

In the functional specification, all the processes in the same partition are considered as a single function. Similar to the process specification, the input and output relation, the precedence constraints and the interactions between different functions are determined. In addition to these, the characteristics of the function are defined. These include:

(i) types of operations to be performed—matrix operations, floating point or integer operations, etc.
(ii) resource requirements—storage requirement, processing power, etc.
(iii) speed requirements—frequency and execution speed of the function.

Based on these information and the processors available, the functions are mapped onto the available processors. In Reference 21, an efficient mapping algorithm of two processors system are discussed. For the general case of n processors, no efficient algorithm is known at this time and more research should be done in this area.

Verification of design

In order to be able to verify the correctness of the design and to evaluate the effectiveness of the control, the system must be modelled in some abstract model. This abstract

model should be amenable to analyze the intercommunication, the synchronization, the performance and the coordination of the functions. In this methodology, the Petri net model is chosen.

Petri nets display clearly the flow of information and control in systems, especially those which exhibit asynchronous and concurrent properties. However, in order to model the time constraints of real-time systems, the Petri net model is extended to include the execution time aspect of a system. In the following sections, the extended Petri net model and the analysis techniques will be discussed. In general, the designed system is modelled by a Petri net at all levels in the design phase. The Petri net is analyzed to guarantee the proper behavior of the system. For example, the Petri net models of the system before and after the decomposition are analyzed to ensure the consistency of decomposition.

Analyses of the system

Throughout the whole design phase, the system is modelled by a Petri net. By analyzing the liveness, the boundness and the proper termination properties of the Petri net,[22-25] the properties of the designed system can be unveiled. A Petri net is live if for each transition in the net, there always exists a firing sequence to fire it. By the liveness property of the Petri net, the designed system is guaranteed to be dead-lock free. A Petri net is bounded if for each place in the net, there exists an upper bound to the number of tokens that can be there simultaneously. By the boundness property of the Petri net, the number of buffers required between asynchronous processes can be determined and therefore information loss due to buffer overflow can be avoided. A Petri net is properly terminated if the Petri net always terminates in a well-defined manner. By the proper termination property, the designed system is guaranteed to function in a well behaved manner. (This point will be elaborated later.)

All the above three properties can be analyzed by constructing the reachability graph. (The method for constructing the reachability graph can be found in Reference 22.) In

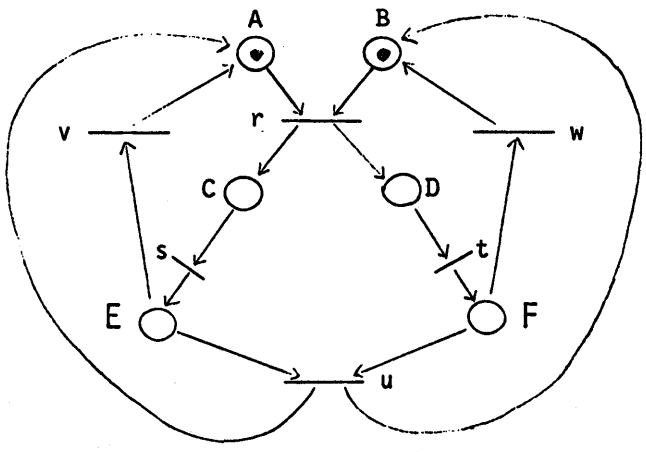

Figure 13—A live and bounded Petri net

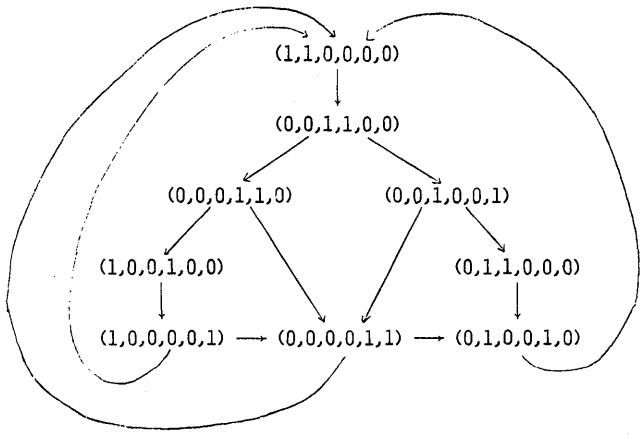

Figure 14—Reachability graph

Figure 13, the Petri net models a concurrent system with five processes: r, s, t, u and v. The reachability graph is shown in Figure 14. Since the reachability graph is strongly connected and all the entries are finite, the concurrent system is live and bounded. By these two properties, the concurrent system is guaranteed to be dead-lock free and to have enough buffers.

Extended Petri net

However in real world problems, especially in real-time systems, the execution time of a process is a very important aspect of a system. In order to model this aspect, the Petri net model is extended to include the notion of time. In the extended net, each transition is associated with two times, $t1$ and $t2$, where

$t1$=minimum time a transition can begin firing after being enabled (it can be zero)
and $t2$=maximum time a transition can remain not fired after being enabled ($t2>t1$)

Whenever a transition is enabled, it has to fire between times $t1$ and $t2$. In the case that a transition has $(t1,t2)$ as defined and an execution duration of u, it can be modelled by cascading two transitions with times $(t1,t2)$ and (u,u) associated to the transitions, Figure 15. By using this ap-

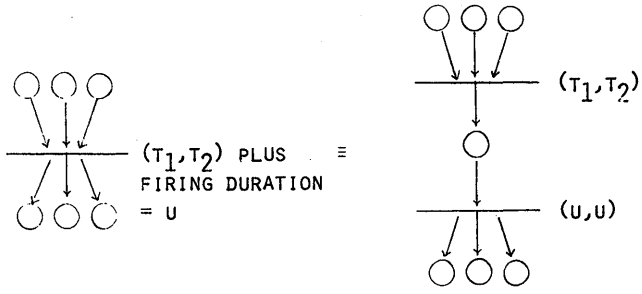

Figure 15—Timed Petri net

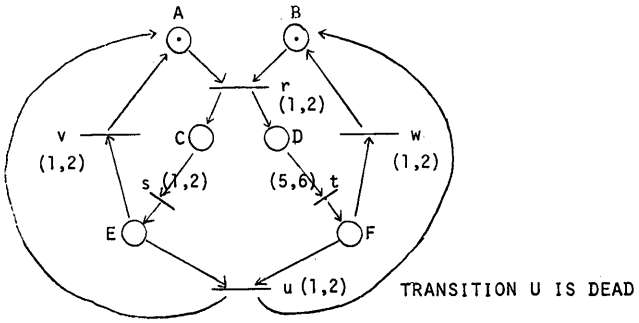

Figure 16—Non-live condition of a timed Petri net

proach, the problem of losing tokens during the firing of a transition is avoided.

By using the extended Petri net, the concurrent system discussed previously is analyzed again. The Petri net model of the concurrent system and its time constraints are shown in Figure 16. A careful study of the system will show that transition u is dead (it will never be fired). This is due to the long delay produced by transition t. After firing transition r, the token in place C will move into place E and then move into place A before the token from place D can move into place F. This situation is shown in the reachability graph in Figure 17. The two times associated to each arc is the earliest and the latest transition times of the arc. The two arcs t^1 and t^2 are blocked because their earliest transition time is longer than the latest transition time of the other transition emitting from the same node. Therefore by using the extended Petri net, the dead-lock situation due to time constraints can be detected. In addition to that, if the Petri net is a marked graph[26] and if the execution time, τ, of a transition is taken to be $t2$, the maximum computation rate, ρ, of each of the transition can be computed by[26]

$$\rho=\min\left\{\frac{N_k}{T_k} \mid k=1,2,\ldots n\right\}$$

where

$$T_k=\sum_{t_i\in C_k}\tau_i$$

is the sum of the times associated with transitions of circuit C_k and

$$N_k=\sum_{V_k\in C_k}M_k$$

is the number of tokens in places of circuit C.

In finding the dead-lock situation in the extended Petri net, the algorithm to find the earliest and latest transition times in the reachability graph is quite lengthy and complicated. For example, the arc t^2 is associated with times (3,5) rather than (5,6) because transition t is enabled before transition s is fired. This type of interdependency can be resolved by tracing back the reachability graph to find the time when the transition is enabled. The computation can be done by a computer. Although it may be very lengthy, it is worth the effort to guarantee the designed system to be dead-lock free.

Proper termination

A Petri net is properly terminated if a token is injected into the input place, the net produces a finite number of tokens and terminates with all the tokens in its output place.[23,24] This implies that if the corresponding system is initiated, it will always execute to completion without any intermediate results or pending conditions left in the system.

The proper termination property of a Petri net can be studied by its reachability graph. For example, the Petri net and its reachability graph are shown in Figure 18 and Figure 19. Since the only maximal node in the reachability graph is the state that place E contains a token, the Petri net is properly terminated.

The notion of proper termination can be used to verify the consistency of decomposition. For example, in Figure 20, transition s in global net N1 is decomposed into the subnet S. Virtual nodes A through G are then added to the subnet to form N2 which is then analyzed for proper termination.

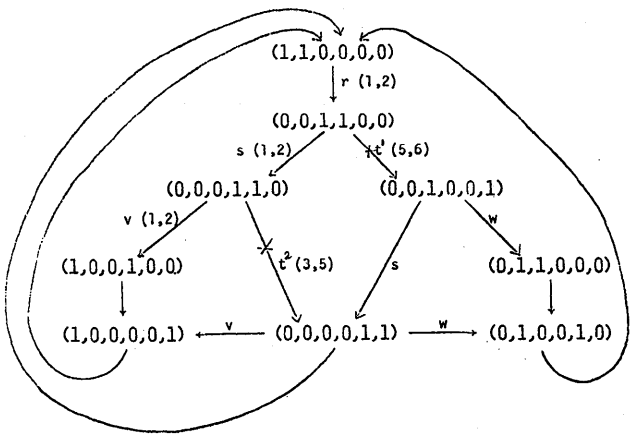

Figure 17—Reachability graph

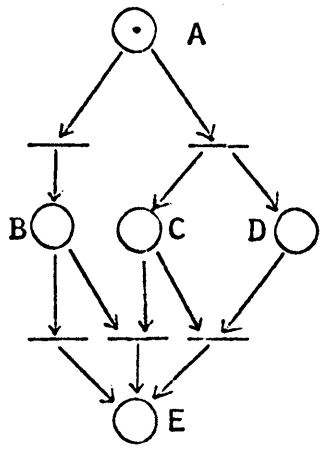

Figure 18—A properly terminated Petri net

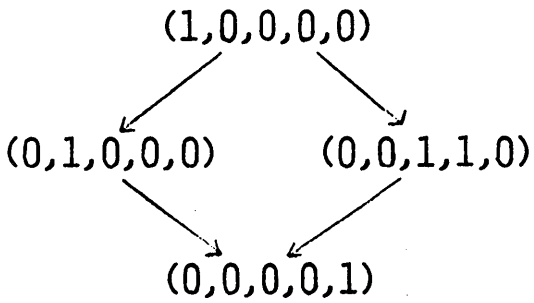

Figure 19—Reachability graph

If N2 is properly terminated, the decomposition is consistent. This guarantees that no data stay in the decomposed process and no extra data are generated when the decomposed process is substituted for the original process in the system. If time constraints, $(t1,t2)$, are added to each of the transitions, the time constraints of transition s can be verified by finding the minimum and maximum path lengths in the decomposed net.

The verification techniques discussed above are by no means complete. They are just some of the approaches for analyzing the synchronization and consistency of interacting

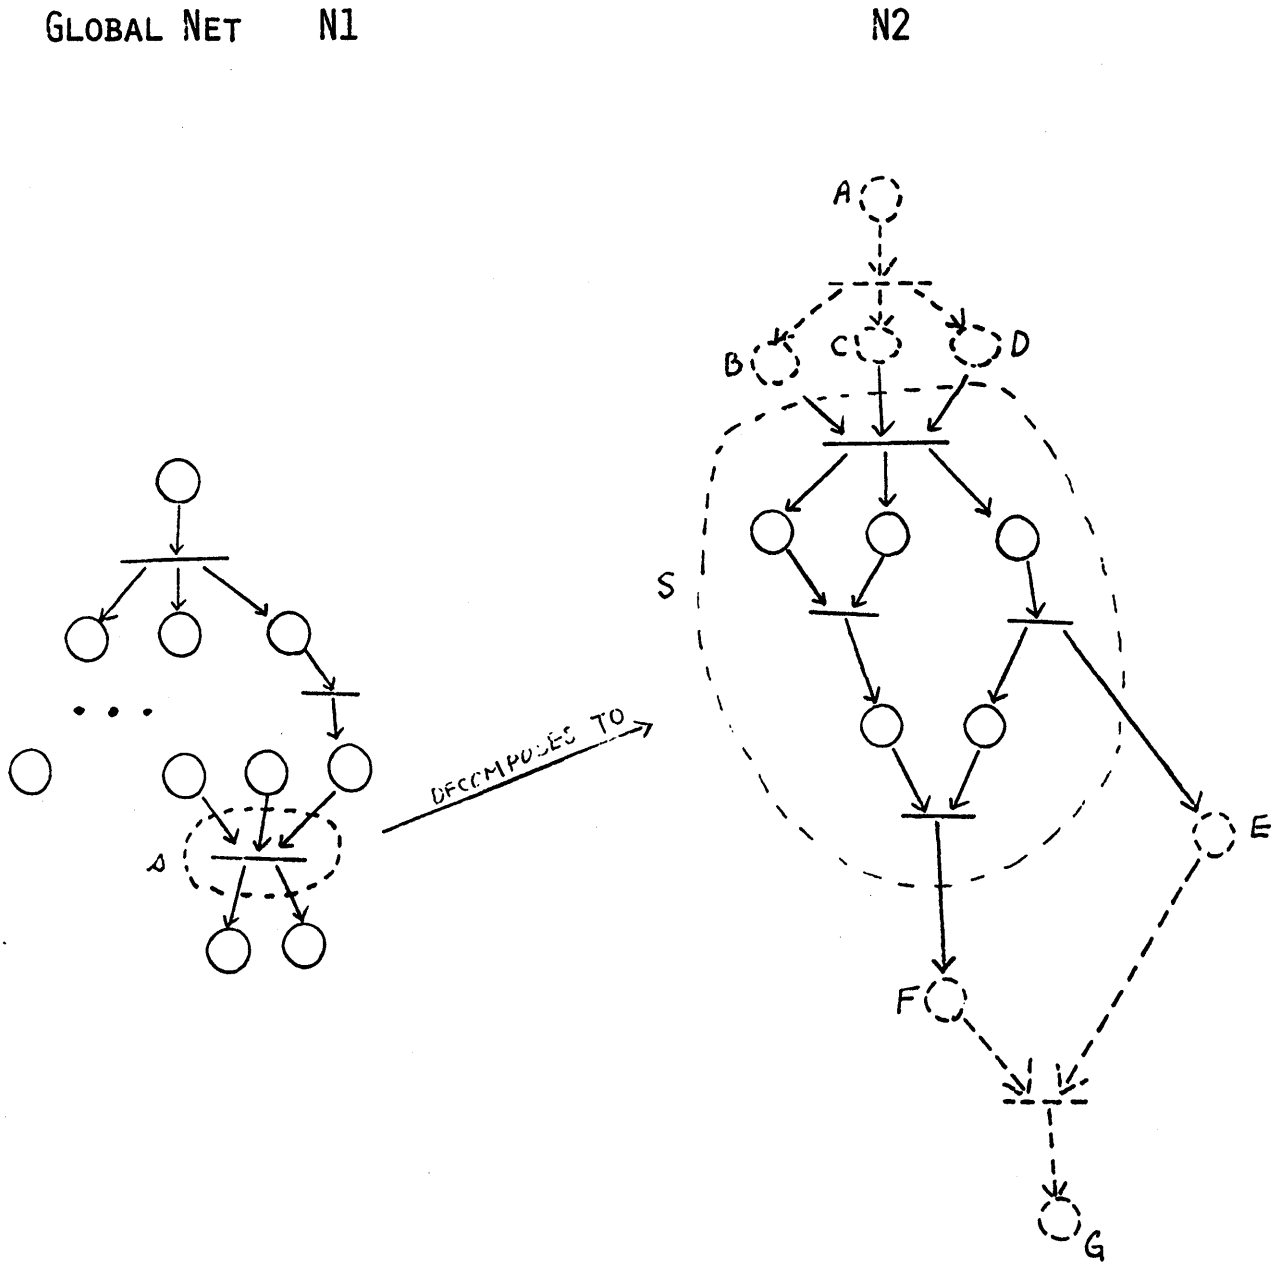

Figure 20—Consistency verification by Petri net

asynchronous processes. It is hoped that through these analysis techniques, synchronization errors in the designed system can be detected before implementation.

IMPLEMENTATION, EVALUATION AND VALIDATION

The implementation phase takes the virtual system and develops the system architecture. It then maps the system functions into either hardware or software functions. This step is greatly dependent on the technology, the architecture chosen, the physical constraints of the system. The final phase is the evaluation and validation of the system. This phase uses the bottom up validation approach. Both analytical modelling and simulation will be used. Because of the hierarchical decomposition, each subsystem to be analyzed should be small and therefore the complexity should be low. Mistakes or unfulfilled requirements found are traced back to the source of error. The system is then redesigned from that point.

CONCLUSION

This paper has discussed a systematic design procedure for a user oriented computer system. The main objective is to develop reliable, effective, modifiable systems with low cost and lead time. The methodology uses the concept of abstraction, stepwise refinement and modularity to design a DPS. By following the design guidelines of the methodology, the system can be developed systematically in a hierarchical manner.

The design methodology is divided into four successive phases: (i) requirement and specification phase, (ii) design phase, (iii) implementation phase, and (iv) evaluation and validation phase. The first two phases have been explored in detail in the previous sections. In the requirement and specification phase, the requirements and the characteristics of the system are elaborated and expressed in a formal specification. The basic steps involved, the primitives to be specified, and the choice of specification language are discussed. In the design phase, the system specifications are analyzed to generate the virtual system. A systematic decomposition procedure is proposed. Analysis and modelling techniques used in this phase are also discussed. By modelling the virtual system in an extended timed Petri net, the performance, the consistency and the liveness of the system can be determined. The last two phases of the methodology are only outlined briefly. They are too technology and architecture dependent and are beyond the scope of this paper.

ACKNOWLEDGMENTS

This research was supported by the Ballistic Missile Defense Advanced Technology Center (BMDATC) under contract DASG60-77-C-0138. We would also like to thank Mr. C. R. Vick, J. E. Scalf, D. Palmer and M. Mariani for many helpful discussions related to this work.

VAX-11/780—A virtual address extension to the DEC PDP-11 family

by W. D. STRECKER
Digital Equipment Corporation
Maynard, Massachusetts

INTRODUCTION

Large virtual address space minicomputers

Perhaps the most useful definition of a minicomputer system is based on price: depending on one's perspective such systems are typically found in the $20K to $200K range. The twin forces of market pull—as customers build increasingly complex systems on minicomputers—and technology push—as the semiconductor industry provides increasingly lower cost logic and memory elements—have induced minicomputer manufacturers to produce systems of considerable performance and memory capacity. Such systems are typified by the DEC PDP-11/70. From an architectural point of view, the characteristic which most distinguishes many of these systems from larger mainframe computers is the size of the virtual address space: the immediately available address space seen by an individual process. For many purposes the 65K byte virtual address space typically provided on minicomputers (such as the PDP-11) has not been and probably will not continue to be a severe limitation. However, there are some applications whose programming is impractical in a 65K byte virtual address space, and perhaps most importantly, others whose programming is appreciably simplified by having a large virtual address space. Given the relative trends in hardware and software costs, the latter point alone will insure that large virtual address space minicomputers play an increasingly important role in minicomputer product offerings.

In principle, there is no great challenge in designing a large virtual address minicomputer system. For example, many of the large mainframe computers could serve as architectural models for such a system. The real challenge lies in two areas: compatibility—very tangible and important; and simplicity—intangible but nonetheless important.

The first area is preserving the customer's and the computer manufacturer's investment in existing systems. This investment exists at many levels: basic hardware (principally busses and peripherals); systems and applications software; files and data bases; and personnel familiar with the programming, use, and operation of the systems. For example, just recently a major computer manufacturer abandoned a major effort for new computer architectures in favor of evolving its current architectures.[1]

The second intangible area is the preservation of those attributes (other than price) which make minicomputer systems attractive. These include approachability, understandability, and ease of use. Preservation of these attributes suggests that simply modelling an extended virtual address minicomputer after a large mainframe computer is not wholly appropriate. It also suggests that during architectural design, tradeoffs must be made between more than just performance, functionality, and cost. Performance or functionality features which are so complex that they appreciably compromise understanding or ease of use must be rejected as inappropriate for minicomputer systems.

VAX-11 overview

VAX-11 is the Virtual Address eXtention of PDP-11 architecture.[2,3] The most distinctive feature of VAX-11 is the extension of the virtual address from 16 bits as provided on the PDP-11 to 32 bits. With the 8-bit byte the basic addressable unit, the extension provides a virtual address space of about 4.3 gigabytes which, even given rapid improvement in memory technology, should be adequate far into the future.

Since maximal PDP-11 compatibility was a strong goal, early VAX-11 design efforts focused on literally extending the PDP-11: preserving the existing instruction formats and instruction set and fitting the virtual address extension around them. The objective here was to permit, to the extent possible, the running of existing programs in the extended virtual address environment. While realizing this objective was possible (there were three distinct designs), it was felt that the extended architecture designs were overly compromised in the areas of efficiency, functionality, and programming ease.

Consequently, it was decided to drop the constraint of the PDP-11 instruction format in designing the extended virtual address space or *native mode* of the VAX-11 architecture. However, in order to run existing PDP-11 programs, VAX-11 includes a PDP-11 *compatibility mode*. Compatibility

mode provides the basic PDP-11 instruction set less only privileged instructions (such as HALT) and floating point instructions (which are optional on most PDP-11 processors and not required by most PDP-11 software).

In addition to compatibility mode, a number of other features to preserve PDP-11 investment have been provided in the VAX-11 architecture, the VAX-11 operating system VAX/VMS, and the VAX-11/780 implementation of the VAX-11 architecture. These features include:

1. The equivalent native mode data types and formats are identical to those on the PDP-11. Also, while extended, the VAX-11 native mode instruction set and addressing modes are very close to those on the PDP-11. As a consequence VAX-11 native mode assembly language programming is quite similar to PDP-11 assembly language programming.
2. The VAX-11/780 uses the same peripheral busses (Unibus and Massbus) as the PDP-11 and uses the same peripherals.
3. The VAX/VMS operating system is an evolution of the PDP-11 RSX-11M and IAS operating systems, offers a similar although extended set of system services, and uses the same command languages. Additionally, VAX/VMS supports most of the RSX-11M/IAS system service requests issued by programs executing in compatibility mode.
4. The VAX/VMS file system is the same as used on the RSX-11M/IAS operating systems permitting interchange of files and volumes. The file access methods as implemented by the RMS record manager are also the same.
5. VAX-11 high level language compilers accept the same source languages as the equivalent PDP-11 compilers and execution of compiled programs gives the same results.

The coverage of all these aspects of VAX-11 is well beyond the scope of any single paper. The remainder of this paper discusses the design of the VAX-11 native mode architecture and gives an overview of the VAX-11/780 system.

VAX-11 NATIVE ARCHITECTURE

Processor state

Like the PDP-11, VAX-11 is organized around a general register processor state. This organization was favored because access to operands stored in general registers is fast (since the registers are internal to the processor and register accesses do not need to pass through a memory management mechanism) and because only a small number of bits in an instruction are needed to designate a register. Perhaps most importantly, the registers are used (as on the PDP-11) in conjunction with a large set of addressing modes which permit unusually flexible operand addressing methods.

Some consideration was given to a pure stack based architecture. However it was rejected because real program data suggests the superiority of two or three operand instruction formats.[4] Actually VAX-11 is quite stack oriented, and although it is not optimally encoded for the purpose, can easily be used as a pure stack architecture if desired.

VAX-11 has 16 32-bit general registers (denoted R0-R15) which are used for both fixed and floating point operands. This is in contrast to the PDP-11 which has eight 16-bit general registers and six 64-bit floating point registers. The merged set of fixed and floating registers were preferred because it simplifies programming and permits a more effective allocation of the registers.

Four of the registers are assigned special meaning in the VAX-11 architecture:

1. R15 is the *program counter* (PC) which contains the address of the next byte to be interpreted in the instruction stream.
2. R14 is the *stack pointer* (SP) which contains the address of the top of the processor defined stack used for procedure and interrupt linkage.
3. R13 is the *frame pointer* (FP). The VAX-11 procedure calling convention builds a data structure on the stack called a stack frame. FP contains the address of this structure.
4. R12 is the *argument pointer* (AP). The VAX-11 procedure calling convention uses a data structure called an argument list. AP contains the address of this structure.

The remaining element of the user visible processor state (additional processor state seen mainly by privileged procedures is discussed later) is the 16-bit *processor status word* (PSW). The PSW contains the N, Z, V, and C condition codes which indicate respectively whether a previous instruction had a negative result, a zero result, a result which overflowed, or a result which produced a carry (or borrow). Also in the PSW are the IV, DV, and FU bits which enable processor trapping on integer overflow, decimal overflow, and floating underflow conditions respectively. (The trapping on conditions of floating overflow and divide by zero for any data type are always enabled.)

Finally, the PSW contains the T bit which when set forces a trap at the end of each instruction. This trap is useful for program debugging and analysis purposes.

Data types and formats

The VAX-11 data types are a superset of the PDP-11 data types. Where the PDP-11 and VAX-11 have equivalent data types the formats (representation in memory) are identical. Data type and data format identity is one of the most compelling forms of compatibility. It permits free interchange of binary data between PDP-11 and VAX-11 programs. It facilitates source level compatibility between equivalent PDP-11 and VAX-11 languages. It also greatly facilitates hardware implementation of and software support of the PDP-11 compatibility mode in the VAX-11 architecture.

The VAX-11 data types divide into five classes:

1. Integer data types are the 8-bit *byte*, the 16-bit *word*, the 32-bit *longword*, and the 64-bit *quadword*. Usually these data types are considered signed with negative values represented in two's complement form. However, for most purposes they can be interpreted as unsigned and the VAX-11 instruction set provides support for this interpretation.
2. Floating data types are the 32-bit *floating* and the 64-bit *double* floating. These data types are binary normalized, have an 8-bit signed exponent, and have a 25- or 57-bit signed fraction with the redundant most significant fraction bit not represented.
3. The *variable bit field* data type is 0 to 32 bits located arbitrarily with respect to addressable byte boundaries. A bit field is specified by three operands: the address of a byte, the starting bit position P with respect to bit 0 of that byte, and the size S of the field. The VAX-11 instruction set provides for interpreting the field as signed or unsigned.
4. The *character string* data type is 0 to 65535 contiguous bytes. It is specified by two operands: the length and starting address of the string. Although the data type is named "character string", no special interpretation is placed on the values of the bytes in the character string.
5. The *decimal string* data types are 0 to 31 digits. They are specified by two operands: a length (in digits) and a starting address. The primary data type is *packed decimal* with two digits stored in each byte except that the byte containing the least significant digit contains a single digit and the sign. Two ASCII character decimal types are supported: *leading separate* sign and *trailing embedded* sign. The leading separate type is a "+", "−", or "⟨blank⟩" (equivalent to "+") ASCII character followed by 0 to 31 ASCII decimal digit characters. A trailing embedded sign decimal string is 0 to 31 bytes which are ASCII decimal digit characters except for the character containing least significant digit which is an arbitrary encoding of the digit and sign.

All of the data types except field may be stored on arbitrary byte boundaries—there are no alignment constraints. The field data type, of course, can start on an arbitrary bit boundary.

Attributes of and symbolic representations for most of the data types are given in Table I and Figure 1.

TABLE I.—Data Types

DATA TYPE	SIZE	RANGE (decimal)	
Integer		Signed	Unsigned
Byte	8 bits	-128 to +127	0 to 255
Word	16 bits	-32768 to +32767	0 to 65535
Longword	32 bits	-2^{31} to $+2^{31}-1$	0 to $2^{32}-1$
Quadword	64 bits	-2^{63} to $+2^{63}-1$	0 to $2^{64}-1$
Floating Point		$\pm 2.9 \times 10^{-37}$ to 1.7×10^{38}	
Floating	32 bits	approximately seven decimal digits precision	
Double Floating	64 bits	approximately sixteen decimal digits precision	
Packed Decimal String	0 to 16 bytes (31 digits)	numeric, two digits per byte sign in low half of last byte	
Character String	0 to 65535 bytes	one character per byte	
Variable-length Bit Field	0 to 32 bits	dependent on intrepretation	

Instruction format and address modes

Most architectures provide a small number of relatively fixed instruction formats. Two problems often result. First, not all operands of an instruction have the same specification generality. For example, one operand must come from memory and another from a register; or one must come from the stack and another from memory. Second, only a limited number of operands can be accommodated: typically one or two. For instructions which inherently require more operands (such as field or string instructions), the additional operands are specified in ad hoc ways: small literal fields in instructions, specific registers or stack positions, or packed in fields of a single operand. Both these problems lead to increased programming complexity: they require superfluous move type instructions to get operands to places where they can be used and increase competition for potentially scarce resources such as registers.

To avoid these problems two criteria were used in the design of the VAX-11 instruction format: (1) all instructions should have the "natural" number of operands and (2) all operands should have the same generality in specification. These criteria led to a highly variable instruction format. An instruction consists of a one or two* byte *opcode* followed by the specifications for n operands ($n \geq 0$) where n is an implicit property of the opcode. An operand specification is one to 10 bytes in length and consists of a one or two byte *operand specifier* followed by (as required) zero to eight

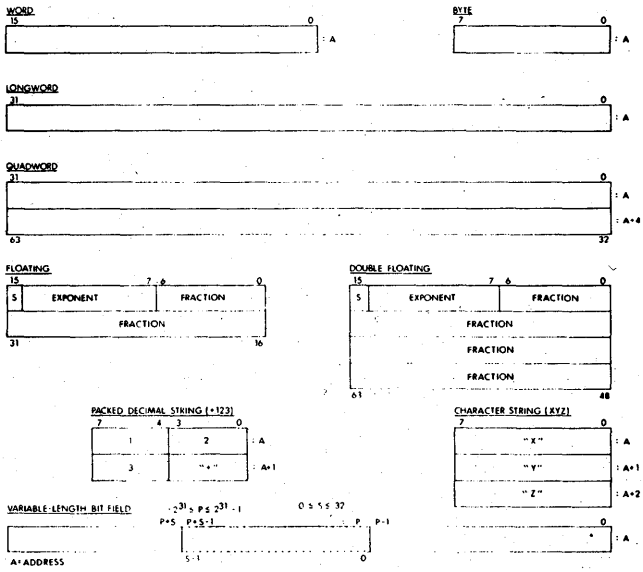

Figure 1—Data formats

* No currently defined instructions use two byte opcodes.

bytes of *specifier extension*. The operand specifier includes the address mode and designation of any registers needed to locate the operand. A specifier extension consists of a displacement, an address, or immediate data.

The VAX-11 address modes are with one exception a superset of the PDP-11 address modes. The PDP-11 address mode autodecrement deferred was omitted from VAX-11 because it was rarely used.

Most operand specifiers are one byte long and contain two 4-bit fields: the high order field (bits 7:4) contains the address mode designator and the lower field (bits 3:0) contains a general register designator. The address modes include:

1. *Register mode* in which the designated register contains the operand.
2. *Register deferred mode* in which the designated register contains the address of the operand.
3. *Autodecrement mode* in which the contents of the designated register are first decremented by the size (in bytes) of the operand and then used as the address of the operand.
4. *Autoincrement mode* in which the contents of the designated register are first used as the address of the operand and are then incremented by the size of the operand. Note that if the designated register is PC, the operand is located in the instruction stream. This use of autoincrement mode is called *immediate* mode. In immediate mode the one to eight bytes of data are the specifier extension.

   Autoincrement mode can be used sequentially to process a vector in one direction and autodecrement mode used to process a vector in the opposite direction. Autoincrement, register deferred, and autodecrement modes can be applied to a single register to implement a stack data structure: autodecrement to "push", autoincrement to "pop", and register deferred to access the top of the stack.
5. *Autoincrement deferred mode* in which the contents of the designated register are used as the address of a longword in memory which contains the address of the operand. After this use, the contents of the register are incremented by four (the size in bytes of the longword address). Note that if PC is the designated register, the absolute address of the operand is located in the instruction stream. This use of autoincrement deferred mode is termed *absolute* mode. In absolute mode the 4-byte address is the specifier extension.
6. *Displacement mode* in which a displacement is added to the contents of the designated register to form the operand address. There are three displacement modes depending on whether a signed byte, word, or longword displacement is the specifier extension. These modes are termed byte, word, and longword displacement respectively. Note that if PC is the designated register, the operand is located relative to PC. For this use the modes are termed byte, word, and longword *relative* mode respectively.
7. *Displacement deferred mode* in which a displacement is added to the designated register to form the address of a longword containing the address of the operand. There are three displacement deferred modes depending on whether a signed byte, word, or longword displacement is the specifier extension. These modes are termed byte, word, and longword displacement respectively. Note that if PC is the designated register, the operand address is located relative to PC. For this use the modes are termed byte, word, and longword *relative deferred* mode respectively.
8. *Literal mode* in which the operand specifier itself contains a 6-bit literal which is the operand. For integer data types the literal encodes the values 0-63; for floating data types the literal includes three exponent and three fraction bits to give 64 common values.
9. *Index mode* which is not really a mode but rather a one byte prefix operator for any other mode which evaluates to a memory address (i.e., all modes except register and literal). The index mode prefix is cascaded with the operand specifier for that mode (called the base operand specifier) to form an aggregate two byte operand specifier. The base operand specifier is used in the normal way to evaluate a base address. A copy of the contents of the register designated in the index prefix is multiplied by the size (in bytes) of the operand and added to the base address. The sum is the final operand address. There are three advantages to the VAX-11 form of indexing: (a) the index is scaled by the data size and thus the index register maintains a logical rather than a byte offset into an indexed data structure, (b) indexing can be applied to any of the address modes which generate memory addresses and this results in a comprehensive set of indexed addressing methods, and (c) the space required to specify indexing and the index register is paid only when indexing is used.

The VAX-11 assembler syntax for the address modes is given in Figure 2. The bracketed ({ }) notation is optional

Literal (Immediate)	{S↑ I↑} #constant	
Register	Rn	
Register Deferred	(Rn)	Indexed [Rx]
Autodecrement	-(Rn)	
Autoincrement	(Rn)+	
Autoincrement Deferred	@(Rn)+	
(Absolute)	@#address	
Displacement	{B↑ W↑ L↑} displacement(Rn) address	
Displacement Deferred	@{B↑ W↑ L↑} displacement(Rn) address	

n = 0 through 15
x = 0 through 14

Figure 2—Assembler syntax

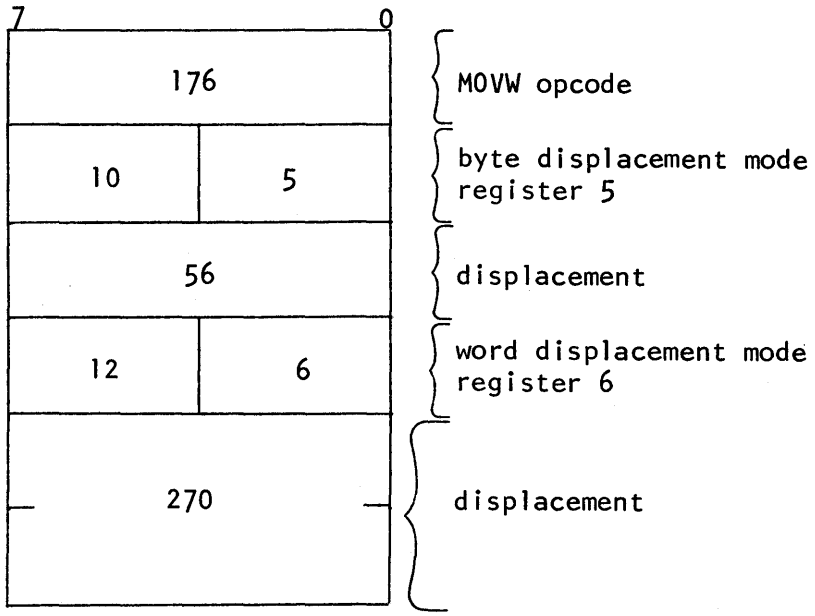

Figure 3—MOVW 56 (R5), 270(R7)

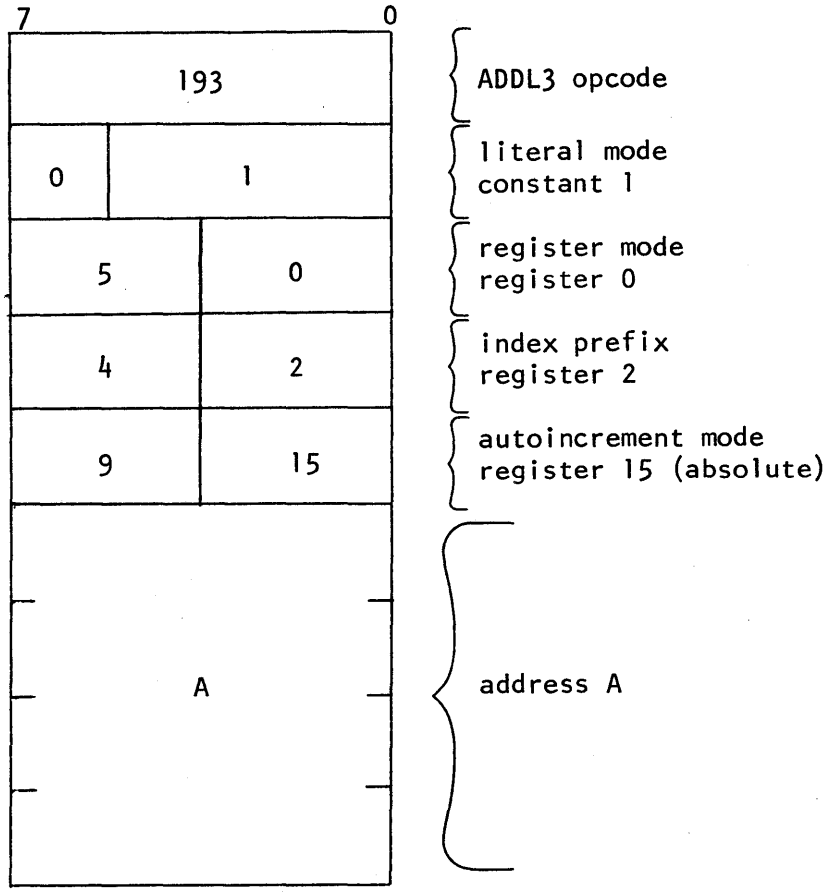

Figure 4—ADDL3 #1, RO, @#A[R2]

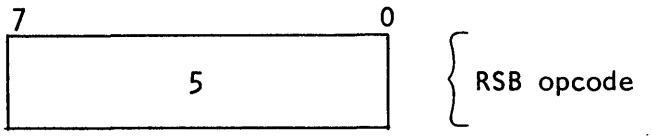

Figure 5—RSB

and the programmer rarely needs to be concerned with displacement sizes or whether to choose literal or immediate mode. The programmer writes the simple form and assembler chooses the address mode which produces the shortest instruction length.

In order to give a better feeling for the instruction format and assembler notation, several examples are given in Figures 3-5. In Figure 3 is an instruction which moves a word from an address which is 56 plus the contents of R5 to an address which is 270 plus the contents of R6. Note, that the displacement 56 is representable in a byte while the displacement 270 requires a word. The instruction occupies 6 bytes. In Figure 4 is an instruction which adds 1 to a longword in R0 and stores the result at a memory address which is the sum of A and 4 times the contents of R2. This instruction occupies 9 bytes. Finally, in Figure 5 is a return from subroutine instruction. It has no explicit operands and occupies a single byte.

The only significant instance where there is non-general specification of operands is in the specification of targets for branch instructions. Since invariably the target of a branch instruction is a small displacement from the current PC, most branch instructions simply take a one byte PC relative displacement. This is exactly as if byte displacement mode were used with the PC used as the register, except that the operand specifier byte is not needed. Because of the pervasiveness of branch instructions in code, this one byte saving results in a non-trivial reduction in code size. An example of the branch instruction branch on equal is given in Figure 6.

Instruction set

A major goal of the VAX-11 instruction set design was to provide for effective compiler generated code. Four decisions helped to realize this goal:

1. A very regular and consistent treatment of operators. Thus, for example, since there is a divide longword instruction, there are also divide word and divide byte instructions.

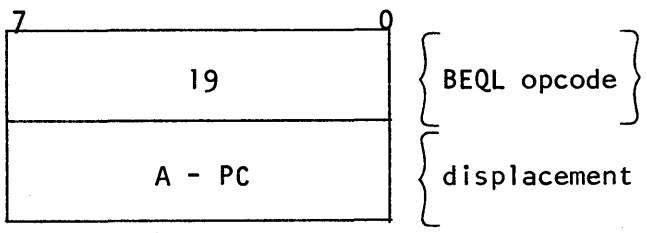

Figure 6—BEQL A

2. An avoidance of instructions unlikely to be generated by a compiler.
3. Inclusion of several forms of common operators. For example the integer add instructions are included in three forms: (a) one operand where the value one is added to an operand, (b) two operands where one operand is added to a second, and (c) three operands where one operand is added to a second and the result stored in a third. Since the VAX-11 instruction format allows fully general specifications of the operands, VAX-11 programs often have the structure (though not the encoding) of the canonic program form proposed in Reference 5.
4. Replacement of common instruction sequences with single instructions. Examples of this include procedure calling, multiway branching, loop control, and array subscript calculation.

The effect of these decisions is reflected in several observations. First, despite the larger virtual address and instruction set support for more data types, compiler (and hand) generated code for VAX-11 is typically smaller than the equivalent PDP-11 code for algorithms operating on data types supported by the PDP-11. Second, of the 243 instructions in the instruction set about 75 percent are generated by the VAX-11 FORTRAN compiler. Of the instructions not generated, most operate on data types not part of the FORTRAN language.

A complete list of the VAX-11 instructions is given in the Appendix. The following gives an overview of the instruction set.

1. *Integer logic and arithmetic*—Byte, word, and longword are the primary data types. A fairly conventional group of arithmetic and logical instructions is provided. The result generating dyadic arithmetic and logical instructions are provided in two and three operand forms. A number of optimizations are included: clear which is a move of zero; test which is a compare against zero; and increment and decrement which are an optimization of add one and subtract one respectively. A complete set of converts is provided which covers both the integer and the floating data types. In contrast to other architectures only a few shift type instructions are provided: it was felt that shifts are mostly used for field isolation which is much more conveniently done with the field instructions described later. In order to support greater than longword precision integer operations, a few special instructions are provided: extended multiply and divide and add with carry and subtract with carry.
2. *Floating point instructions*—Again a conventional group of instructions are included with result producing dyadic operators in two and three operand forms. Several specialized floating point instructions are included. The extended modulus instruction multiplies two floating operands together and stores the integer and fraction parts of the product in separate result operands. The polynomial instruction computes a polynomial

from a table of coefficients in memory. Both these instructions employ greater than normal precision and are useful in high accuracy mathematical routines. A convert rounded instruction is provided which implements the ALGOL rather than FORTRAN conventions for converting from floating point to integer.

3. *Address instructions*—The move address instructions store in the result operand the effective address of the source operand. The push address optimizations push on the stack (defined by SP) the effective address of the source operand. The latter are used extensively in subroutine calling.
4. *Field instructions*—The extract field instructions extract a 0 to 32-bit field, sign- or zero-extend it if it is less than 32 bits, and store it in a longword operand. The compare field instructions compare a (sign- or zero-extended if necessary) field against a longword operand. The find first instructions find the first occurrence of a set or clear bit in a field.
5. *Control instructions*—There is a complete set of conditional branches supporting both a signed and, where appropriate, an unsigned interpretation of the various data types. These branches test the condition codes and take a one byte PC relative branch displacement. There are three unconditional branch instructions: the first taking a one byte PC relative displacement, the second taking a word PC relative displacement, and the third—called jump—taking a general operand specification. Paralleling these three instructions are three branch to subroutine instructions. These push the current PC on the stack before transferring control. The single byte return from subroutine instruction returns from subroutines called by these instructions. There is a set of branch on bit instructions which branch on the state of a single bit and, depending on the instruction, set, clear, or leave unchanged that bit.

   The add compare and branch instructions are used for loop control. A step operand is added to the loop control operand and the sum compared against a limit operand. The result of the comparison determines whether the branch is taken. The sense of the comparison is based on the sign of the step operand. Optimizations of loop control include the add one and branch instructions which assume a step of one and the subtract one and branch instructions which assume a step of minus one and a limit of zero.

   The case instructions implement the computed go to in FORTRAN and case statements in other languages. A selector operand is checked to see that it lies in range and is then used to select one of table of PC relative branch displacements following the instruction.
6. *Queue instructions*—The queue representation is a doubly linked circular list. Instructions are provided to insert an item into a queue or to remove an item from a queue.
7. *Character string instructions*—The general move character instruction takes five operands specifying the lengths and starting addresses of the source and destination strings and a fill character to be used if the source string is shorter than the destination string. The instruction functions correctly regardless of string overlap. An optimized move character instruction assumes the string lengths are equal and takes three operands. Paralleling the move instructions are two compare character instructions. The move translated characters instruction is similar to the general move character instruction except that the source string bytes are translated by a translation table specified by the instruction before being moved to destination string. The move translated until escape instruction stops if the result of a translation matches the escape character specified by one of its operands. The locate and skip character instructions find respectively the first occurence or non-occurence of a character in a string. The scan and span instructions find respectively the first occurence or non-occurence of a character within a specified character set in a string. The match characters instruction finds the first occurence of a substring within a string which matches a specified pattern string.
8. *Packed decimal instructions*—A conventional set of arithmetic instructions is provided. The arithmetic shift and round instruction provides decimal point scaling and rounding. Converts are provided to and from longword integers, leading separate decimal strings, and trailing embedded decimal strings. A comprehensive edit instruction is included.

VAX-11 procedure instructions

A major goal of the VAX-11 design was to have a single system wide procedure calling convention which would apply to all inter-module calls in the various languages, calls for operating system services, and calls to the common run time system. Three VAX-11 instructions support this convention: two call instructions which are indistinguishable as far as the called procedure is concerned and a return instruction.

The call instructions assume that the first word of a procedure is an *entry mask* which specifies which registers are to be used by the procedure and thus need to be saved. (Actually only R0-R11 are controlled by the entry mask and bits 15:12 of the mask are reserved for other purposes.) After pushing the registers to be saved on the stack, the call instruction pushes AP, FP, PC, a longword containing the PSW and the entry mask, and a zero valued longword which is the initial value of a condition handler address. The call instruction then loads FP with the contents of SP and AP with the argument list address. The appearance of the stack frame after the call is shown in the upper part of Figure 7.

The form of the argument list is shown in the lower part of Figure 7. It consists of an argument count and list of longword arguments which are typically addresses. The CALLG instruction takes two operands: one specifying the procedure address and the other specifying the address of the argument list assumed arbitrarily located in memory.

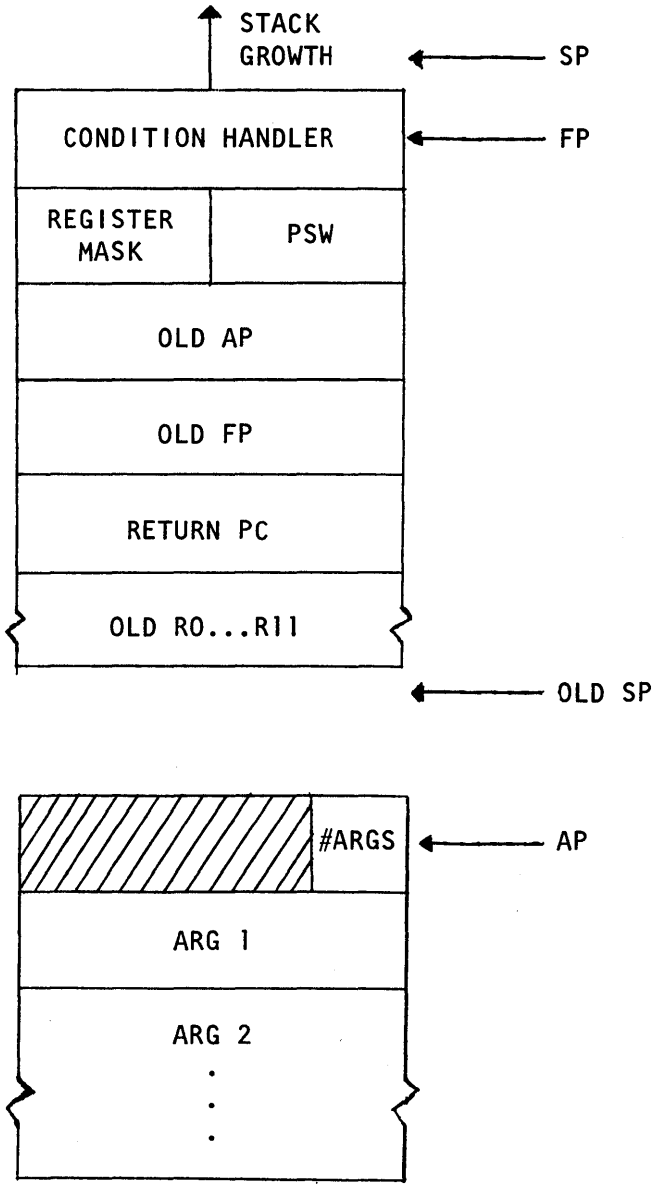

Figure 7—Stack frame

The CALLS instruction also takes two operands: one the procedure address and the other an argument count. CALLS assumes that the arguments have been pushed on the stack and pushes the argument count immediately prior to saving the registers controlled by the entry mask. It also sets bit 13 of the saved entry mask to indicate a CALLS instruction was used to make the call.

The return instruction uses FP to locate the stack frame. It loads SP with the contents of FP and restores PSW through PC by popping the stack. The saved entry mask controls the popping and restoring of R11 through R0. Finally if the bit indicating CALLS was set, the argument list is removed from the stack.

Memory management design alternatives

Memory management comprises the mechanisms used (1) to map the virtual addresses generated by processes to physical memory addresses, (2) to control access to memory (i.e., to control whether a process has read, write, or no access to various areas of memory), and (3) to allow a process to execute even if all of its virtual address space is not simultaneously mapped to physical memory (i.e., to provide so called virtual memory facilities). The memory management proved to be the most difficult part of the architecture to design. Three alternatives were pursued and full designs were completed for the first two alternatives and nearly completed for the third. The three alternatives* were:

1. A paged form of memory management with access control at the page level and a small number (4) of hierarchical access modes whose use would be dedicated to specific purposes. This represented an evolution of the PDP-11/70 memory management.
2. A paged and segmented form with access control at the segment level and a larger number (8) of hierarchical access modes which would be used quite generally. Although it differed in a number of ways, the design was motivated by the Multics[6,7] architecture and the Honeywell 6180 implementation.
3. A capabilities[8,9] form with access control provided by the capabilities and the ability to page larger objects described by the capabilities.

The first alternative was finally selected. The second alternative was rejected because it was felt that the real increase in functionality provided inadequately offset the increased architectural complexity. The third alternative appeared to offer functionality advantages that could be useful over the longer term. However, it was unlikely that these advantages could be exploited in the near term. Further it appeared that the complexity of the capabilities design was inappropriate for a minicomputer system.

Memory mapping

The 4.3 gigabyte virtual address space is divided into four regions as shown in Figure 8. The first two regions—the *program* and *control* regions—comprise the per process virtual address space which is uniquely mapped for each process. The second two regions—the *system* region and a region reserved for future use—comprise the system virtual address space which is singly mapped for all processes.

Each of the regions serves different purposes. The program region contains user programs and data and the top of the region is a dynamic memory allocation point. The control

* It should not be construed that memory management is independent of the rest of the architecture. The various memory management alternatives required different definitions of the addressing modes and different instruction level support for addressing.

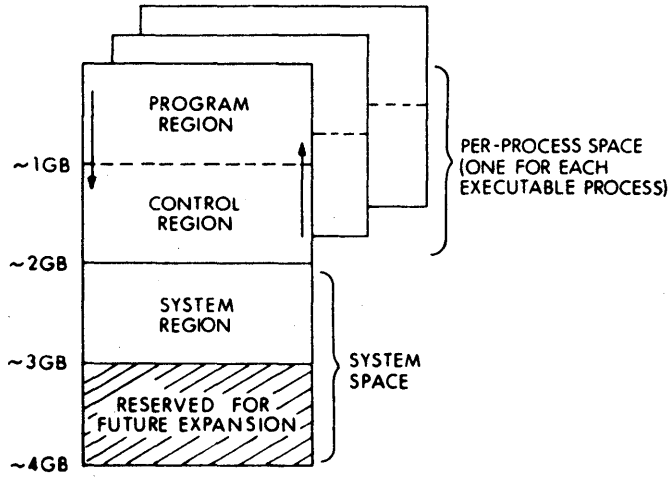

Figure 8—Virtual address space

region contains operating system data structures specific to the process and the user stack. The system region contains procedures which are common to all processes (such as those that comprise the operating system and RMS) and (as will be seen later) page tables.

A virtual address has the structure shown in the upper part of Figure 9. Bits 8:0 specify a byte within a 512 byte *page* which is the basic unit of mapping. Bits 29:9 specify a *virtual page number* (VPN). Bits 31:30 select the virtual address region. The mechanism of mapping consists of using the region select bits to select a *page table* which consists of *page table entries* (PTEs). After a check that it is not too large, the VPN is used to index into the page table to select a PTE. The PTE contains either (1) 21-bit physical *page frame number* which is concatenated with the nine low order byte in page bits to form a 30-bit physical address shown in the lower part of Figure 9, or (2) an indication that the virtual page accessed is not in physical memory. The latter case is called a *page fault*. Instruction execution in the current procedure is suspended and control is transferred to an operating system procedure which will cause the missing virtual page to be brought into physical memory. At this point instruction execution in the suspended procedure can resume transparently.

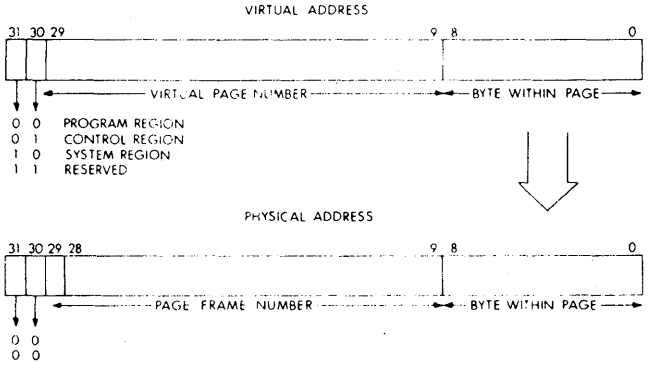

Figure 9—Virtual and physical addresses

The page table for the system region is defined by the *system base register* which contains the physical address of the start of the system region page table and the *system length register* which contains the length of the table. Thus the system page table is contiguous in physical memory.

The per process space page tables are defined similarly by the *program* and *control region base registers* and *length registers*. However, the base registers do not contain physical addresses: rather, they contain system region virtual addresses. Thus the per process page tables are contiguous in the system region virtual address space and are not necessarily contiguous in physical memory. This placement of the per process page tables permits them to be paged and avoids what would otherwise be a serious physical memory allocation problem.

Access control

At a given point in time a process executes in one of four *access modes*. The modes from most privileged to least are called *kernel, executive, supervisor* and *user*. The use of these modes by VAX/VMS is as follows:

1. Kernel—Interrupt and exception handling, scheduling, paging, physical I/O, etc.
2. Executive—Logical I/O as provided by RMS.
3. Supervisor—The command interpreter.
4. User—User procedures and data.

The accessibility of each page (read, write, or no access) from each access mode is specified in the PTE for that page. Any attempt to improperly access a page is suppressed and control is transferred to an operating system procedure. The accessibility is assumed hierarchically ordered: if a page is writable from any given mode, it is also readable; and if a page is accessible from a less privileged mode, it is accessible from a more privileged mode. Thus, for example, a page can be readable and writable from kernel mode, only readable from executive mode, and inaccessible from supervisor and user modes.

A procedure executing in a less privileged mode often needs to call a procedure which executes in a more privileged mode: e.g., a user program needs an operating system service performed. The access mode is changed to a more privileged mode by executing a change mode instruction which transfers control to a routine executing at the new access mode. A return is made to original access mode by executing a return from exception or interrupt instruction (REI).

The *current access mode* is stored in the *processor status longword* (PSL) whose low order 16 bits comprise the PSW. Also stored in the PSL is the *previous access mode*; i.e., the access mode from which the current access mode was called. The previous mode information is used by the special probe instructions which validate arguments passed in cross access mode calls.

Procedures running at each of the access modes require a

separate stacks with appropriate accessibility. To facilitate this, each process has four copies of SP which are selected according to the current access mode field in the PSL. A procedure always accesses the correct stack by using R14.

In an earlier section, it was stated that the VAX-11 standard CALL instruction is used for all calls including those for operating system services. Indeed procedures do call the operating system using the CALL instruction. The target of the CALL instruction is the minimal procedure consisting of an entry mask, a change mode instruction, and a return instruction. Thus access mode changing is transparent to the calling procedure.

Interrupts and exceptions

Interrupts and exceptions are forced changes in control flow other than that explicitly indicated by the executing program. The distinction between them is that interrupts are normally unrelated to the currently executing program while exceptions are a direct consequence of program execution. Examples of interrupt conditions are status changes in I/O devices while examples of exception conditions are arithmetic overflow or a memory management access control violation.

VAX-11 provides a 31 priority level interrupt system. Sixteen levels (16-31) are provided for hardware while 15 levels (1-15) are provided for software. (Level 0 is used for normal program execution.) The current *interrupt priority level* (IPL) is stored in a field in the PSL. When an interrupt request is made at a level higher than IPL, the current PC and PSL are pushed on the stack and new PC obtained from a vector selected by the interrupt requester (a new PSL is generated by the CPU). Interrupts are serviced by routines executing with kernel mode access control. Since interrupts are appropriately serviced in a system wide rather than a specific process context, the stack used for interrupts is defined by another stack pointer called the *interrupt stack pointer*. (Just as for the multiple stack pointers used in process context, an interrupt routine accesses the interrupt stack using R14.) An interrupt service is terminated by execution of an REI instruction which loads PC and PSL from the top two longwords on the stack.

Exceptions are handled like interrupts except for the following: (1) since exceptions arise in a specific process context, the kernel mode stack for that process is used to store PC and PSL and (2) additional parameters (such as the virtual address causing a page fault) may be pushed on the stack.

Process context switching

From the standpoint of the VAX-11 architecture, the process state or context consists of:

1. The 15 general registers R0-R13 and R15.
2. Four copies of R14 (SP): one for each of kernel, executive, supervisor, and user access modes.
3. The PSL.
4. Two base and two limit registers for the program and control region page tables.

This context is gathered together in a data structure called a *process control block* (PCB) which normally resides in memory. While a process is executing, the process context can be considered to reside in processor registers. To switch from one process to another it is required that the process context from the previously executing process be saved in its PCB in memory and the process context for the process about to be executed to be loaded from its PCB in memory. Two VAX-11 instructions support context switching. The save process context instruction saves the complete process context in memory while the load process context instruction loads the complete process context from memory.

I/O

Much like the PDP-11, VAX-11 has no specific I/O instructions. Rather, I/O devices and device controllers are implemented with a set of registers which have addresses in the physical memory address space. The CPU controls I/O devices by writing these registers; the devices return status by writing these registers and the CPU subsequently reading them. The normal memory management mechanism controls access to I/O device registers and a process having a particular device's registers mapped into its address space can control that device using the regular instruction set.

Compatibility mode

As mentioned in the VAX-11 overview, compatibility mode in the VAX-11 architecture provides the basic PDP-11 instruction set less privileged and floating point instructions. Compatibility mode is intended to support a user as opposed to an operating system environment. Normally a compatibility mode program is combined with a set of native mode procedures whose purpose is to map service requests from some particular PDP-11 operating system environment into VAX/VMS services.

In compatibility mode the 16-bit PDP-11 addresses are

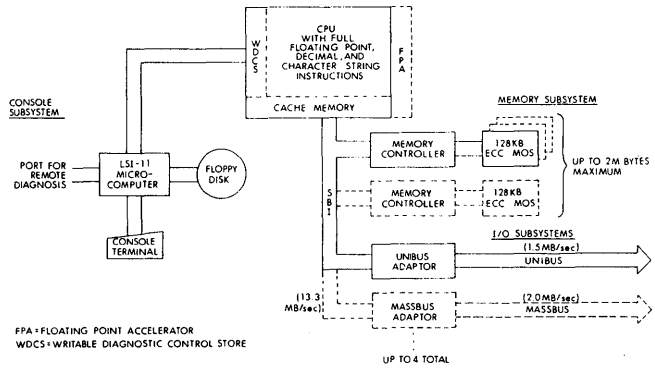

Figure 10—VAX-11/780 system

zero-extended to 32-bits where standard native mode mapping and access control apply. The eight 16-bit PDP-11 general registers overmap the native mode general registers R0-R6 and R15 and thus the PDP-11 processor state is contained wholly within the native mode processor state.

Compatibility mode is entered by setting the compatibility mode bit in the PSL. Compatibility mode is left by executing a PDP-11 trap instruction (such as used to make operating service requests), and on interrupts and exceptions.

VAX-11/780 IMPLEMENTATION

VAX-11/780

The VAX-11/780 computer system is the first implementation of the VAX-11 architecture. For instructions executed in compatibility mode, the VAX-11/780 has a performance comparable to the PDP-11/70. For instructions executed in native mode, the -11/780 has a performance in excess of the -11/70 and thus represents the new high end of the -11 (LSI-11, PDP-11, VAX-11) family.

A block diagram of the -11/780 system is given in Figure 10. The system consists of a central processing unit (CPU), the console subsystem, the memory subsystem, and the I/O subsystem. The CPU and the memory and I/O subsystems are joined by a high speed synchronous bus called the *Synchronous Backplane Interconnect* (SBI).

CPU

The CPU is a microprogrammed processor which implements the native and compatibility mode instruction sets, the memory management, and the interrupt and exception mechanisms. The CPU has 32-bit main data paths and is built almost entirely of conventional Shottky TTL components.

To reduce effective memory access time the CPU includes an 8K byte write through cache or buffer memory. The cache organization is 2-way associative with an 8-byte block size. To reduce delays due to writes, the CPU includes a write buffer. The CPU issues the write to the buffer and the actual memory write takes place in parallel with other CPU activity.

The CPU contains a 128 entry address translation buffer which is a cache of recent virtual to physical translations. The buffer is divided into two 64 entry sections: one for the per process regions and one for the system region. This division facilitates permitting the system region translations to remain unaffected by a process context switch.

A fourth buffer in the CPU is the 8-byte instruction buffer. It serves two purposes. First, it decomposes the highly variable instruction format into its basic components and, second, it constantly fetches ahead to reduce delays in obtaining the instruction components.

The CPU includes two standard clocks. The programmable real-time clock is used by the operating system for local timing purposes. The time-of-year clock with its own battery backup is the long term time reference for the operating system. It is automatically read on system startup to eliminate the need for manual entry of data and time.

The CPU includes 12K bytes of writable diagnostic control store (WDCS) which is used for diagnostic purposes, implementation of certain instructions, and for future microcode changes. As an option for very sophisticated users, another 12K bytes of writable control store is available.

A second option is the floating point accelerator (FPA). Although the basic CPU implements the full floating point instruction set, the FPA provides high speed floating point hardware. It is logically invisible to programs and only affects their running time.

Console subsystem

The console subsystem is centered around an LSI-11 computer with 16K bytes of RAM and 8K bytes of ROM (used to store the LSI-11 bootstrap, LSI-11 diagnostics, and console routines). Also included are a floppy disk, an interface to the console terminal, and a port for remote diagnostic purposes.

The floppy disk in the console subsystem serves multiple purposes. It stores the main system bootstrap and diagnostics and serves as a medium for distribution of software updates.

SBI

The SBI is the primary control and data transfer path in the -11/780 system. Because the cache and write buffer largely decouple the CPU performance from the memory access time, the SBI design was optimized for bandwidth and reliability rather than the lowest possible access time.

The SBI is a synchronous bus with a cycle time of 200 nsec. The data path width of the SBI is 32 bits. During each 200 nsec cycle either 32 bits of data or a 30-bit physical address can be transferred. Since each 32-bit read or write requires transmission of both address and data, two SBI cycles are used for a complete transaction. The SBI protocol permits 64-bit reads or writes using one address cycle and two data transfer cycles: the CPU and I/O subsystem use this mode whenever possible. For read transactions the bus is reacquired by the memory in order to send the data: thus the bus is not held during the memory access time.

Arbitration of the SBI is distributed: each interface to the SBI has a specific priority and its own bus request line. When an interface wishes to use the bus, it asserts its bus request line. If at the end of a 200 nsec cycle there are no interfaces of higher priority requesting the bus, the interface takes control of the bus.

Extensive checking is done on the SBI. Each transfer is parity checked and confirmed by the receiver. The arbitration process and general observance of the SBI protocol are checked by each SBI interface during each SBI cycle. The processor maintains a running 16-cycle history of the SBI:

any SBI error condition causes this history to be locked and preserved for diagnostic purposes.

Memory subsystem

The memory subsystem consists of one or two memory controllers with up to 1M bytes of memory on each. The memory is organized in 64-bit quadwords with an 8-bit ECC which provides single bit error correction and double bit error detection. The memory is built of 4K MOS RAM components.

The memory controllers have buffers which hold up to four memory requests. These buffers substantially increase the utilization of the SBI and memory by permitting the pipelining of multiple memory requests. If desired, quadword physical addresses can be interleaved across the memory controllers.

As an option, battery backup is available which preserves the contents of memory across short term power failures.

I/O subsystem

The I/O subsystem consists of buffered interfaces or adapters between the SBI and the two types of peripheral busses used on PDP-11 systems: the Unibus and the Massbus. One Unibus adapter and up to four Massbus adapters can be configured on a VAX-11/780 system.

The Unibus is a medium speed multiplexor bus which is used as a primary memory as well as peripheral bus in many PDP-11 systems. It has an 18-bit physical address space and supports byte and word transfers. In addition to implementing the Unibus protocol and transmitting interrupts to the CPU, the Unibus adapter provides two other functions. The first is mapping 18-bit Unibus addresses to 30-bit SBI physical addresses. This is accomplished in a manner substantially identical to the virtual to physical mapping implemented by the CPU. The Unibus address space is divided into 512 512-byte pages. Each Unibus page has a page table entry (residing in the Unibus adapter) which maps addresses in that page to physical memory addresses. In addition to providing address translation, the mapping permits contiguous transfers on the Unibus which cross page boundaries to be mapped to discontiguous physical memory page frames.

The second function performed by the Unibus adapter is assembling 16-bit Unibus transfers (both reads and writes) into 64-bit SBI transfers. This operation (which is applicable only to block transfers such as from disks) appreciably reduces SBI traffic due to Unibus operations. There are 15 8-byte buffers in the Unibus adapter permitting 15 simultaneous buffered transactions. Additionally there is a un-buffered path through the Unibus adapter permitting an arbitrary number of simultaneous un-buffered transfers.

The Massbus is a high speed block transfer bus used primarily for disks and tapes. The Massbus adapter provides much the same functionality as the Unibus adapter. The physical addresses into which transfers are made are defined by a page table: again this permits contiguous device transfers into discontiguous physical memory.

Buffering is provided in the Massbuss adapter which minimizes the probability of device overruns and assembles data into 64-bit units for transfer over the SBI.

ACKNOWLEDGMENTS

Although the final architecture is the result of several design iterations involving many hardware and software engineers, the author would like to acknowledge the other members of the initial architectural group: Gordon Bell, Peter Conklin, Dave Cutler, Bill Demmer, Tom Hastings, Richy Lary, Dave Rodgers and Steve Rothman. Mary Jane Forbes and Louise Principe deserve special thanks for typing this manuscript.

APPENDIX—VAX-11 INSTRUCTION SET

Integer and Floating Point Logical Instructions

MOV-	Move(B,W,L,F,D,Q)*
MNEG-	Move Negated(B,W,L,F,D)
MCOM-	Move Complemented(B,W,L)
MOVZ-	Move Zero-Extended(BW,BL,WL)
CLR-	Clear(B,W,L=F,Q=D)
CVT--	Convert(B,W,L,F,D)(B,W,L,F,D)
CVTR-L	Convert Rounded(F,D) to Longword
CMP-	Compare(B,W,L,F,D)
TST-	Test(B,W,L,F,D)
BIS-2	Bit Set(B,W,L)2-Operand
BIS-3	Bit Set(B,W,L)3-Operand
BIC-2	Bit Clear(B,W,L)2-Operand

* B = byte, W = word, L = longword, F = floating, D = double floating, Q = quadword, S = set, C = clear.

BIC-3	Bit Clear(B,W,L)3-Operand
BIT-	Bit Test(B,W,L)
XOR-2	Exclusive OR(B,W,L)2-Operand
XOR-3	Exclusive OR(B,W,L)3-Operand
ROTL	Rotate Longword
PUSHL	Push Longword

Integer and Floating Point Arithmetic Instructions

INC-	Increment(B,W,L)
DEC-	Decrement(B,W,L)
ASH-	Arithmetic Shift(L,Q)
ADD-2	Add(B,W,L,F,D)2-Operand
ADD-3	Add(B,W,L,F,D)3-Operand
ADWC	Add with Carry
ADAWI	Add Aligned Word Interlocked
SUB-2	Subtract(B,W,L,F,D)2-Operand
SUB-3	Subtract(B,W,L,F,D)3-Operand
SBWC	Subtract with Carry
MUL-2	Multiply(B,W,L,F,D)2-Operand
MUL-3	Multiply(B,W,L,F,D)3-Operand
EMUL	Extended Multiply
DIV-2	Divide(B,W,L,F,D)2-Operand
DIV-3	Divide(B,W,L,F,D)3-Operand
EDIV	Extended Divide
EMOD-	Extended Modulus(F,D)
POLY-	Polynomial Evaluation (F,D)

Index Instruction

INDEX	Compute Index

Packed Decimal Instructions

MOVP	Move Packed
CMPP3	Compare Packed 3-Operand
CMPP4	Compare Packed 4-Operand
ASHP	Arithmetic Shift Round and Packed
ADDP4	Add Packed 4-Operand
ADDP6	Add Packed 6-Operand
SUBP4	Subtract Packed 4-Operand
SUBP6	Subtract Packed 6-Operand
MULP	Multiply Packed
DIVP	Divide Packed
CVTLP	Convert Long to Packed
CVTPL	Convert Packed to Long
CVTPT	Convert Packed to Trailing
CVTTP	Convert Trailing to Packed
CVTPS	Convert Packed to Separate
CVTSP	Convert Separate to Packed
EDITPC	Edit Packed to Character String

Character String Instructions

MOVC3	Move Character 3-Operand
MOVC5	Move Character 5-Operand
MOVTC	Move Translated Characters
MOVTUC	Move Translated Until Character
CMPC3	Compare Characters 3-Operand
CMPC5	Compare Characters 5-Operand
LOCC	Locate Character
SKPC	Skip Character
SCANC	Scan Characters
SPANC	Span Characters
MATCHC	Match Characters

Variable-Length Bit Field Instructions

EXTV	Extract Field
EXTZV	Extract Zero-Extended Field
INSV	Insert Field
CMPV	Compare Field
CMPZV	Compare Zero-Extended Field
FFS	Find First Set
FFC	Find First Clear

Branch on Bit Instructions

BLB-	Branch on Low B(S,Cl)
BB-	Branch on Bit(S,Cl)
BBS-	Branch on Bit Set and(S,Cl)Bit
BBC	Branch on Bit Clear and(Set,lear)Bit
BBSSI	Branch on Bit Set and Set Bit Interlocked
BBCCI	Branch on Bit Clear and Clear Bit Interlocked

Queue Instructions

INSQUE	Insert Entry in Queue
REMQUE	Remove Entry from Queue

Address Manipulation Instructions

MOVA-	Move Address(B,W,L=F,Q=D)
PUSHA-	Push Address(B,W,L=F,Q=D)on Stack

Processor State Instructions

PUSHR	Push Registers on Stack
POPR	Pop Registers from Stack
MOVPSL	Move from Processor Status Longword
BISPSW	Bit Set Processor Status Word
BICPSW	Bit Clear Processor Status Word

Unconditional Branch and Jump Instructions

BR-	Branch with(B,W)Displacement
JMP	Jump

Branch on Condition Code

BLSS	Less Than
BLSSU	Less Than Unsigned
(BCS)	(Carry Set)
BLEQ	Less Than or Equal
BLEQU	Less Than or Equal Unsigned
BEQL	Equal
(BEQLU)	(Equal Unsigned)
BNEQ	Not Equal
(BNEQU)	(Not Equal Unsigned)
BGTR	Greater Than
BGTRU	Greater Than Unsigned
BGEQ	Greater Than or Equal
BGEQU	Greater Than or Equal Unsigned
(BCC)	(Carry Clear)
BVS	Overflow Set
BVC	Overflow Clear

Loop and Case Branch

ACB-	Add, Compare and Branch(B,W,L,F,D)
AOBLEQ	Add One and Branch Less Than or Equal
AOBLSS	Add One and Branch Less Than
SOBGEQ	Subtract One and Branch Greater Than or Equal
SOBGTR	Subtract One and Branch Greater Than
CASE-	Case on(B,W,L)

Subroutine Call and Return Instructions

BSB	Branch to Subroutine with(B,W)Displacement
JSB	Jump to Subroutine
RSB	Return from Subroutine

Procedure Call and Return Instructions

CALLG	Call Procedure with General Argument List
CALLS	Call Procedure with Stack Argument List
RET	Return from Procedure

Access Mode Instructions

CHM	Change Mode to (Kernel,Executive,Supervisor,User)
REI	Return from Exception or Interrupt
PROBER	Probe Read
PROBEW	Probe Write

Privileged Processor Register Control Instructions

SVPCTX	Save Process Context
LDPCTX	Load Process Context
MTPR	Move to Process Register
MFPR	Move from Processor Register

Special Function Instructions

CRC	Cyclic Redundancy Check
BPT	Breakpoint Fault
XFC	Extended Function Call
NOP	No Operation
HALT	Halt

Pepe architecture—Present and future*

INTRODUCTION

PEPE (Parallel Element Processing Ensemble) was designed, developed, and produced for the U.S. Army Ballistic Missile Defense Advanced Technology Center (BMDATC) for research on Ballistic Missile Defense (BMD) systems. With its host computer, the CDC 7600, it is potentially the world's most powerful computer system. PEPE employs parallel processing and associative data-access techniques, and while it can operate in a stand alone mode, it is designed primarily to augment more conventional computers in BMD service. Potential applications besides BMD for which the machine is adapted include weather forecasting, air traffic control, image data processing, signal processing, and other applications exhibiting inherent parallelism and requiring extensive computational power.

The PEPE system can be considered simply as a large master computer, called a host, controlling many smaller slave processors, called elements. In the present design, the host is a CDC 7600, and there are 288 elements. Each element comprises three processors sharing a common data memory. One of these processors, called a correlation unit, is used for inputting data and has an instruction repertoire especially suited for the rapid association of new data with data already on file. The second processor, called the arithmetic unit, has a repertoire similar to that featured in conventional high-power general-purpose machines; i.e., fixed and floating point arithmetic operations, load and store, and logical operations. The third processor, called the associative output unit, is used for ordering and outputting data and is especially designed to perform complex, multidimensional file searches rapidly and efficiently. Each of the three processors is driven by its own control unit, which simultaneously drives all of the corresponding processors in the ensemble of elements. The three control units are also capable of executing their own sequential programs. They are combined into a control console, which drives the ensemble of elements in parallel and interfaces the ensemble with the host. The complete PEPE/Host system, then, is a multiprocessor employing seven processor types in all (host, three sequential processors, and three parallel processors). All seven processor types are capable of simultaneous, overlapped operation.

Software for the PEPE includes the compilers and assemblers for the seven PEPE processors and a linkage editor for binding programs into executable load modules. The entire machine can be programmed in a single language called PFOR, which is a superset of FORTRAN. System software also includes an instruction-level simulator for PEPE, a general-purpose real-time operating system, and a general utilities package.

The PEPE program was a complete system effort, requiring problem analysis; generation of a hierarchy of system, functional, and implementation specifications; hardware design, development, production, and test; system support software design, development, production and test; tactical/problem software design, development, and test; and integration into a total real-time systems environment employing other computers, missiles, radars, and command, communications, and control networks. All of these activities were carried on concurrently. Moreover, much of the hardware architecture and programming techniques had never before been attempted on such a large scale for real-time service. It was obvious, therefore, that conventional procedures for executing a development program of this magnitude and in particular developing the PEPE architecture would not be adequate. Such procedures, employing the traditional sequence of problem analysis, design, hardware development, hardware fabrication and test, program design, development, production and test, and finally system test and validation, often result in major system errors being discovered in the last phase of the sequence when it is too late to do much about them. Because of the complexity of the PEPE development program, major system design errors would almost certainly occur (under the conventional pro-

cedures) and would propagate through the various stages of the program to be discovered in the final stage, system validation. To avoid the high risk inherent in the conventional procedures, PEPE system designers decided to employ a top-down design approach in which system validation started early and continued throughout the entire program. Thus, the program would be executed in a logical progression of *validated* baseline steps. The validation would be accomplished through a combination of functional and analytic simulations. Early in the project, the architecture and the operating system were validated via functional simulations which modeled the operation of the PEPE in a BMD environment employing a variety of attack scenarios. Further functional simulations of more complex environments employing PEPE in the National BMD Site Defense System were completed during the first half of 1975. A 36-element version of the PEPE hardware was delivered to the BMDATC Advanced Research Center in Huntsville in April 1976. Analytic simulations, employing the instruction-level hardware simulator and the PEPE hardware itself, were conducted during the last three years.

BMD DATA PROCESSING PROBLEM

Figure 1 portrays a simplified subset of the BMD data processing problem; only that part of the total problem associated with detecting, tracking, and classifying targets in the field of view of the radar is considered in this paper. The radar generates a pencil beam capable of being pointed, within a few microseconds, in any direction within the surveillance volume. Beams are either transmit or receive beams; each transmit beam can generate any one of a number of different pulse configurations (carrier frequency, number of pulses, pulse coding, frequency modulation, pulse length, etc., can be varied) and each receive beam can likewise assume any one of a number of configurations (carrier frequency, range extent, matched filter, etc., can be varied). Typically, the radar generates several thousand transmit beams per second and a proportionate number of receive beams. Generally, several hundred transmit and receive beam pairs are reserved for searching the upper part of the surveillance volume; these are generated in a raster scan pattern designed so that no object can penetrate the volume without being detected by at least one search beam. Interleaved at random in both time and space among the search beams, as required by the target environment and battle situation, are a variety of special beams for verifying search detections, precision tracking of previously detected and acquired targets, transmitting guidance commands to interceptors, target discrimination and classification, and several other functions. It is the job of the computer to initiate a file on each detected object, associate each radar return with its proper file, employ the information in each return to update the file, perform complex mathematical functions on the files, and generate requests for additional radar information. Each request becomes part of the file on a particular target. Periodically, the files are searched in some sort of priority fashion to generate orders for radar pulses. Details on each pulse are formulated individually by the computer based on the requests in the target files; those requests which are granted are transmitted to the radar in the form of orders. The objective is to select, for each pulse, that order which will be of most benefit to the defense system at that time. The radar transmits the ordered pulses, new returns are thereby obtained, and the radar computer loop is closed. The foregoing functions must all be performed within rather severe time deadlines. The BMD data processing problem, then, can be described as keeping a large, complex data base updated in real time. Moreover, the means for acquiring the information required for updating is under control of the computer.

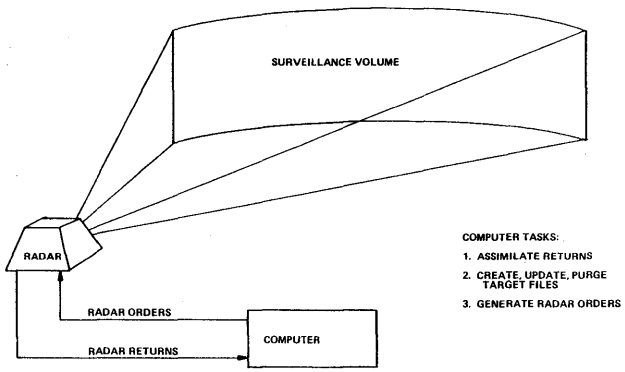

Figure 1—Partial BMD system

Considering the above rather simplified description of a representative part of the BMD data processing problem, one can deduce the types of processing required, and then synthesize a machine architecture to satisfy the requirements; this was done in the case of the PEPE design.

First, means must be provided to associate verified radar search returns with target data already on file in computer memory. Every such return must be compared with all target data on file. Each comparison, or association operation, requires a forward prediction of all filed target positions to the time of the return, calculation of three-dimensional gates (gate dimensions may be more or less than 3, depending on correlation criteria) about the positions, and a match of the radar return against all gate volumes.

A conventional sequential computer must execute the foregoing operations as an $m \times n$ number of operations, where m is the number of new returns in a given time interval and n is the number of targets on file. This means that the data processing resources required for correlation of new returns is an exponential function of the target traffic. Since correlation is one of the major consumers of sequential computer resources in BMD service, an architecture that performs correlation more efficiently is indicated. Associative processors perform the correlation function as an $m \times 1$ number of operations, independent of the number of targets on file. Therefore, a computer architecture for BMD service could advantageously possess associative data input characteristics.

Second, lengthy scientific computations must be made on a large number of separate, independent data sets, as in Kalman filtering of radar returns. Computations are identical

for all targets, so that considerable leverage could be obtained by assigning targets to separate, dedicated execution units operating on data in dedicated memories, all driven simultaneously from a single control unit executing a single program. Therefore, a computer architecture for BMD service could advantageously possess parallel processing characteristics.

Third, multidimensional, prioritized file searches must be made through target files for radar pulse requests, so that the radar pulses can be scheduled efficiently, in observance of a variety of constraints, and in accordance with the immediate needs of the instantaneous total battle environment. Such searches are made inefficiently in conventionally addressed memories, but very efficiently in associative memories. Therefore, a computer architecture for BMD service could advantageously employ associative data retrieval and output characteristics. Moreover, associative data retrieval would be of great assistance in one of the most critical and resource-consuming functions which must be performed in a total BMD system, a function largely ignored in this paper. The function is that of real-time control, or assigning resources and adjusting algorithms, procedures, function execution rates, and overall system behavior dynamically and optimally in accordance with instantaneous system demands, status, and defense strategy. This function, because it is sequential and decision-making in general, is best handled on a conventional sequential computer. However, the complex data interrogation functions which are necessary to efficient execution of the real-time-control task are greatly simplified when the sequential computer has associative access to the dynamic system data base.

In addition to the foregoing three primary BMD data processing requirements of correlation, scientific computation, and multidimensional file search (which are incidentally found to a similar degree in other problems), there are additional requirements common to military computers in general and to BMD computers in particular. First, the computer must be extremely reliable, and this reliability should preferably be an inherent characteristic of the architecture. High reliability is difficult to achieve in a computer suitable for BMD service, because of the very large amount of hardware such computers must contain. The latter is true because, in the final analysis, great computational power (estimates for BMD requirements run from tens to hundreds of millions of instructions per second) is achieved only via the employment of large amounts of CPU hardware. An architecture acceptable for BMD service must allow high reliability despite the large amount of hardware required. Parallel associative architectures provide opportunities for meeting this requirement, so long as the individual elements in the parallel array can be kept independent of one another. Then, individual elements can fail without affecting others, and without affecting the problem solution. Fortunately, many of the data sets dealt with in BMD computations are themselves independent, and lend themselves to assignment to independent processing elements. Since the data sets are independent, there is no need for interelement communication. This permits the arrangement of processing elements to be almost completely unstructured, so that no particular one or combination of elements is needed for successful problem completion.

A final architectural requirement, important for BMD applications, is that the data processing system be capable of easy expansion to meet increased requirements. A parallel, associative architecture, where the number and organizational structure of processing elements can be arbitrary, lends itself to this requirement too. Additional elements could be added to handle additional target traffic, and all of the programs could be written to be independent of the number and/or location of processing elements, so that programs need not be modified to accommodate hardware expansion.

Summarizing, the foregoing requirements led to consideration of a parallel, associative architecture. However, such computers which have been designed and/or built in the past fall generally into two categories, neither of which are really optimized for BMD service. First, past and contemporary associative processors are characterized by very primitive per-element computational capability (usually bit-serial); they achieve high processing speed by virtue of keeping a very large number of elements (say thousands) busy simultaneously. Computers for BMD service would not require the extremely large number of elements possible in such machines, but they do require fairly powerful elements because of the extensive per-target scientific calculations required. The second category is exemplified by the ILLIAC IV, which certainly has sufficient per-element computation capability, but an insufficient number of elements (tens), assuming that one wants to assign one target to an element (this is not really necessary, but not to do so leads to other complications and is beyond the scope of this paper). Moreover, ILLIAC IV contains features such as interelement communication which are not essential for BMD service, but which contribute to lower reliability because of the more or less rigid structure imposed upon the array by the intercommunication facilities. It would seem then, that the parallel associative architecture specified for BMD service should have capabilities somewhere between those offered by associative processors and ILLIAC IV. It should have a moderately large number of elements (hundreds), and each element should have a fairly powerful scientific computation capability. Moreover, each element should comprise three execution units, one each for input data correlation, parallel scientific computation, and associative file search for data output. To maximize throughput, all three execution units in the elements should be capable of simultaneous operation. The elements should have no positional significance; i.e., they should be organized into a completely unstructured array—an ensemble. Interelement communication and local indexing of data, while of considerable value in parallel computers designed to operate on interdependent data sets, can be eliminated because they are not needed and in fact are not even desirable. Finally and perhaps most important, the total data processing system should have high throughput in sophisticated branching and decision-making operations, but these operations should not reduce throughput on the less complex but resource-consuming parallel data processing functions. This means that the total data processing

system should have separate but closely cooperating facilities for both sequential and parallel processing tasks. The architecture which evolved from the foregoing considerations, PEPE, is described in the following section.

PEPE ARCHITECTURAL OVERVIEW

A system block diagram of the PEPE is shown in Figure 2. The Host, a CDC 7600, is connected to the three PEPE Control Units (collectively, the Control Console) via three standard CDC 7600 MUX (Input/Output Multiplexor) channels, one for each Control Unit. The CDC 7600 then sees the PEPE as three independent PPUs (Peripheral Processing Units). Each Control Unit is equipped with a modular Host Interface Unit; by replacing Interface Units, other interface connections with different Host machines are possible. The Host provides overall executive control, through its operating system, of the Host-PEPE configuration. It loads program and initial data into the PEPE memories, schedules and dispatches appropriate tasks to the PEPE, executes those sequential tasks which it does more efficiently than the PEPE, and executes utility functions such as compiling PEPE programs and reading and writing to peripheral devices.

The Control Console contains three independent Control Units (See Figure 3); they are similar but the Correlation Control Unit is optimized for inputting data to the elements, the Arithmetic Control Unit is optimized for scientific calculation in the elements, and the Associative Output Control Unit is optimized for outputting data from the elements. Each Control Unit is a multiprocessor which splits one instruction stream into two parts, one sequential which is executed within the Control Unit, and one parallel which is executed in the ensemble of elements.

Arithmetic control unit and parallel arithmetic units

The Arithmetic Control Unit is shown in block-diagram form in Figure 4. This unit contains a 32,768-word, 32 bit-

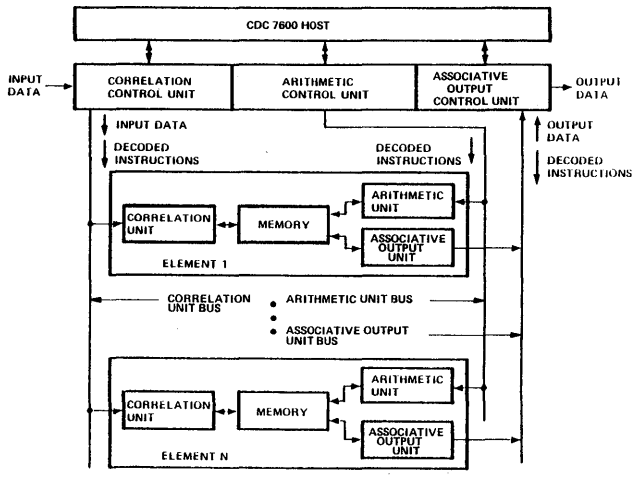

Figure 2—PEPE architecture

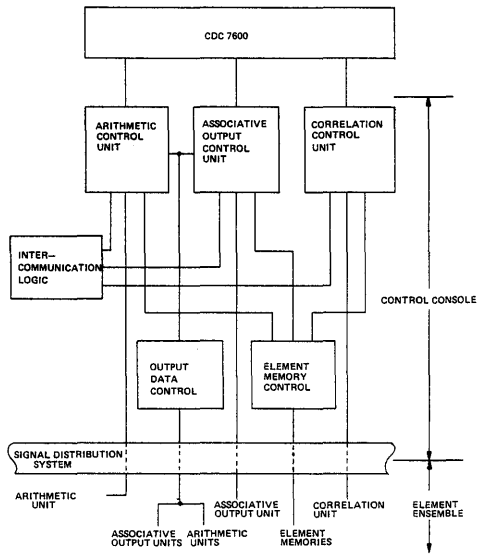

Figure 3—PEPE control console

per-word, random access semiconductor memory with a cycle time of 200 ns. A separate data memory contains 2048 random-access 32-bit words, implemented in ECL with a cycle time of 100 ns. The Sequential Control Logic (SCL) is a fairly conventional processor containing the usual A (Accumulator), B (operand), and Q (quotient/product) registers, plus 15 index registers. It executes integer (24-bit) arithmetic, and logical and branch instructions fetched from program memory on data obtained from data memory. Program memory contains a mixture of sequential and parallel instructions. The SCL executes the sequential instructions itself, but passes the parallel instructions, via the Parallel Instruction Queue (a conventional instruction stack) to the Parallel Instruction Control Unit (PICU). This unit decodes

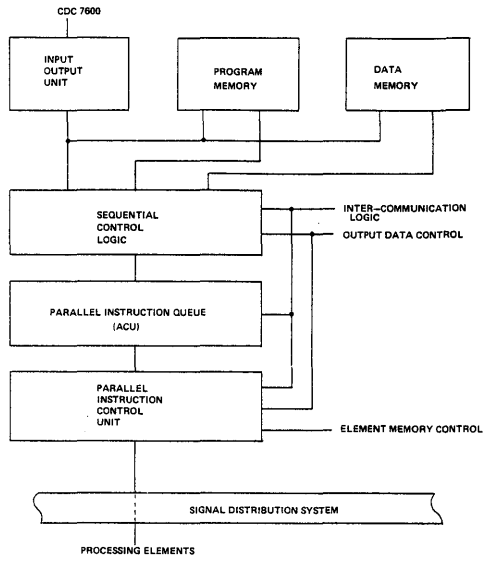

Figure 4—PEPE arithmetic control unit

the parallel instructions and broadcasts the resulting microoperation signals to all of the Arithmetic Units in the ensemble. The Arithmetic Units, provided they are active, all execute the same instructions simultaneously on data obtained from their own local data memories. The parallel instruction set is quite rich, containing the conventional arithmetic operations (plus square root) in both integer and floating point, load, store, and logical operations. In addition, the instruction set contains associative instructions which activate and deactivate elements based on element accumulator content and/or element tag register content. Only active elements execute instructions. Each Arithmetic Unit can execute about one million instructions per second, based on averages over instruction mixes encountered in typical scientific calculations.

Correlation control unit and parallel correlation units

The Correlation Control Unit (CCU) is similar to the Arithmetic Control Unit, but has a smaller, faster program memory and no Parallel Instruction Queue. Moreover, its PICU does not include a floating-point arithmetic capability, nor can it execute sequential floating-point operations. The CCU broadcasts a sequential stream of input data from the Host, or some other source, to all elements, and enters words from the input stream into properly activated elements. The Correlation Control Unit parallel instruction set is rich in associative match and compare operations, so that incoming data can be rapidly and efficiently correlated with data already in element memory, and thus be placed in the proper elements. Instructions are fetched from the CCU program memory and decoded, then the resulting microoperation signals are broadcast to the Correlation Units of all elements. The Correlation Units can be activated and deactivated independently of the element Arithmetic Units; only active Correlation Units execute instructions.

Each Correlation Unit contains a B register and 16 Correlation Registers which support execution of integer and logical operations, plus associative match and comparison operations among entering data and data retrieved from element memory. The Correlation Unit shares element memory with the Arithmetic Unit and the Associative Output Unit. Since the Correlation Unit does not perform floating point operations, its average instruction execution rate is about five million instructions per second, much faster than that of the Arithmetic Unit.

Associative output control unit and parallel associative output units

The Associative Output Control Unit (AOCU) is similar to the Arithmetic Control Unit, but, like the CCU, has a smaller, faster program memory, no Parallel Instruction Queue, and no capability for sequential or parallel floating-point arithmetic operations. Its function is to extract data sequentially from properly activated element memories, based on associative search instruction sequences which it fetches from its own program memory, decodes, and broadcasts (microoperation signals) to all element Associative Output Units (AOU). The AOUs can be activated independently of the element Arithmetic Units; only active AOUs execute instructions.

Each AOU contains conventional A and B Registers which support operation of integer and logical operations plus the aforementioned associative search operations. Parallel searches can be based on multidimensional search criteria, and data can be ordered in several different ways as they are obtained from the ensemble of elements. As in any associative memory, data output is sequential (in PEPE, sequential by 32-bit word). Data are buffered into AOCU Data Memory before transfer to the Host or some other device. Like the CUs, the AOUs execute instructions at an average rate of five million instructions per second, and they share element memory.

Internal interfaces

As shown in Figure 3, three major internal interfaces exist within the Control Console.

First, the Intercommunication Logic provides means for transferring data and control words among the control units. It contains a real-time clock and an interval timer accessible to all control units, and it provides means for the CCU and/or the AOCU to interrupt the ACU.

Second, the Element Memory Control receives requests from the three control units for element memory access. It performs any needed conflict resolution and transmits memory addresses to the elements.

Third, the Output Data Control is provided to resolve conflicts between AU and AOU requests to output data to the ACU and AOCU, respectively, over a common output data bus. The CUs have no capability for outputting data.

Design considerations

Several major design tradeoff decisions were made in assigning various functional capabilities to the different PEPE machine resources. These tradeoffs were made after extensive experiments involving simulated BMD exercises for a variety of attack scenarios and defense configurations. The tradeoffs were optimized for BMD service, and are not necessarily the ones that would have been made for PEPE application to other problems.

First, no provisions were made in the PEPE design for interelement communication. Data can be moved from element to element, but only through the Control Console, and the data transfer is sequential, one word at a time. This lack of a parallel interelement data transfer capability limits PEPE speed on problems involving computation performed on interrelated data sets (as encountered, for instance, in numerical solutions of partial differential equations), but for computations involving independent data sets, it is a real advantage. For the latter class of problem, each independent data set (for instance, a file on an aircraft, a missile, a

person) is assigned to an element, and each element performs identical operations simultaneously on the independent files. Since there is seldom, if ever, any interaction among the files, no interelement communication is required. The hardware simplification achieved by not providing interelement communication is obvious, but there are other more important advantages. The ensemble of elements can be completely unstructured (accordingly, the collection of elements is called an ensemble rather than an array); no element has any positional significance. Thus, the elements can be accessed, ordered, and grouped for data manipulation purposes purely on the basis of their contents, or associatively. An element can fail, with no impact on the calculations occurring in the other elements. Moreover, for many problems where data are periodically updated on the basis of continually arriving new data, only the historical state of an independent file is lost when an element fails. New data destined for that element are unable to correlate, so the data are automatically entered into an empty element to begin a new file. Thus, graceful degradation and automatic recovery are achieved naturally. Further, elements can be added as required with no effect on software or program execution. In fact, PEPE programs are oblivious of the number of elements, and programmers do not know or care either, as long as there are enough.

Another design decision involved floating-point versus fixed-point arithmetic. This decision had to be made for each of the six different processor types in PEPE (one sequential and one parallel processor for each control unit). The sequential processors in the control units are used mainly for comparison, branching, control of program flow, and supervisory operations, all of which can be executed with only integer, branching, load, store, and logical operations. Therefore, no floating-point hardware was provided in the control unit sequential processors. The Arithmetic Units in the elements have scientific calculations as their primary responsibility; therefore, they were provided with a full, powerful, floating-point arithmetic instruction repertoire in addition to all of the other conventional and associative grouping instructions. The CUs and AOUs are mainly required to input/output data and perform associative comparisons, matches, searches, and ordering functions, all of which can be handled with logical and integer arithmetic operations. However, they are occasionally called upon to execute short subroutines containing floating-point operations. Rather than provide expensive floating-point hardware in all of the CUs and AOUs to accommodate the rather infrequent requirements, it was decided to include instead provision for the CCU and AOCU to interrupt the ACU. Then, the ACU could perform the floating-point routines on demand for the CCU and the AOCU. A considerable amount of hardware was thereby saved, and simulations show that the performance degradation caused by lack of floating-point capability in the CUs and AOUs is insignificant.

A third design decision involved the Parallel Instruction Queue, which was provided only in the parallel instruction stream in the ACU. It was provided there because the ACU program memory is much larger and therefore slower than the other PEPE memories (200 ns vs 100 ns cycle time). Also, the average ACU instruction time is one microsecond, so that ACU parallel program execution time could be significantly reduced by inserting a fast stack (the PIQ has 16 ECL registers) between the program memory and the PICU. Since the CCU/CU and AOCU/AOU average instruction speed is 200 ns and the smaller CCU and AOCU program memories have cycle times of 200 ns, no such speedup could be realized in these processors with instruction stacks, and none were provided.

A fourth decision involved the output data bus from the parallel element to the Control Console. Although most element data are output from the AOUs to the AOCUs, occasionally the AUs contain data in registers destined for output to the ACU. To accomplish this transfer, the data could be stored back into element memory, retrieved by the AOU, output to the AOCU, and then transferred to the ACU. Alternatively, a separate AU/ACU data bus could be provided. Since the first alternative was too slow and the second too expensive, it was decided to allow the AUs and AOUs to share the same output data bus, and logic to implement this was provided. Since the AUs output data infrequently relative to the AOUs, output operations are not significantly degraded.

A final decision arose because the element CU, AU, and AOU share a common data memory, and since they can all operate simultaneously, conflicts inevitably occur and must be resolved. Since the element memory has a cycle time of 100 ns, and the average instruction time is one microsecond for the AU and 200 ns for both the CU and the AOU, it would seem that either the CU or the AOU should have first priority. This priority, however, is problem-dependent so simulations were held to establish priorities for memory conflict resolutions. The simulations demonstrated that the priorities should be CU first, AOU second, and AU last. With this priority assignment, the AU program execution time was extended only about five percent over what it would be if the AU had exclusive memory access.

Since memory access conflicts are rare (for typical BMD problems) and since the CU, AU, and AOU can operate simultaneously, average instruction rates for a single element can approach 11 million instructions per second. When all elements are operating, an ultimate rate of over a billion instructions per second can be achieved, but this rate is highly problem-dependent and would occur infrequently.

PEPE APPLICATION IN BMD

A simplified subset of the BMD data processing problem, as implemented on PEPE for its solution, will be described here to convey an idea of how PEPE is used in real-time control applications. Extensions to other similar data processing problems should be obvious, or at least not difficult. The problem comprises the maintenance of data files in real time on all targets (typically several hundred) within view of the phased-array radar. This requires matching each radar return against all target files to determine which file should accept the return data, and placing the return data in that file (typically ten to a hundred instructions per return per

file). If no match is possible, the return is assumed to be from a new target and is used to initialize a new file. Then, the new return is used to update the target file (typically several thousand instructions per update). Finally, based on the updated file, a request for a subsequent radar pulse to gather new data on the target is generated (typically tens to several hundred instructions per update). The request is then scheduled on the radar time line based on a multiplicity of complex radar/environmental/situation constraints (typically several hundred instructions per file per request). The real-time constraint is that, for each return (several hundred to several thousand per second), a request for a subsequent radar pulse must be generated and delivered to the radar within a specified time interval. The time interval, generally called port-to-port time, is usually different for different functions and can be extremely critical for some of them.

The problem is implemented on PEPE by assigning each individual target and its file to one element (other implementations are possible but this is most straightforward). For simplification, initialization of files and starting the problem on the PEPE will be ignored; instead the course of the problem will be picked up in the middle of a BMD engagement and carried on from there. Several hundred target files occupy the ensemble memory, one target file to an element. Periodically, the files are updated in parallel by the ACU/AUs using appropriate mathematical routines. Generally, time enablement of the routines is used; the frequency of enablement is chosen high enough so that port-to-port timing restrictions are not exceeded. For any one enablement, not all files are updated; only those elements which have received new radar return data since the last update are activated and only they participate in the parallel updating.

While the file updating is proceeding in the ACU/AUs, radar return data are streaming sequentially into the CCU data memory, either through the host or directly from the radar. As each return enters (a block of about ten 32-bit words describing target position, time of return, etc.) the CCU interrupts the ACU. The ACU then executes a prediction routine which predicts forward, to the time of the return, the positions of all targets on file. Then, the ACU constructs multidimensional windows around the positions. These operations are performed simultaneously for all targets on file. The ACU is then released, and the CCU orders the transfer of all of the window parameters into the CU correlation registers. The new return data are broadcast to all CUs, and the target position is compared simultaneously to all windows. Where a comparison is successful, the return data are placed in the element where success was achieved, and are used to update the target file during the next AU update interval. When no successful comparisons are made, the target is assumed to be detected by the radar for the first time, and the return data are placed in an empty element to start a new target file. This sequence of events is continuous, and it occurs simultaneously and asynchronously with the updating operations taking place in the AUs. The sophisticated reader will note that the foregoing procedure is a gross simplification of the target correlation problem, no account being given for practical considerations such as crossing targets, ghosts, and redundant targets. However, such problems are common to all computers and depend upon algorithms, not architecture, for their solution. As expected, the associative properties of PEPE make it an especially efficient implementer of algorithms designed to solve practical target correlation problems.

As a final operation in each update occurring in the AUs, requests for subsequent radar transmit/receive pairs, one request per target, are generated. Request formats include time of pulse, type, beam direction cosines, range windows, special pulse characteristics, etc., depending upon target type, priority, and a variety of other considerations. Resolution of conflicting pulse requests, allocation of pulses to targets, and scheduling of requests in the form of pulses and receive windows on the radar time line, are tasks assigned to the AOCU/AOUs. Generally, the objective is to schedule each pulse so as to maximize the BMD system response at the current instant, subject to a large variety of constraints and demands. This requires that target files be searched for highest-priority requests, where priority is a function of many variables. These requests must then be matched against a set of dynamic constraints (generally stored in the Host) in order to build a block of radar orders. Obviously, the procedure calls for complex multidimensional file-searches and matching and comparison operations, and is extremely time and resource-consuming for conventional sequential computers with location-addressed memories. Since the AOCU/AOU conducts the file searches and makes the matches and comparisons associatively, the procedure is considerably simplified and speeded up.

PEPE CONSTRUCTION

PEPE construction is rather straightforward, and employs circuit devices, hardware, structure, and wiring which may be considered state-of-the-art for supercomputers. The Control Console is contained in one cabinet 84″ high, 82″ wide, and 30″ deep. Elements are contained in identical cabinets, 36 elements to a cabinet. Eight element cabinets therefore comprise a full 288-element ensemble.

A complete element is contained in six 16″×18″ printed circuit plug-in boards, two each for the AU and the AUO, and one each for the memory and the CU. All board wiring is contained in eight printed circuit layers, four for signals and four for voltages and ground. Signal layers are designed to maintain a constant 50-ohm impedance. The boards connect to cabinet back-plane wiring through four plug-in connectors per board, 100 pins per connector. All logic is implemented in MECL 10K Dual-in-Line (DIL) integrated circuit packages which plug into sockets on the boards, Each board has space for 300 DILs, but there are only about 1000 DILs per element.

The boards plug into the cabinets vertically in four rows, nine elements to a row. Each row has its own power supply which supplies 5.2 volts at 560 amperes and 2.0 volts at 540 amperes to all of the elements in its row. The right-hand side of the cabinet contains these four power supplies arranged vertically, and the left hand side contains signal distribution

logic and circuitry. The four backplanes (one for each row) into which the elements are plugged are fabricated from three heavy laminated copper plates, which provide dc power distribution, signal ground plane, and power-supply bypass capacitance. Backplane interelement signal wiring is implemented entirely in 50-ohm subminiature coaxial cable. All of the nine elements in a row are connected to one signal distribution bus comprised of about 300 separate balanced-pair high-speed signal lines (PEPE uses a 10-mHz clock). The bus consists of flat belted cables which maintain constant impedance throughout the signal distribution system. The cables are connected to paddle boards which plug into the rear of the back plane to make connection to the elements. The four busses in a cabinet are fanned out from signal distribution circuitry in the left end of the cabinet. The eight cabinets are all connected to the Control Console signal distribution system via balanced-pair, constant-impedance flat belted cables.

Cooling is provided by a water-cooled chill plate located under the bottom row in the cabinet, and forced-air dual blowers located in a plenum beneath the cabinet. Total power dissipation is about 20 kW per element cabinet.

The Control Console cabinet construction is similar to that of the element cabinet, except that the Control Console printed-circuit boards use only six printed circuit layers, plus some conventional wire-wrap signal interconnection.

PEPE SUPPORT SOFTWARE

A detailed discussion of PEPE software is beyond the scope of this paper, but a summary of the capabilities of the support software system developed for PEPE will be given here. The support software system comprises a real-time executive system, a PEPE operating system, an instruction-level hardware simulator, a procedure-oriented language and translation system, and a general utilities package. All of the foregoing operate under control of the CDC 7600 SCOPE 2.0 Operating System.

The real-time executive has two primary responsibilities. First, it schedules tasks for execution on the host and the various PEPE processors in accordance with requests generated by other tasks, data enablements, time enablements, and system status. Second, it dispatches tasks in accordance with priorities and satisfied precedence relationships. The real-time executive resides and operates in both the CDC 7600 Host and the PEPE ACU.

The PEPE Operating System, which includes the real-time executive and supplies support service for it, has components which reside and operate in the CDC 7600 Host and all three control units. It includes mainly interrupt handlers and input/output handlers. Data buffers for Host/Control Console input/output operations, as well as storage space for the process control tables which support the real-time executive are also provided in the CDC 7600 small-core memory and the data memories in the PEPE control units.

The instruction-level hardware simulator is a program which runs on the CDC 7600 and executes interpretively on real PEPE problem code to simulate the operation of the PEPE/Host configuration (except, of course, for run time). It was produced to support the development of PEPE system and problem software prior to hardware availability, but it has additional important uses. Since the initial PEPE hardware installation will comprise only 11 of the 288 elements, it will be used in combination with the hardware to run tests where 11 elements are insufficient. Also, since the entire PEPE Project is at present an experimental one, the simulator will be used to check proposed hardware modifications before they are implemented.

PEPE is programmed in PFOR, a procedure-oriented, higher order superset of FORTRAN. PFOR also includes PAL, the PEPE Assembly Language. In summary, PFOR adds to FORTRAN additional statements which permit the declaration of parallel variables (those variables stored in the element memories), and which implement and exploit the parallel processing and associative access/grouping properties of PEPE. The PFOR compiler is a set of compilers and assemblers, together with a linkage editor, which accepts a single PFOR source program and expands it into object programs and load modules for all of the PEPE processors. Current experience shows that PFOR is an easy language to use and PEPE is easy to program; FORTRAN programmers can learn to program PEPE in a week or so. PEPE programs are generally characterized by a structural simplicity which makes them easy to read, understand, debug, and modify. Of particular interest is the relative absence of complicated program loops and housekeeping operations on data locations.

The PEPE Utilities package is quite conventional; it comprises the usual loaders, debug aids, and data recording programs. However, the actual implementation of the package components is unique because of the PEPE parallel/associative architecture.

PEPE IN NON-BMD APPLICATIONS

BMD data processing can be characterized as parallel computation on independent data sets; this characterization can also be applied to air defense, air traffic control, and several other applications. Such applications, when implemented on parallel architectures, do not benefit from a capability for parallel interelement data transfer among the parallel elements; in fact, there are disadvantages, as discussed previously in this paper, in providing such a transfer capability. However, there is a large class of problems which require operations on interdependent data sets, such as weather forecasting and other fluid dynamics problems requiring the numerical integration of nonlinear partial differential equations. Such problems can be solved much faster when implemented on parallel architectures, but parallel interelement transfer capability seems, at first look, to be required for efficient execution. In this section of the paper, the operation of PEPE, which has no provision for parallel interelement data transfer, on such problems will be discussed.

In fluid dynamics problems, interest focuses on the time-

variant behavior of several dependent variables at a multiplicity of fixed points in 3-dimensional space. This behavior is described (for a continuum) by a set of partial differential equations, generally nonlinear. The only practical procedures for integrating these equations are numerical ones, in which the region of interest is divided into a 3-dimensional grid, and the partial differential equations are replaced by their linear-difference approximations at each point in the grid. The resulting system of linear equations is then solved by any one of a number of methods developed for that purpose. Generally, these methods involve iteration and most of them fall within a broad class of operations called relaxation techniques. Computer architects do not need to know details of the specific algorithms used. It is sufficient to know that the relaxation procedure is started in a computer by assigning to each interior grid point estimated values for the dependent variables. Further, variables at exterior grid points are assigned values fixed by boundary conditions or if not, estimated values. Then, for each grid point, the computer performs several hundred to several thousand mathematical operations (only the instruction mix and count are of interest to a computer architect) to "update" the values of the dependent variables at that point. These operations involve the variables at that point, and all the variables at the surrounding six points. After each grid point in the total volume of interest is thus treated (one relaxation), there are better estimates of the variables at all the grid points. The computer then repeats the whole procedure for as many relaxations as are required to achieve convergence. The foregoing is a simplified and incomplete description of how a computer proceeds to solve problems in fluid dynamics, but it is sufficient for this paper.

A sequential computer can operate on only one grid point at a time; therefore, run times can be extraordinarily long. Obviously, there is a considerable amount of parallelism in relaxation techniques of the type described above, so one should be able to do better with a parallel processor. The most direct approach would be to assign an element to each grid point, store the initial values of the variables at each grid point in its assigned element, and carry out all of the grid-point computations simultaneously. There are, however, at least two problems which make this approach impractical. First, there are requirements for fluid dynamics calculations in regions containing several hundred thousand grid points, and this is not a practical number of elements.

Second, each element needs variables from other elements to perform its calculations, and moving these variables into the proper elements prior to calculations for each relaxation is a formidable engineering problem if a large number of elements are involved.

The first problem can be solved by employing a mass storage device to store a complete grid image, and to have the parallel processor operate on one section of the grid image at a time. Thus, the variables at the grid points in a section of the grid image would be transferred to the parallel elements, calculations would be performed on all of the grid points in that section, and the updated variables would be transferred back to that section in the grid image to replace the old values. Moreover, variables representing more than one grid point could be stored in an element, the number depending on the size of element memory. A complete sweep through the entire grid image would be made per relaxation, with the size of each section depending on the number of parallel elements and the number of grid points assigned per element. Sweeping through the grid image on mass storage and in effect replacing the image with a better estimate of it represents a lot of data transfer between the mass store and the parallel processor, but it cannot be avoided as long as there are not enough elements to contain the entire grid image, which will almost always be the case for the sizes of problems faced by fluid dynamicists. This data-transfer operation, incidentally, is independent of the second problem and is encountered in all parallel processors whether or not they have efficient facilities for transferring data among elements. The mass store data transfer problem must be handled by suitable choice of mass store and its interface to the parallel processor.

The second problem can be handled in several different ways. First, provision can be made in the hardware for efficient interelement transfer, as was done in the ILLIAC IV. This complicates the hardware and forces a rigidly structured implementation of the problem on the processor array, which in turn leads to reliability problems and perhaps topographical mapping problems with grids of unconventional geometry.

Second, an external data manipulator, or permuter, can be attached to the parallel processor array to allow parallel transfer of data from any ordering of elements to any other ordering of elements. This is the approach taken by the STARAN flip network and Feng's "Versatile Data Manipulator." It requires a lot of extra hardware, but can handle any grid geometry.

Third, interelement data transfer can be dispensed with entirely, as in the PEPE, so long as all of the data needed for one relaxation calculation is entered into the proper elements at the time a grid section is transferred from mass memory to the parallel processor array. This requires more storage per element, since each element must store not only the variables it is responsible for updating, but also all those additional variables needed to do the updating. This could mean a factor of up to six times the element storage required by the other two schemes. However, the hardware is simple, complicated grid geometries are no problem, and the parallel array could employ an associative data transfer scheme between the mass storage and the array to counter the reliability problem of failed elements. This scheme would allow use of an essentially unmodified PEPE in fluid dynamic problems.

Assume a global circulation problem, in which we place on the globe a grid point at every five degrees of latitude and longitude, and at six altitude levels. Unwrapped from the globe, this is a rectangular $72 \times 36 \times 6$ grid. At each of these grid points, we are interested in the behavior of eight dependent variables. We will, therefore, be performing calculations at each grid point iteratively to continuously update the values of the variables. To perform one update of the eight variables at one grid point requires that we have available the previous eight values at that point and the

current 48 values from the six neighboring points (north, south, east, west, above, below), and that we must perform 2000 arithmetic operations for each grid point. One complete relaxation requires an update of all $36\times72\times6=15{,}552$ grid points. All of the foregoing numbers are realistic, being derived from the NCAR Global Circulation Model.

To solve the above problem on PEPE, we store the entire grid image on mass storage. We assume the mass storage is connected, via simple interface, to the CCU and the AOCU. Alternatively, it could be connected to the host via a standard interface. Now our general approach is to compute on a section of the grid at a time, to always store the required neighboring grid points in the same element as the point being updated so that interelement data transfer is never needed, and to simultaneously compute, input, and output on three different grid sections. Specifically, for each grid-section relaxation we will assign to each element responsibility for updating the six points in one column. That means we store in each element one column and the four neighboring columns, or $5\times6\times8=240$ words. Now we have all the data needed to update the six points in the center column. Since PEPE will be simultaneously computing on one grid section, inputting from mass store on the next, and outputting to mass store the updated values of the previous section, we need $3\times240=720$ words of storage per element.

To update the center column requires 2000 instructions per grid point, or $6\times2000=12000$ per column. Since the PEPE AU computes at a rate of one MIP, this takes 12 ms. Now, how many columns can be updated simultaneously, or stated another way, how many elements can be kept busy? The answer will give the performance that can be obtained from PEPE, or the number of MIPS that can be applied to the problem.

As soon as one set of columns is updated, computation should start on the next set of columns, to keep the AUs busy continuously. That means the loading of the next five columns in the next grid section, and the unloading of the previous five columns should be complete in 12 ms. Unloading (center column only) of 48 words/element at 2.4 μs/word=115.2 μs/element (2.4 μs/word is the AOU to AOCU transfer time; we assume that AOCU to mass memory time can keep up with this). Therefore $12000/115.2=107$ elements can be unloaded during the 12 ms compute time.

Loading is a little more complicated. Five columns per element must be loaded in 12 ms, but five elements can be loaded simultaneously, provided we can steer the columns to the right elements. If we can do this perfectly, then loading time will be the same as if we only had to load one column per element. Assume we cannot do it perfectly, so that we have to load the equivalent of two columns per element. Then, loading takes 96 words/element at 1.2 μs/word, so 107 elements can be loaded during the 12 ms compute time (1.2 μs/word is the CCU to CU transfer time).

All of the foregoing means we can keep 107 elements concontinuously busy, giving a computational rate of 107 MIPS on the global circulation problem. This is better than any other existing machine can achieve, especially when one considers that the MIPS required for I/O are overlapped with the compute MIPS and do not subtract from them. In other machines, of equivalent MIP rating, the I/O MIPS (and/or interelement transfer MIPS) must be subtracted, which effectively lowers computational rates.

There are several advantages to the foregoing implementation. The formulation is independent of grid size and geometry; these can be changed easily. The implementation is straightforward and should be easy to program. Data management should be simple, especially when compared to that required for sequential and vector machines. The use of associative input to the elements should permit element failures without program abort, so throughput per shift should be higher than can be obtained from less reliable machines of equivalent MIP rating. Finally, the more sophisticated and complex the updating algorithms are (which is the trend), the better the performance. For instance, 4000 instructions (rather than 2000) would result in keeping 214 elements continuously busy, or 214 MIPS.

ARCHITECTURAL ENHANCEMENT TO THE PEPE

The major architectural improvement that can be made in the present PEPE design is simplification of the signal distribution system. Such a modification would result in a capability for incorporating recent technological advances, primarily the use of available bit-slice microprocessor chips, into the element design. It would also result in an ability of several subsets of the PEPE ensemble to be executing programs at the same time, instead of only one as in the present design. The signal distribution system of PEPE is also the limiting physical factor involved in increasing the number of elements in a parallel processor. Studies show that the PEPE signal distribution system (drivers, receivers, logic transmission lines, connectors) can be simplified about two orders of magnitude. The price paid is some additional complication in the elements. To understand this, consider the original concept of PEPE. A single control unit, containing instruction memory, and instruction fetching, interpretation, and decoding circuitry drives a large number of execution units, each with its own memory. This concept of multiple execution units and only one control unit saves a great deal of hardware in a parallel processor, because the control unit in a computer generally contains a significant amount of complicated hardware. However, the interface between the control unit and the execution unit is the most complicated interface in a computer, and it is this interface which, under the original PEPE concept, must be carried by the signal distribution system to all elements. At the time of the original PEPE concept, engineering tradeoffs favored the single control unit and the complicated distribution system.

Tradeoffs would produce different results now. With thousands of elements, one probably cannot tolerate a complicated signal distribution system. Moreover, control unit circuitry is much cheaper; in fact, microprocessors contain both instruction decoder and execution unit on a single chip. The interface between the instruction decoder and the execution unit is not even available outside the chip.

So, one can put both the instruction decoder and the execution unit in the element much easier and cheaper than

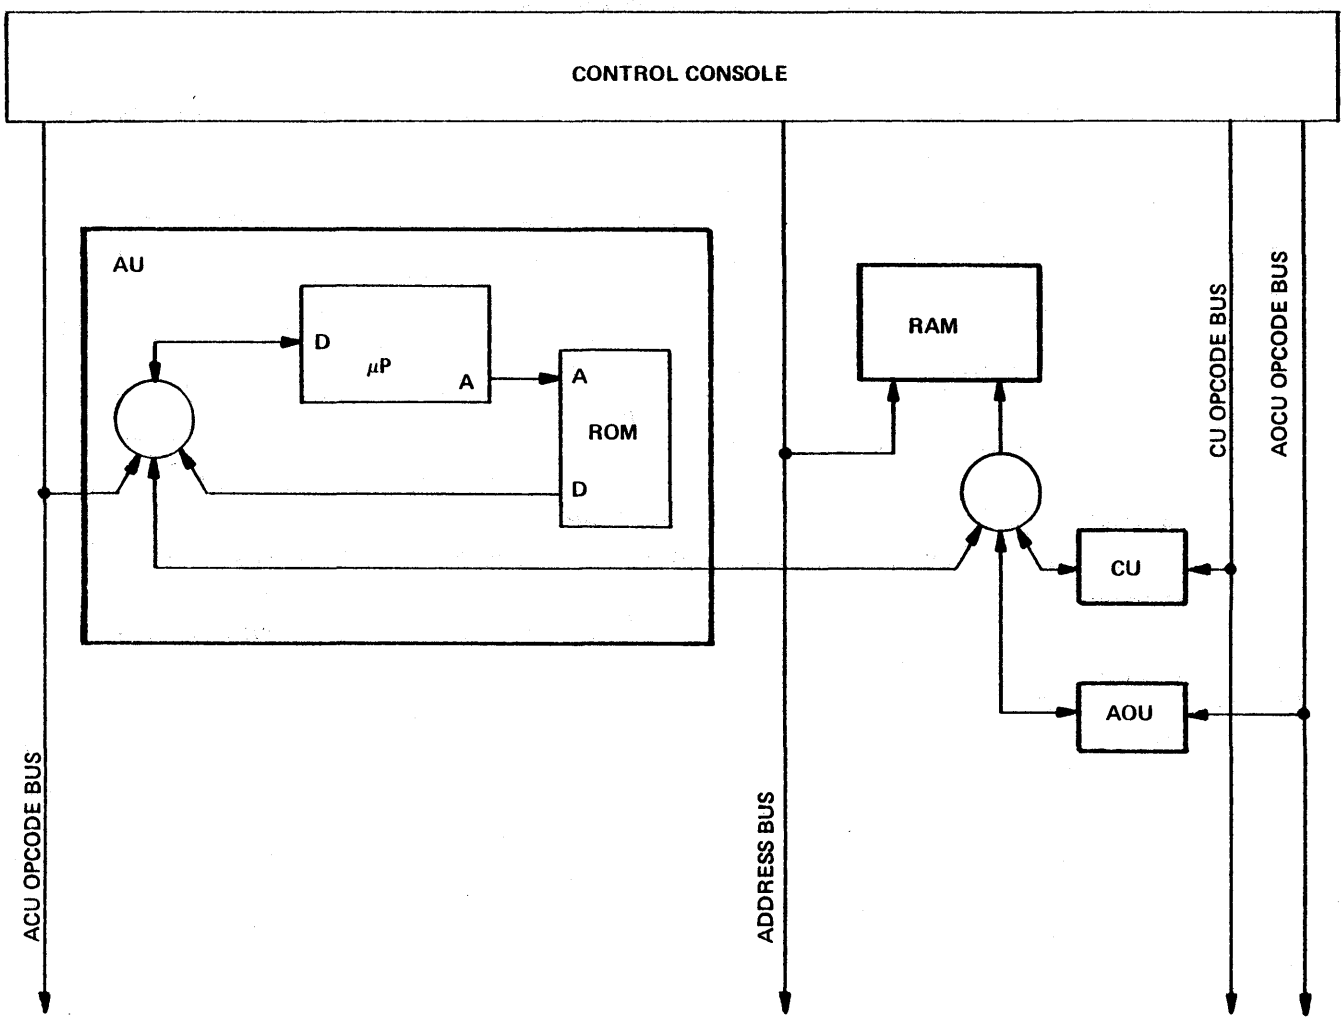

Figure 5—New PEPE scheme

was possible a few years ago, by making extensive use of LSI in the elements (possibly even off-the-shelf microprocessor chips). Then, the PEPE control unit would contain only a program memory and instruction fetching circuitry. This control unit broadcasts only the opcode to the elements, rather than decoded opcode signals. Fewer than ten signal paths are required to broadcast opcodes, rather than a hundred or so, as is the case when the decoded opcode must be broadcast. Moreover, the signal levels on the signal distribution system must change only once every instruction, rather than once every clock pulse. Thus, for the same instruction rate, the switching signals on the signal distribution system can be about ten times slower. These two factors, fewer signal paths and slower switching speeds, will permit great simplification in the signal distribution system.

Figure 5 shows the scheme. Only the details of the AU are shown, although the CU and AOU can be handled identically. The AU contains a microprocessor chip, which contains both instruction decoder and execution unit. In operation, the simplified ACU in the control console fetches an instruction, and places the address on the element address bus and the opcode on the opcode bus. The opcode first enters the data pins on the microprocessor chip, then the data from element memory is entered into the same pins. The instruction is decoded and executed on the chip and the result is returned to element memory. This sequence is conventional for almost all microprocessors. A further refinement can be made by storing special subroutines, such as trigonometric or exponentials, in ROM in the AU. Thus, the control console can include these functions within its opcode set and slow down the signal distribution system switching speed even more, while actually increasing the PEPE instruction rate.

Other useful operations can be done with a PEPE configured as described above. Since the ACU executes on the average about ten microinstructions for every opcode, more than one subset of AUs (same statement goes for CUs and AOUs) can be active at the same time, which is not possible with the present PEPE design. All that is needed is for the opcode bus to carry an activity number with it; only that set

of elements holding that activity number would execute that opcode. Then, while the selected subset of elements is executing the instruction, another instruction could be broadcast on the same bus to a different subset of elements.

This type of operation (it could be viewed as the logical equivalent of two or more ensembles) would keep more elements busy at the same time. Even further, the ensemble elements could store complete subroutines in their program memories, so that the control units need only broadcast subroutine calls rather than instructions. This would decrease signal-distribution system traffic even more, and would allow further exploitation of the ability of the subsets of the ensemble to execute several operations simultaneously.

PEPE—A user's viewpoint; a powerful real time adjunct

by M. P. MARIANI and E. J. HENRY
TRW—Defense and Space Systems Group
Redondo Beach, California

INTRODUCTION

The Parallel Element Processing Ensemble (PEPE) offers a cost-effective means of obtaining significant improvements in data driven real time systems. The inherent parallelism and programmability of the PEPE architecture make it an extremely effective growth option for data driven systems developed around a large-scale centralized Host. With the PEPE architecture, incremental system growth with minimum software impact can become a reality.

The purpose of this paper was to investigate the implementation of PEPE in real time data driven systems. For the purpose of an example, we have chosen the Ballistic Missile Defense (BMD) problem—a real time highly data driven system in its own right. The BMD problem desires a data processing system architecture which is not only highly resilient to the threat but also provides for cost-effective growth to accommodate changing technology. With the PEPE architecture, the system growth can be achieved through the addition of PEPE elements—the system designer can incrementally purchase only those parallel processing elements needed.

THE BMD DATA PROCESSING SYSTEM ARCHITECTURE

The assumed data processing subsystem (DPS) used in this study is responsible for controlling the radar and interceptor subsystems to insure that a sufficient number of defended missiles survives an offensive ICBM attack. To accomplish this objective the DP subsystem performs twelve basic functions (Figure 1). These functions are categorized as either module level or unit level.

The module level functions are oriented toward operational control of multiple Defense Units operating asynchronously. The unit level functions perform the detection, discrimination and intercept of the threatening objects within the Unit's operational sector. Each Defense Unit contains a CDC 7700 data processor, a single, phased array radar and a complement of interceptors. BMD research is currently focused on only the Defense Unit level of the system, and the first eight basic functions.

The eight unit level functions constitute the application programs (AP) operating in each Defense Unit's CDC 7700. The AP contains an array of independent tasks which are either data or time enabled, and scheduled and dispatched by the real time operating system. Of the array of tasks, a subset constitutes the bulk of the real time resource load on the CDC 7700.

Normally, each of the applications tasks consists of multiple subroutine modules which, for testability and growth, are usually limited in size. Within each task is a task control routine which controls the execution sequence of the subroutines within the task, performs all global data base READ operations prior to task execution, and performs all global data base WRITE operations at the termination of the task execution. This access approach reduces the real time data management overhead.

The array of tasks can range in size from less than 2500 executable instructions* to well over 40000 executable instructions for each instance of data processed. In order to prevent any single task from monopolizing the system, a maximum task execution time can be imposed. This design constraint limits the number of data instances which can be processed per task execution. As a result, there are large variations from task-to-task, in the number of instances which could be processed per enablement. These variations when combined with variations in task execution priorities can result in queue buildups. In high threat load situations the queue buildups of some of the more data sensitive tasks can experience increases in execution wait times.

Under severe loads, system saturation will be characterized by queue overflows and corresponding increases in critical response time. The parallelism of PEPE provides the potential for handling such high load conditions by reducing the data processing system's sensitivity to the threat and increasing the system threshold of saturation.

PEPE ARCHITECTURAL OVERVIEW

The PEPE is a 32-bit super-computer of the SIMD and MIMD[1] class. The PEPE[2] (Figure 2) can contain up to 288 parallel processing elements. Each element is itself a multiprocessor containing three independently operating pro-

* Average Machine Language Instructions (MLI) derived from simulations of the applications process over a full engagement scenario.

cessors—an input correlation unit (CU) and an arithmetic output unit (AOU) operating at 5 MIPS*, and an arithmetic unit (AU) operating at 1 MIPS. Each processor in the multiprocessor element is under the control of a separate control unit which broadcasts decoded parallel instructions simultaneously to all 288 of the processing elements. The control units are themselves processors capable of executing sequential instructions while simultaneously issuing parallel instructions to the PEPE elements. The PEPE architecture, therefore, permits the concurrent execution of as many as six instruction streams; three serial instruction streams driving the control unit computations and three parallel instruction streams driving each of the three processors in the parallel elements.

In an operational environment in which PEPE is used as an adjunct processor to a large high speed Host, such as the CDC 7700, the PEPE will execute only highly data parallel computations. The PEPE will operate in a dedicated manner and will contain its own application load modules and operating system. The PEPE-Host communications will be used to only support process control and global data shared between separate processes executing on the Host and PEPE.

*Based on typical BMD computational instruction mixes.

PEPE IMPLEMENTATION—OBJECTIVE

The parallel architecture of PEPE, coupled with its inherent throughput potential offers an available low cost method for responding to the advances in threat technology. An implementation of PEPE which does not accompany a redesign of the software results in an inefficient use of the PEPE

resources. However, the optimal allocation of a PEPE architecture to the dual CPU CDC 7700 architecture could involve substantial breakage.* The initial objective of the investigation was then to consider alternatives for low-cost (minimal breakage) implementations of PEPE. Therefore, any offload design requiring either a significant software redesign and/or a significant redesign of the PEPE-Host-Radar hardware interface was not considered. Similarly the optimization of the offloaded code was considered less critical than maintaining the original task software.

For each offload design considered both the application

*Breakage as related to the current DP system architecture (both software and hardware) was considered to include:

a. *New* Architecture (SW or HW) components.

b *Modification* of existing Architecture components.

c. *Disposing* of existing Architecture components.

task and operating system software were analyzed for breakage. Results of potential offload designs indicated that the application software breakage was highly sensitive to the number of application tasks included in the offload, while the indirect software breakage of the CDC 7700 operating system is essentially insensitive to the number of application tasks offloaded.

PEPE IMPLEMENTATION

Under the minimum breakage guidelines, there were two fundamental PEPE-Host architectures which were considered (Figure 3). One architecture (Figure 3B) employed PEPE as a radar interface preprocessor to the Host. As a preprocessor the PEPE would perform the radar interface function; correlation of radar returns and scheduling of radar pulses. However, designs of the radar interface software for centralized computers would execute extremely inefficiently on the PEPE, and the necessary software modification to improve the efficiency would be significant. The second architecture (Figure 3C) employed PEPE as an offload processor to the CDC 7700 in its current configuration. As an offload processor the PEPE would be dedicated to performing such highly data parallel operations as verification of detection returns, track initiate and track and discrimination processing.

Analysis of conventional applications programs was used as a basis for developing the offload options and selection of the preferred offload configuration. The analysis provided performance data which expressed resource requirements for: task computation (TASK), operating system support directly related to task execution (TOSC) (e.g., data base access), and operating system support indirectly related to task execution (e.g., external communication). All analysis was conducted within the high load periods of the engagement scenarios investigated.

PEPE IMPLEMENTATION—DESIGN APPROACH

Offload candidate identification

In an attempt to achieve the most cost-effective offload, the applications tasks were evaluated with respect to their current CDC 7700 resource requirements and their PEPE offload efficiency. Three aspects of the task resource requirements were studied,

(1) *Task Execution (TASK):* the resources (msec) required to execute the task instructions only.
(2) *OS Chargeable (TOSC):* the overhead directly associated with task execution (e.g., OS service requests: task load from secondary store, file read and write, task termination, etc.)
(3) *Other OS (TOSO):* the overhead not directly associated with task execution; not occurring during task execution (e.g., external I/O, interrupt handling, scheduling and dispatching).

The resource breakdown was used to provide an indication of each task's overhead sensitivity to the execution of instruction (TASK), handling of global data (TOSC), and external communication and polling loop priority (TOSO). Only those tasks which exhibited high resource requirements were considered as candidates for offload to PEPE. In addition, the general sensitivity of the tasks to the threat traffic was investigated by studying each in further detail during high load periods.

Those tasks which were rated as high resource users were then examined for inherent parallelism (both data and logic), as a basis for assessing the efficiency (breakage) with which a candidate task could be offloaded to the PEPE. Data parallelism was related directly to the task input data rates. With the minimum breakage guideline, algorithmic parallelism was not considered; instead, logic parallelism was evaluated at the subroutine level using the functional flow block diagrams. Tasks with a high degree of conditional branching along equal probability paths (Pb≈40-60 percent) would result in an inefficient use of PEPE resources. The lock-step architecture of PEPE can cause degraded performance in key processing tasks directly proportional to the number of branches in the offloaded processing logic.

A collection of six basic performance parameters was identified as providing the basis for assessing PEPE offload potential; they are,

(1) Total resource requirement
(2) Total number of instances processed
(3) Task resource distribution: TASK, TOSC, TOSO
(4) Total number of Task executions
(5) Peak data rates
(6) Task polling loop wait

Based on these performance parameters a set of five (5) performance criteria was established for paring down the application tasks to preferred offload candidates. These criteria were,

(1) high frequency of task execution
(2) high number of instances processed
(3) high instruction execution resources
(4) low data handling overhead
(5) high data queue buildup

In addition, the task structure was evaluated to identify those tasks with

(1) high probability logic paths ($Pb_n \geq 90$ percent)
(2) low offload instruction count with high frequency execution.

Using the above criteria the applications tasks were evaluated for their resource requirement. The results indicated that a small subset of the applications tasks accounted for over 90 percent of the total system resource requirements.

Analysis during a prolonged engagement interval provided performance profiles for the principal resource users. However, the analysis did little to indicate the sensitivity of the

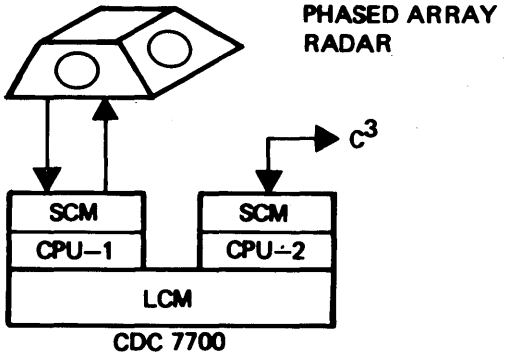

Figure 3A – CURRENT ARCHITECTURE

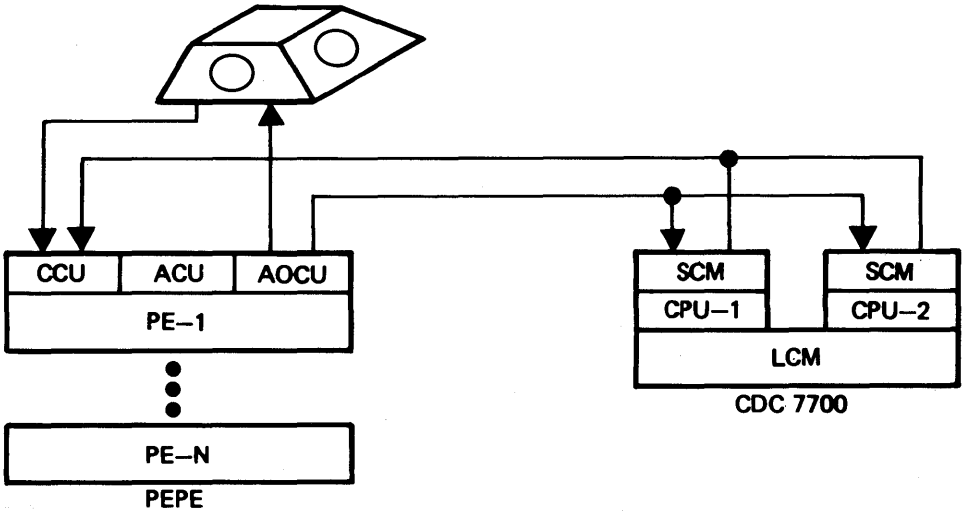

Figure 3B – PEPE PREPROCESSOR

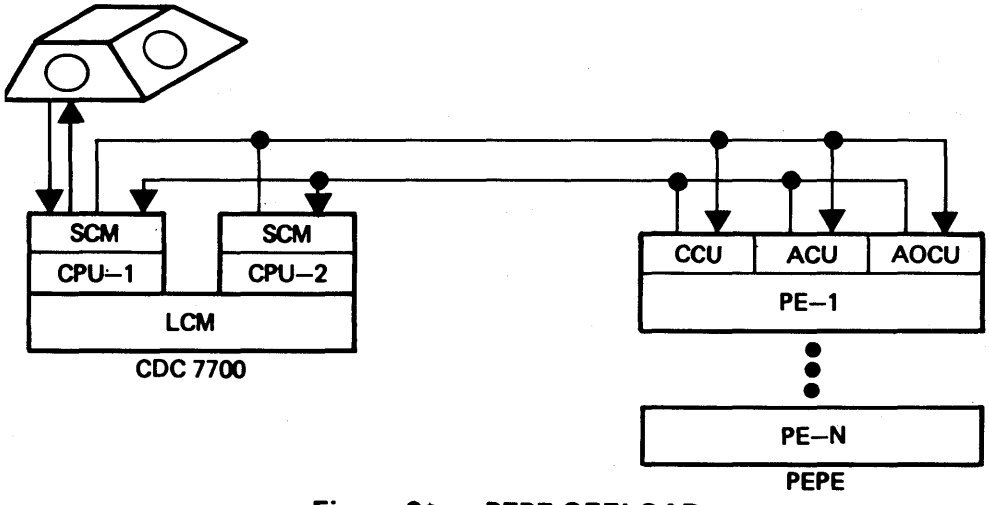

Figure 3C – PEPE OFFLOAD

Figure 3—BMD terminal defense architectures

tasks to threat traffic. Any offload configuration was restricted by the critically short processing response thresholds and limited offload storage available on PEPE. As a result, there was a need to develop criteria with which to assess the relative offload potential of each candidate task. The initial criterion was the resource offload percentage available due to each task. Tasks whose individual Host resource requirements failed to exceed at least five percent of the total applications program, were not considered as potential offload candidates. This test singled out five tasks as having the independent resource potential to justify offload.

The throughput capability of the PEPE relative to the Host, and the inherent parallelism of the PEPE architecture dictated two data related requirements. First, in order to exploit PEPE's parallelism large data loads were desired by the tasks for offload. Second, the cost to process a single instance should preferably be small when taking into account the potential expansion in processing times due to the relative PEPE-CDC clock cycles (100ns−27.5ns).

The first criterion strongly favored three of the tasks, with two of the tasks being marginal. One task did not meet the throughput requirement although the task's resource requirement is among the highest.

The second criterion of single instance processing costs strongly favors four tasks showing a high throughput requirement, with one task (interceptor control) exhibiting extremely high single instance processing costs. In addition, the stringent response requirement of interceptor control also makes it a poor selection for offload to PEPE.

A third performance consideration is the potential PEPE-Host communication overhead accompanying each task offload to PEPE. Large data communication overhead has negative impacts on both the PEPE-Host interface bandwidth requirements, and the responsiveness of the offloaded processing. Since the TOSC resource component is primarily influenced by data management costs associated with the global data, the TOSC component is a strong indicator of the potential PEPE-Host interface overhead. The ratio of TOSC to TASK resource distribution was then used to evaluate the inherent resource offload efficiency available with each offload candidate. The ratio ranged from approximately .25 to 1.14 and was found to remain fairly constant regardless of system loading.

Another consideration for evaluating task offload potential was the frequency of task execution. The execution rate of tasks when compared with their associated data rates provided another indication as to the efficiency with which tasks will execute on the PEPE. Each task execution is accompanied by a basic overhead cost (TOSC) consisting of loading the task module from large core memory (LCM) and the READ/WRITE of global data which support the task execution. This basic overhead is virtually insensitive to the number of data instances processed during a single task execution. If an execution time restriction were not imposed on the process designer, it would be much more efficient to have each task totally deplete the data queue on each execution. The parallel processing architecture of PEPE provides a means of processing a much larger number of data instances per task execution while still maintaining an execution time design restriction.

Offload design—General approach

Minimization of the impact of any offload design required the development of a technique for restructuring the current application software to support offload to PEPE. The technique which we developed was based on partitioning the applications tasks along their current subroutine structure. In addition, the table driven design for the current operating system allowed the offload to be implemented with no impact to the OS software.

The partitioning approach to PEPE offload involved the segmentation of each offload task into three components (Figure 4) operating as three tasks. Two new data files were defined which serve as data enablement queues for the second and third segments. The first and third segments of the task would continue to reside in the Host computer. These segments provide all access to the global data base, and interface with the remainder of the application process. The second segment would reside on the PEPE. One objective of the partitioning was to maintain the total cost of executing the two segments residing on the Host≤the original cost of the task prior to offload.

In general the segmentation will be performed across loosely coupled routine interfaces in the task logic, and produce a segmentation in which the largest segment of the task is placed on the PEPE.

The initial segment will continue to execute in the Host as a data enabled task. The primary purpose of this Host segment will be to format and write into the newly defined PEPE input queue all data necessary to support the second task segment residing in the PEPE. The data will typically include the data instances, such as radar returns, and dynamic data which is needed to support the execution of the PEPE segment.

The second segment would be offloaded to the PEPE and allocated to either the CCU, ACU, or AOCU. The PEPE will contain the complete load module of the second segment loaded into the program memories of the CCU, ACU, or AOCU. Any fixed point arithmetic or logical operations of the offloaded segment, such as unpacking/packing operations, will generally be performed by the CCU or AOCU. The ACU will perform all floating point computations. In

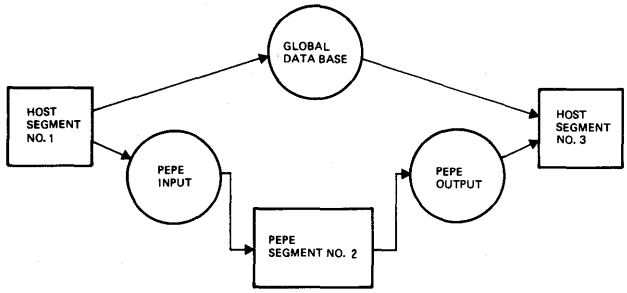

Figure 4—Task offload segmentation technique

addition, new PEPE software must be developed for the CCU and AOCU to support data manipulation within the PEPE, such as loading the PEPE elements prior to parallel computations and retrieving the processed data from the elements for retransmission back to the Host following computations. In addition, for data management operations such as large file searches/correlations, new software must be incorporated into the offloaded segment which exploits the PEPE's associative capabilities. The PEPE Fortran (PFOR) possesses instructions specifically designed to support associative search operations within the PEPE elements. Typically operations such as object redundancy checks and nuclear interference prediction which could be extremely costly when implemented on the Host, will be executed with only a couple of associative search instructions on PEPE.

Alternative offload designs

One of the major applications tasks consistently displayed performance characteristics indicative of efficient PEPE offload. That task performed the object track function. The keys to the offload desirability of the track task were four operational characteristics,

- *high task execution frequency* with highest execution rates occurring during periods of highest threat traffic.
- *high task throughput requirement* with highest data loads (75 percent) occurring during periods of highest threat traffic.
- *high CDC resource requirement* with largest load (80 percent) occurring during periods of highest threat traffic.
- *low task execution overhead* (30 percent) throughout the operational period.

Because of the task's offload desirability it was used to form the foundation of two alternative offload designs.

In addition, the task has a moderate per instance execution cost, a highly favorable characteristic for tasks belonging to short response threads.

Using the track task as a basis, two multi-task offload designs were developed. The first design was directed at significantly reducing the total Host resources requirement. The second design was directed at substantially improving the responsiveness of key processing threads in high threat traffic situations. The first design incorporated the detection and track initiate and discrimination processing tasks with the track task into an offload module for the PEPE. This design provided the largest offload benefit in the early portion of the engagement. In addition, the detection and track initiate tasks are on processing threads with less stringent response requirements than the track thread which reduces the impact of resource contention. The second offload incorporated the interceptor control task with the track task into an offload module for the PEPE. The interceptor control task was a high resource user with an expensive per instance execution cost. In addition, the interceptor control task was on the most stringent response processing thread in the applications program.

A comparison of the two integrated offload designs indicated the first design to be far more preferable. The offload of a sizable portion of the Host resources, also had a significant indirect effect on improving the responsiveness of the threads remaining on the Host. The offload to PEPE of tasks within high response processing threads had less effect on improving system responsiveness than the first offload design. This was attributed to the fact that, (1) less absolute resources were offloaded from the Host to PEPE, and (2) the offload of tasks with equal response priority created resource contention on the PEPE. An important point of both offload designs was the ability of PEPE to substantially improve the performance and predictability of both system throughput and responsiveness.

PEPE IMPLEMENTATION—ANALYSIS

Offload design—S/W portability analysis

Parallel Fortran (PFOR)

Parallel Fortran[3] is a high level, procedural extension to USA Standard Fortran and provides a powerful and efficient set of language extensions for the associative parallel processing capabilities of PEPE. Through the use of the PFOR statements, the user has the capability of simultaneous execution of instructions in all n PEPE elements or a selected subset of the n elements. The user can nest the levels of element activity through PFOR.

In order to identify specific variables which are allocated to PEPE element memory, PFOR has parallel type declaration statements.[4] A set of parallel "system" functions to handle type conversion, square root, and special mathematical functions on parallel arguments and a set of powerful statements are included in PFOR for the subsetting of the current set of active elements. This set includes statements of the form WHERE, CONVERGE, parallel IF, and parallel DO. In addition, a statement is provided for moving data between element memories.

CDC 7700 S/W conversion

In order to determine the amount of code breakage and time required to convert existing code in FORTRAN to PFOR (Parallel FORTRAN), typical code representative of the object track task was converted. The routines were selected as being strongly indicative of the types of code which were contained in the PEPE segments of the offload design.

Some of the code was highly logic oriented and designed to control the hi-fidelity Kalman filter for the track task. The other code contained mostly arithmetic operations and little branching.

There are two options which can be considered when placing the selected subroutines and their associated data base on PEPE. Option one permits only one object maintained per PEPE element and requires a larger set of PEPE

CDC 7700/FTN

```
      SUBROUTINE XYZ

      COMMON/D3T0000/A3T00 (132)
      INTEGER ZDBQN, . . .
      EQUIVALENCE (A3T00(1), ZDBQN)
      IF (Z3DØF .EQ.0) GO TO 10
      Z3BPF = 1
10    CONTINUE

      IF (Z3DØF.EQ.0) GO TO 70
      ZNC (1, Z3ØDV) = ZNC (1, Z3ØDV) +
      FLØAT (ZNCNL (Z3BQV))
      GO TO 80
70    ZNC (1, Z3ØDV) = ZNC (1, Z3ØDV) +
      FLØAT (ZNCNL (Z3BQV)) + 1.
80    CONTINUE
```

PEPE/PFOR (OPTION 1)

```
      SUBROUTINE XYZ, ACU

      PAR COMMON/D3T0000/ZDBQN, . . .
      PAR INTEGER ZDBNQ

      WHERE (Z3DØF.NE.0) 10
      Z3BPF = 1
10    CONTINUE

      WHERE (Z3DØF.NE.0) 70
70    ZNC (1) = ZNC (1) + PFLØAT (ZNCNL(Z3BQV))

      WHERE (Z3DØF.EQ.0) 80
      ZNC (1) = ZNC (1) + PFLØAT (ZNCNL(Z3BQV)) + 1.
80    CONTINUE
```

Figure 5—Relative code comparison

elements. In converting the code for this option, the user must change the doubly subscripted variables currently used throughout the software (e.g., object state estimate) into singly subscripted variables. The second subscript associated with the instance number (e.g., object identification) would be implied by mapping each instance into a unique PEPE element. This option results in significant code modification, however, the code conversion would be simple, straightforward and could be automated.

Option two would permit more than one object maintained per PEPE element and can significantly reduce the size of the PEPE element array required. This option requires doubly subscripted variables to identify the current instance being processed in an active element. This option would result in much less code breakage than option one but would require much larger data storage per element. Once the user develops some familiarity with PFOR a set of existing routines can be transformed into PFOR in relatively short time. As an illustration, Figure 5 provides an example of a logical segment of the subroutine and the FORTRAN code changes required to convert it to PFOR. In practically all cases of code conversion, the code which required modification was directly associated with data management and manipulation. The actual scientific computations written in FORTRAN were directly transportable to the PEPE. For the three subroutines that were selected, approximately 76 percent of the executable statements would require modification for option one and 4 percent for option two.

In the offload design, the current CDC 7700 data base design is not effective when directly installed on PEPE. In each offload design the subroutines executing on the PEPE require only small segments of the data contained in current common blocks. To conserve element memory we elected to restructure the common blocks within the PEPE. The restructuring involves eliminating unused variables and redefining the nonexecutable statements which define these variables. Since the current set of declarative statements (i.e., INTEGER, REAL, EQUIVALENCE) have to be converted to PFOR (i.e., PAR INTEGER, PAR REAL) there is total breakage for these nonexecutable statements.

It is felt that other applications which are suited to the type of parallel processing offered by PEPE could just as easily be converted to PFOR. In some cases the code conversion could even be automated. Applications which would require movement of data between elements may require a longer time to convert to efficient PFOR, but once the user becomes familiar with PFOR, the code conversion is straightforward.

Offload design—performance impact

Analysis indicates that the first offload design exhibits a significant overall potential for reducing the load on the Host computer. Over the complete engagement the offload design provides a net reduction in the average Host resource requirement of the applications program by over 25 percent. This is accomplished by a 54 percent reduction in the resource requirements originally required by the offloaded tasks. The offload design provides the most significant reductions during the major peak load periods of the engagement; specifically early during initial acquisition of the threat and later during track and discrimination prior to intercept

commit of the threat. The early load is caused by high Host resource requirements imposed by the track initiate loads. The later Host load is caused by high Host resource requirements imposed by the object track and discrimination processing. The offload to the PEPE provides a significant reduction in the Host loads during both the early (~28 percent) and later (~23 percent) portions of the engagement.

An analysis of the PEPE under this offload design indicated that both storage and utilization requirements were well within available limits. The program storage requirements for each of the three control units were all less than 35 percent of available storage. Data storage requirements were higher and reached 84 percent of that available in the CCU, and 65 percent of that available in the PEPE element memories. Evaluation of the PEPE resource requirement during the engagement indicated that none of the control units exceeded 80 percent utilization. The average utilization of these units was substantially less, never exceeding 60 percent (ACU), indicating resources are available for additional applications tasks to be offloaded.

The size of the Host resource offload is directly related to the traffic load on the system and as a result varies during the engagement. A major benefit of the PEPE offload design is the reduction in sensitivity of the PEPE-Host system resource requirement to increases and unpredictable perturbations in data (threat) traffic patterns.

The impact of resource offloads on the system responsiveness was also investigated. In the original Host environment there were two principal components of system response, the first component being that of execution wait times, which includes the time from enablement to dispatch. The second component is the actual execution time once dispatched. In high load periods of resource contention, the task wait times become a major component of the overall system responsiveness for the Host alone system. With the offload to the PEPE, a third resource component must be considered, that of PEPE-Host communication. In the offload design, the contention for resources is reduced, and the execution wait times are decreased. In addition, the execution wait times tend to be more stable with the PEPE adjunct than with the Host alone.

When combining the effects of reduced task execution wait time, increased task throughput and the addition of the communication delays, the results indicate that the PEPE-Host system provides improved system responsiveness. This responsiveness is substantially improved during periods of high load conditions.

One of the major offload issues addressed the impact that the PEPE adjunct, and its associated PEPE-Host communication, had on the Host Large Core Memory (LCM) utilization overhead. Analysis indicated that the LCM overhead actually decreased with the offload. Although the Host LCM overhead necessary to support real time input/output (RTIO) increased with the addition of the PEPE, the reduction in the overhead associated with management of some of the larger data files and load modules, now resident in the PEPE, more than compensated for the RTIO overhead increase.

SUMMARY

THE PEPE provides a highly cost-effective method of improving the data handling capacity of a real time system developed around a single large-scale Host. Analysis of conventional terminal defense systems for BMD indicates that the addition of a PEPE adjunct can provide a means to substantially offload the Host computer. As a result of the Host offload, an improvement can be achieved in the capacity and predictability of both the system's throughput and responsiveness.

In addition, the implementation of PEPE can be accomplished with only a minimum breakage to software developed for the Host. In most cases the software breakage is repetitive but not complex and can be automated without significant cost. For the specific offload design investigated, the PEPE storage and throughput requirements were well within limitations and PEPE had the resources to accommodate additional offloads. Based on the current design the apparent threshold in PEPE offload will be the availability of data storage. Analysis indicated that through a redesign of some of the larger common areas the data storage requirements on the PEPE can be significantly reduced.

Further analysis of the offload design indicated that the PEPE adjunct provided several direct performance improvements for the data processing system,

(1) increased data throughput for tasks offloaded to the PEPE,
(2) reduced execution delays for entire application program,
(3) reduced data management overhead,
(4) reduced system sensitivity to data traffic,
(5) improved predictability of the system's real time resource demand.

It is felt that these performance improvements can be achieved as well with non-BMD applications which possess the parallelism which is suited for the PEPE. Once the PEPE user becomes familiar with the operation and the computing power of the PEPE, suitable applications can be mapped onto PEPE in a simple and straightforward manner.

CONCLUSIONS

Results of this PEPE application case study have general applicability to most data driven, real time systems. The inherent parallelism and programmability of the PEPE make it an extremely attractive mechanism for achieving significant improvements in a centralized systems data handling capability.

The implementation of PEPE as a Host adjunct allows the offload of resources to the PEPE. This offload can produce a substantial improvment in the data processing system's throughput and response. The improvement is effected in both the system's capacity and performance predictability to data loading.

Special computer architectures for pattern recognition and image processing—An overview

by K. S. FU
Purdue University
West Lafayette, Indiana

INTRODUCTION

It has been recognized for a long time that a conventional sequential processor is inefficient for operations on pictorial data where relatively simple operations need to be performed on a large number of data elements (pixels).

Though many parallel processing architectures for picture processing have been proposed in the past, very few have actually been implemented due to the costs involved. With LSI technology, it is becoming possible to realize parallel architectures at a modest cost.

In the following we review some of the proposed architectures for pattern recognition and image processing.

PREVIOUS WORK AND COMMENTS

Previous work in the field of special purpose computer architecture for image processing basically falls into two categories: bit-plane processing and distributed processing. The bit-plane processing approach performs the arithmetic computation on the image points which are stored in Boolean bit-plane. For example, if the image has eight grey levels, then the image points are stored in three Boolean planes. The bit-plane processing approach tends to have a large number of processors which perform Boolean operations. The distributed computing approach utilizes processors which have powerful computation capability. These processors are designated by microprogram or hardware to execute certain specific tasks. Thus, this configuration forms a distributed computing architecture. In this section we will briefly illustrate each special purpose computer, concentrating on the special features of each computer for image processing and pattern recognition.

Unger[1] realized as early as 1958 that a sequential processor is inefficient for problems involving spatial relations and proposed an array computer (Figure 1). The system is made up of central control (Master Control) controlling a large rectangular array of identical modules interconnected as shown. The master control performs all instruction fetches and decoding and broadcasts the decoded instruction to all the modules in the array.

Each module consists of a 1 bit accumulator and a small number of memory elements (a,b,c . . .). Inputs to each module are from the M.C. and the accumulators of the four neighbors (above, below, left, right). Each module can perform the following basic operations:

1. LOGICAL OR (AND)
   The accumulator is ORed (ANDed) with specified memory register (a,b,c . . .) and the inputs from the specified neighbors. The results are either stored in the accumulator or one of the memory registers.
2. LOGICAL NOT
3. LOAD (STORE)
4. SHIFT (ROTATE) LEFT (RIGHT,UP,DOWN)
   The entire image is shifted (rotated) in the direction specified.
5. LINK/EXPAND H (V,UP,DN)

These operators are used to determine the connectivity in the specified direction. Thus, for example, it is possible to determine all the cells in a given field which are connected to a specified cell through a chain of horizontally linked ones (Figure 2). Using these commands, many interesting image processing operations can be performed. But the actual programming of algorithms is nontrivial.

Unger's architecture has influenced that of many later researchers. Kruse's PPM, the CLIP array, as well as the ILLIAC III computer were inspired by it.

ILLIAC III

The Illinois Pattern Recognition Computer, ILLIAC III,[2] was designed for automatic scanning and analysis of massive amounts of relatively homogeneous visual data, in particular, bubble chamber negatives. The computation is performed by three units, the pattern articulation unit (PAU), the taxicrinic unit, and the arithmetic unit. The pattern articulation unit performs local preprocessing on the digitized raster, such as track thinning, gap filling, line element recognition, etc. The logic design of the digital computer has been optimized for the idealization of the input image to a line drawing. Nodes representing end points, bends, points of intersection are labeled in parallel by appropriate programs. The abstract graph describing the interconnection of

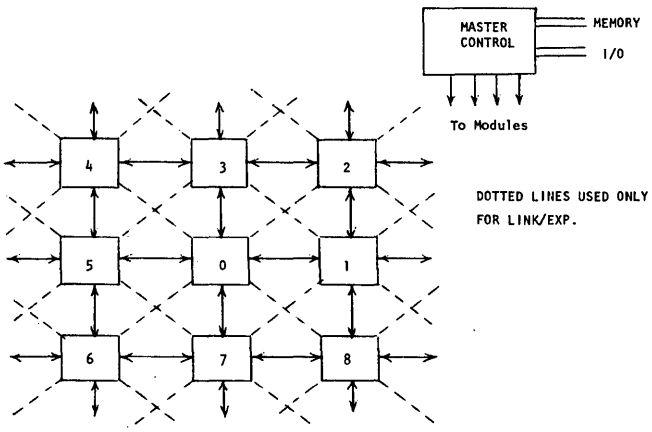

Figure 1—Module interconnection pattern for Unger's machine

labeled nodes is then extracted as a list structure, which comprises the normal output of the processing element (stalactite). The pattern articulation unit consists of an iterative array of 1024 identical stalactites (32×32). A schematic diagram of the stalactite is shown in Figure 3. The iterative array of the stalactite can be connected in, either rectangularly or hexagonally, at the programmer's option. Each stalactite can accept an input from any of the eight neighboring stalactites, S0, S1, . . . , and S7 shown in Figure 3 (rectangular) or six neighboring stalactites (hexagonal) in the plane and from itself, M shown in Figure 3. The input signals are logically "OR"ed, optionally complemented, and stored in one (or more) of the nine planes. Communication with the supplementary planes in the core buffer is through the "M" plane, which serves as the buffer register of this memory. For output, the output of any selected set of planes can be logically "AND"ed and passed on to neighboring stalactites. With a special signal, the stalactite allows an input signal to pass through it directly, without interim storage. It is this feature which allows path-building within the machine. The set of 32×32 stalactites processes the pixels of a 32×32 pixel image window simultaneously. The whole image is to be processed by one image window (32×32) after another sequentially by the set of 32×32 stalactites. The taxicrinic unit assembles the graphs, which are outputs of the pattern articulation unit, into coherent list structures and categorizes these graphs to complete the visual recognition function. The arithmetic unit is designed for executing mathematical analysis, such as stereoreconstruction, statistical summarization, etc. involved in processing pictorial data. The block diagram of ILLIAC III is illustrated in Figure 4.

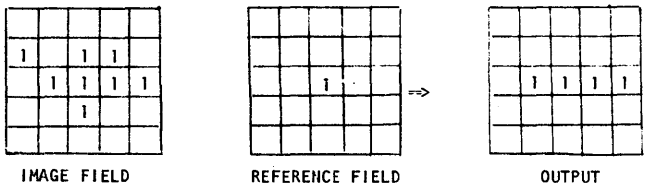

Figure 2—Link/expand operator

The generic stalactite contains 10 one-bit registers (flip flops). Since asynchronous logic is employed, it is required that no flip flop be both read from and written into during the same instruction to avoid races.

The pattern articulation instruction code is of 40 bits length, made up of 4 groups.

Flow group

C	G	CI	F	B	U	D	N2	N1	N0
1									10

C, CI are used to control the outgoing and incoming signal complementation respectively.

G=1 indicates that at least one input gate is opened.

F=1 indicates a flash through operation, i.e., the input signal is transferred directly to the output bypassing the stalactite.

B=1 indicates a bubbling operation.

In bubbling the values of the nearest neighbors are read. Using a sort, the bubble register (flip flop 1,2,. . . ,8) 15 ordered such that zeros are at the top and the ones at the bottom. The number of ones is counted and the cell is marked if it exceeds a threshold. This operation is used extensively in line thinning and other preprocessing operations. U specifies bubble up, D specifies bubble down, N2, N1, N0 specify the number of iterations needed for bubbling.

FF Read control group

M	0	1	2	3	4	5	6	7	8
1									10

This field is used to select the FF's to be read out.

Input gate control group

C	0	1	2	3	4	5	6	7	8
1									10

C=0 All inputs signals enabled C=1 Only specified signals enabled

FF Load control group

M	0	1	2	3	4	5	6	7	8
1									10

This field specifies the FF's to be loaded.

Mark command

This command is of the form MARK(Z). It sets the M register of the cell at coordinate Z=(X,Y).

LIST Command

List serially compiles a list of all coordinates Z which have a zero in the M FF. Coordinate Z of the next point found is transferred to the LIST register automatically on storage of the previous contents of the register.

The use of the above two instructions is illustrated below. A sparsely populated image is complemented and loaded into M reg of the PAU array. The black points in the image correspond to a 0 in the M plane. A first black point is identified by the LIST command. The coordinate obtained is used to mark the corresponding M FF (and thus erase the point). Now the black points connected to this point are in

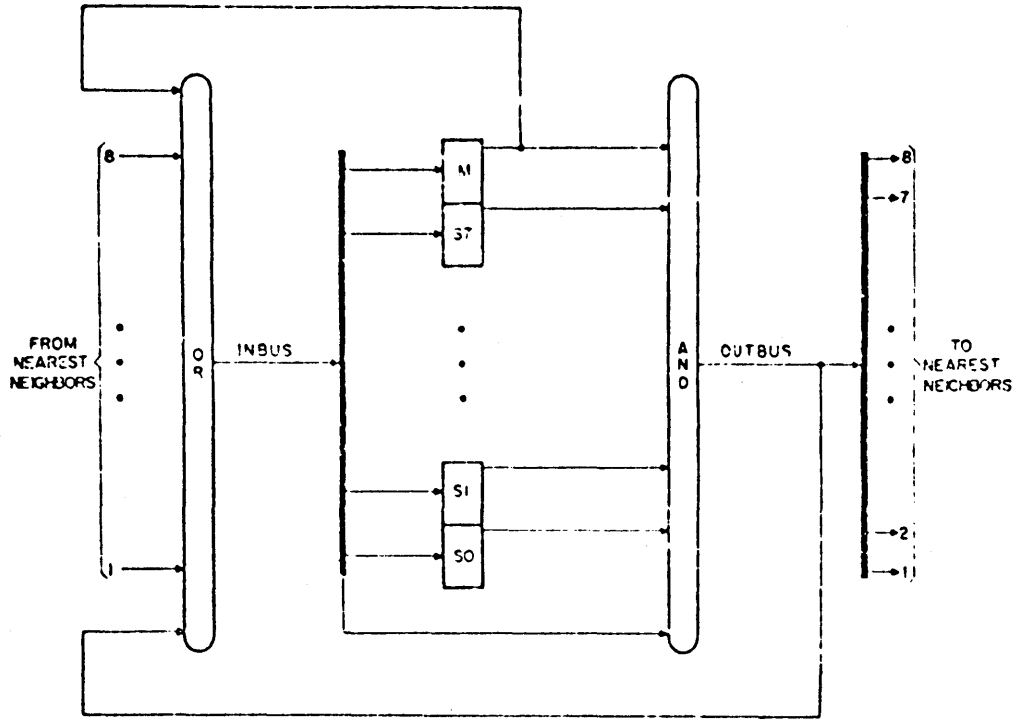

Figure 3—Schematic diagram of stalactite of pattern articulation unit in ILLIAC III computer

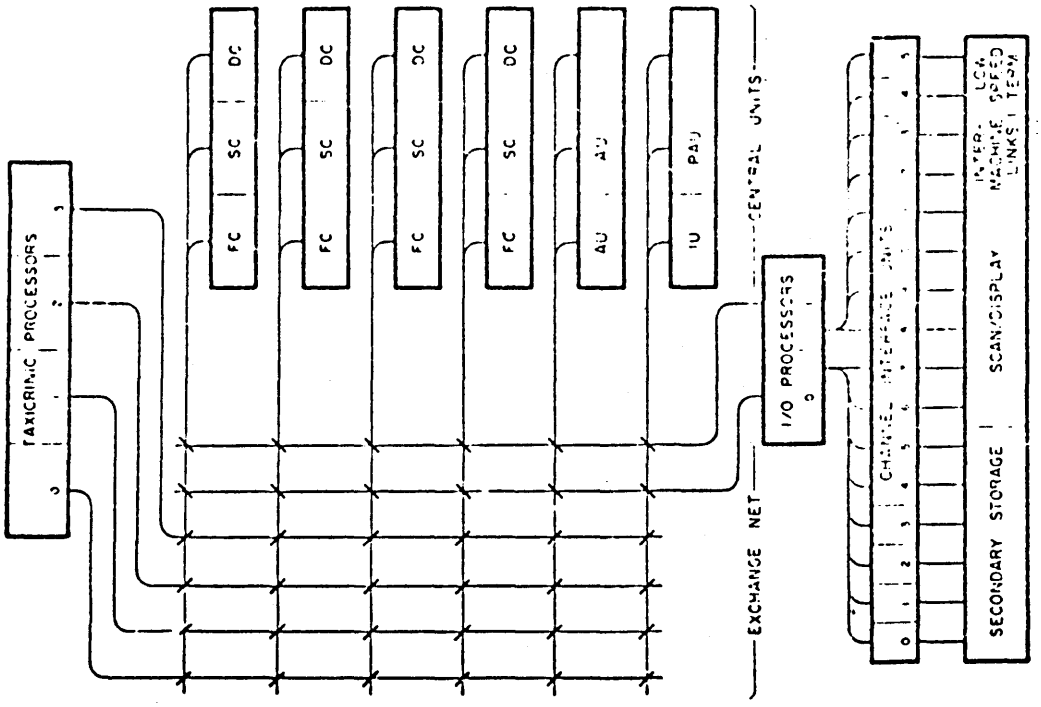

Figure 4—Block diagram of Illinois pattern recognition computer ILLIAC III

turn listed using Flash through. This technique builds a paired list of nodes, i.e., the branches of the associated graph.

One special feature of ILLIAC III for image processing is the use of an auxiliary memory. The auxiliary memory is used for the processing of images frame to frame, and for retaining intermediate partial results. The necessity of storing intermediate results of the iterative array stems directly from the manner of executing homogeneous logic transformations in the processor. The complexity of the iterative array can be greatly simplified if various digital filtering operations can be performed serially storing the intermediate results (32×32=1024 bit words). For example, local track segment orientation can be designated as being predominantly horizontal, vertical, left-diagonal, or right-diagonal in four serial tests, whereas simultaneous identification requires approximately four times as much hardware.[2] Unfortunately, ILLIAC III has never been completely built since 1967.

The ILLIAC III represents a pioneering effort in designing a special processor for a specific image processing task. The processing capability is, however, limited due to the technology available at the time. The complexity of the system can be imagined from the fact that each stalactite occupies one circuit board, and 1024 boards make up the PAU array. Recent advances in LSI technology make building of such arrays economically viable as demonstrated in such systems as the CLIP array described later. By using more complex logic in the modules, it is possible to realize truly general image processing capability.

CLIP Series

Digital Parallel Processors (DPP's),[3-8] using cellular logic, are real-time machines in which the action resulting from a program statement is simultaneous on all the points of the array. The action may be symmetrical or directional and the tessellations of various types, the most common being the square and the hexagonal ones. An example of this kind of machine is the parallel cellular logic image processor, CLIP 3.[6,7] The CLIP 3 is comprised of an array of 192 cells arranged in a block of dimensions 16 cells (vertically) by 12 cells (horizontally). The array interconnection pattern can be either square or hexagonal. The required architecture is determined by one bit in each instruction word and is therefore under the control of the programmer. The block diagram of the cell logic of CLIP 3 is shown in Figure 5. The Boolean processor can perform, under program control, two independent Boolean functions from its two inputs A and P. D is one output and can be regarded as the processed pattern bit corresponding to the cell. The other output, N, fans out to the adjacent cells. The N inputs from neighboring cells (G_1, G_2, . . . , and G_8) are summed (Σ) and compared with a threshold (f). The programmer is allowed, for each PROCESS instruction, to select several inputs to be put into the summing unit and he can also choose the threshold value. The summed and thresholded output, T, is then "OR"ed with the second pattern input to form the input, P, to the Boolean processor. D outputs are addressed into any one of 16 single bits of store; buffers A and B are loaded from addressed location in the same store. The CLIP 3 was actually built.

One drawback of both the ILLIAC III and CLIP 3 is that the "edges" caused by moving image windows, (in ILLIAC III 32×32 windows and 16×12 windows in CLIP 3)) are not taken care of by the computer. The computing power of the CLIP 3 is obviously limited because of the fixed small number of (Boolean operator) cells. (16×12=192 cells).

In order to process larger images, CLIP 3 has been interfaced to a television camera through the hardwired scanning unit. This is called a hybrid CLIP 3 array[8] which is shown schematically in Figure 6. This unit scans the 192 cell CLIP 3 array across the 96 by 96 cell data-field and provides edge stores to handle the propagation signals which cross between

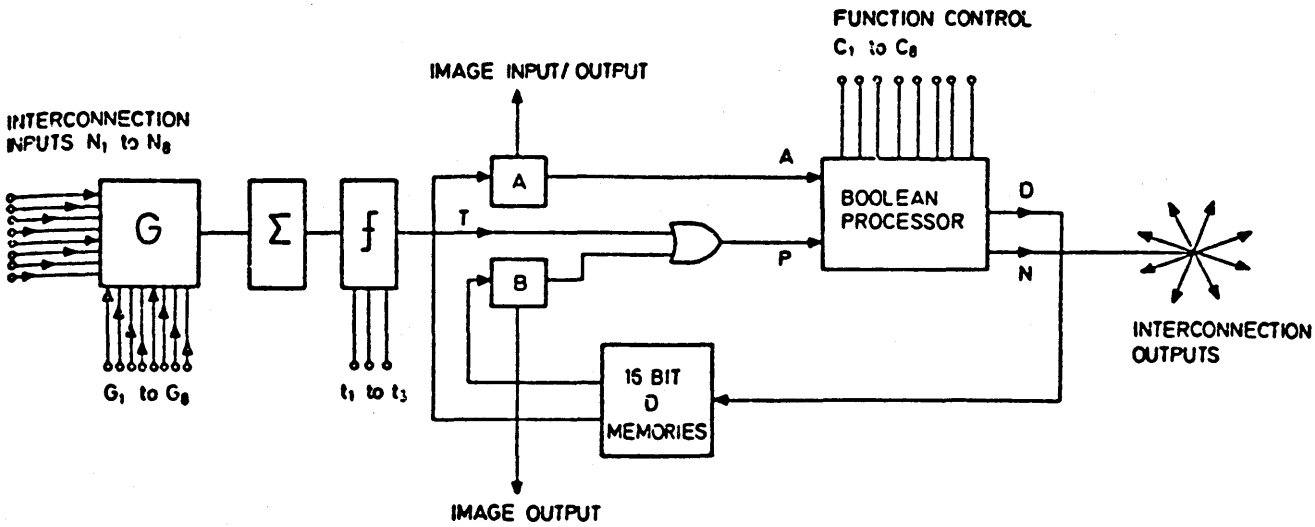

Figure 5—CLIP 3 cell logic

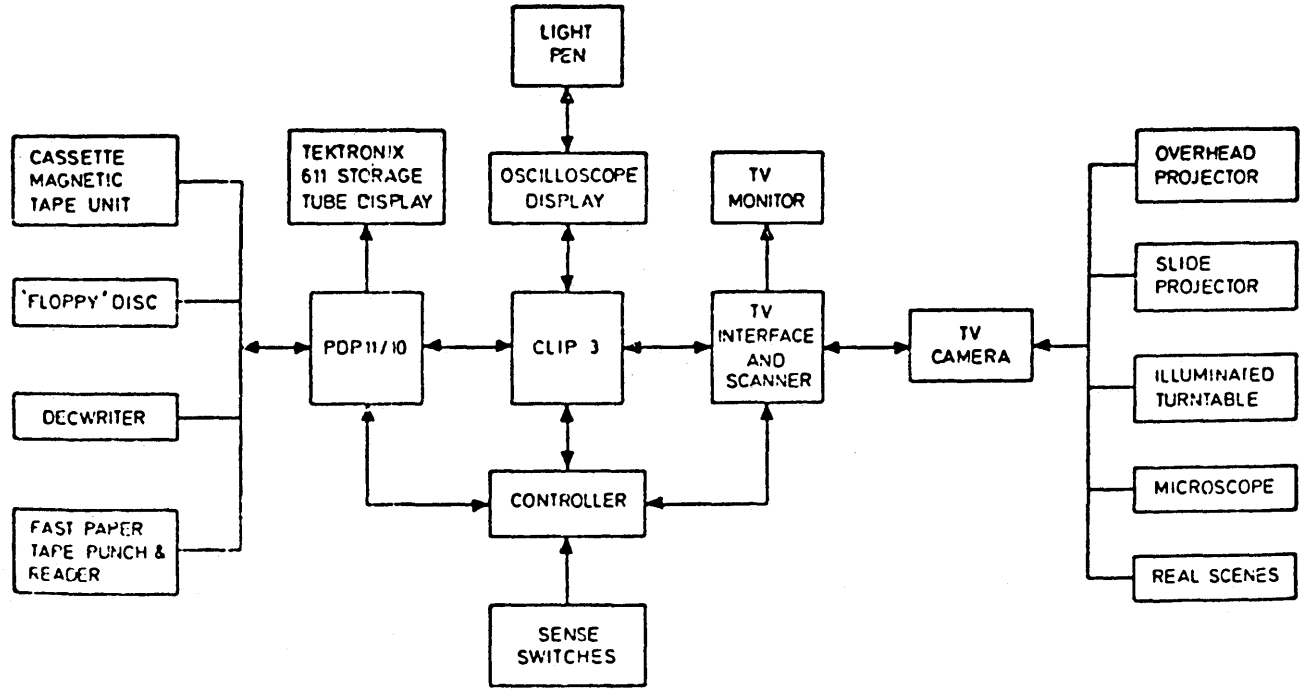

Figure 6—Schematical diagram of hybrid CLIP 3 system

adjacent sectors. The complete system is interfaced to a PDP 11/10 computer which serves to extend the available data and instruction storage and also provides program editing and assembling facilities.

CLIP 4[8] is the Large Scale Integrated circuit (LSI) version of CLIP 3 with some small changes in the cell design. The CLIP 4 uses N-MOS (N type Metal Oxide Silicon) LSI to incorporate eight processor cells in a four by two block onto one chip. The block diagram of CLIP 4 cell logic is shown in Figure 7. The "D" store has been increased from the 8

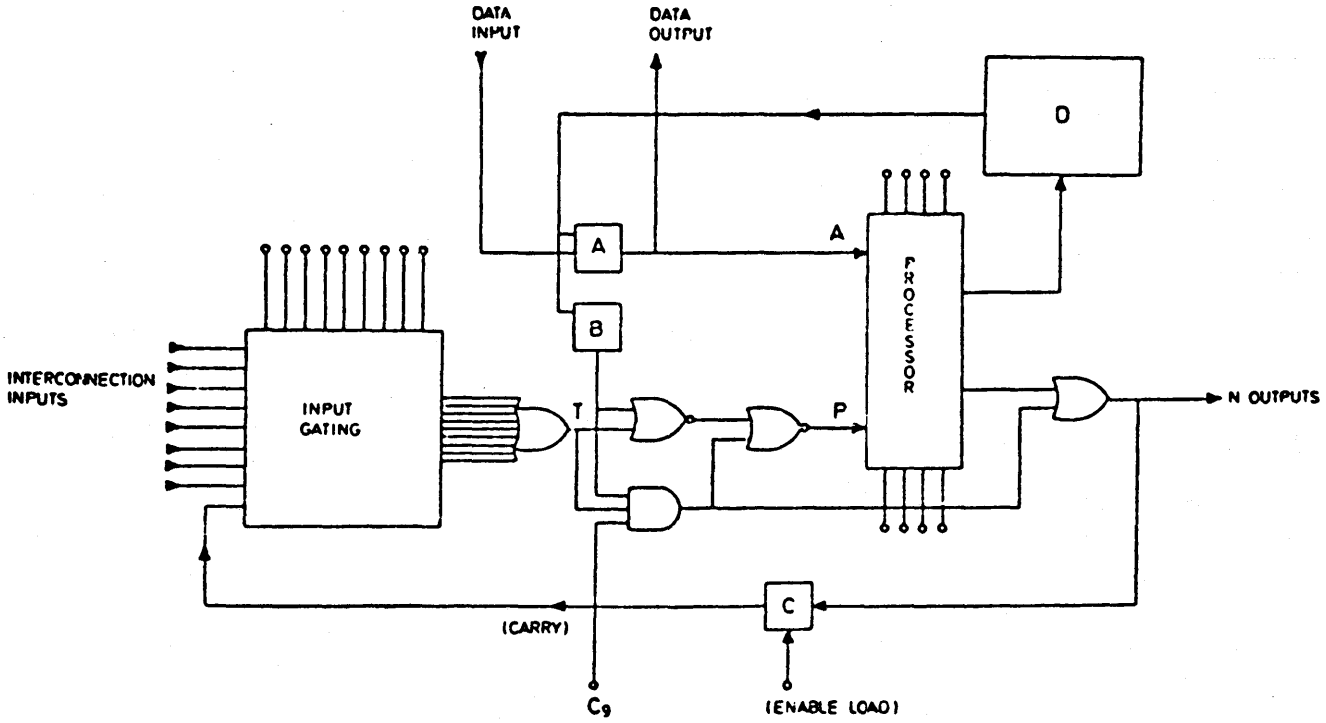

Figure 7—CLIP 4 cell logic diagram

bits of CLIP 3 to 32 bits which allow the processing of 32 grey levels. The interconnecting threshold gate has been replaced by an "OR" gate, and a few extra gates and an additional buffer store have been included to provide automatic carry-in arithmetic operations.

The experimental CLIP 4 system consists of 16×12 identical cells. The array interconnection pattern can be either square or hexagonal with six neighbors. The desired architecture is programmed by a bit in the instruction. The processor in the CLIP 4 is a Boolean processor capable of implementing any Boolean function of inputs A,P. Thus,

$$D=b2(P,A),\ N=b3(P,A)$$

The actual functions b2,b3 are determined by the control lines c1, c2, . . ., c4 and c5, c6, . . . , c8 respectively. (All 16 possible Boolean functions are implemented for D and N).

The B register is primarily intended for comparing two images. D is a 32 bit random access storage in each module. The input gating is used to enable/disable inputs from neighboring modules. This permits selective propagation of the interconnection signal in desired directions within the array. Thus,

$$T=G1.I1+G2.I2+. . .+G8.I8+G9).Carryin$$

Carryin is a carry bit used to perform bit serial arithmetic.

The normal mode of operation of the array is as follows. The input image is digitized by a flying spot scanner and loaded into the A register of the array modules. Once the A registers are loaded with the desired image we can perform operations on it. The results may be stored in the D memory. A CRT is used to display the output.

Instruction set

The array is controlled by a sequence of instruction words stored in external memory. Instructions which do not involve signal propagation through the entire array are executed in 1 microsecond. Delays for operations involving propagation depend on the array size as well as the image being processed.

There are basically three types of instructions recognized by the assembler:

1. LOAD
   LD (A addr), (B addr), (D addr)

The instruction loads A and B registers from the locations specified in the D memory. The D address is used by the subsequent PROCESS instructions as the destination address for the operations.

2. PROCESS
   PR (Direction list) b3, b2, E S

The 'Direction list' specifies which neighbor inputs are to be enabled (G1, . . . , G8). b3 is the Boolean function for the interconnection output, b2 is the Boolean function for the image output, which is stored in the D memory location specified by the previous LOAD instruction. E is a binary number (0 or 1) specifying the inputs at the array edges and S indicates whether square or hexagonal interconnection pattern is desired.

3. BRANCH
   This is a conventional program branch instruction.

Analysis of CLIP operation

Each cell in the CLIP array may be partitioned into three parts:

1. Next state logic
2. Propagation Logic
3. Memory

The interconnect signal propagation logic is combinational and there is no delay between elements. Thus, during each clock period, signals propagate through the entire array, the propagation depending on the function b3 (set by c5, . . . , c8).

For simplicity in the following analysis, we assume that register B=0, c9=0. The operation is best studied in terms of interconnect signal propagation as below.

1. ZERO ORDER
   Here D=0 or 1 independent of interconnection signal. Thus this is a trivial case.
2. FIRST ORDER
   In this case D=A or D=NOT.A independent of N.
3. SECOND ORDER
   D=b2(A,T), N=b3(A)

Note that T is the input from the neighbors. Also the interconnect signal N depends only on the module state A and not on the interconnection signal input T. Thus the output of each module depends only on the current state of the module and that of its immediate neighbors (determined by G1, . . . G8). Hence the maximum delay is only 2+t where t is the delay per module.

4. THIRD ORDER
   These functions result when N depends both on the input T as well as the state of A. All stable functions in this category are third order functions. Since interconnect signal propagation occurs through the entire array the execution of these instructions is slow. These are the most interesting functions that may be executed on the CLIP array.
5. FOURTH ORDER
   These correspond to those operations for which the output is unpredictable due to logical races within the array. An example is the operation

$$N=A.T$$

Two consecutive 1 cells can result in a latch up with unpredictable output.

Comparing the performance of CLIP 3 and CLIP 4, the processing speed of the CLIP 4 cell is slower than that of CLIP 3 by at least a factor of five. A single operation which required a pair of instructions (LOAD and PROCESS) in CLIP 3, taking 2 μsec, is expected to require about 10 μs in CLIP 4. Propagation from cell to cell took 0.1 μs in CLIP 3 and may take 1 μs in CLIP 4.[8] However, the processing speed of the overall system of the CLIP 4 is improved by the larger array of processors of CLIP 4 (96×96 cells).

PPM and PICAP

The Parallel Picture Processing Machine (PPM)[9] is a special processor which is connected to and controlled by a conventional computer. The block diagram of PPM is shown in Figure 8(a). The PPM consists of the following principal parts: the processing unit, a set of nine general purpose picture registers, and a control unit. The picture registers which are shown in Figure 8(b) comprise nine shift registers

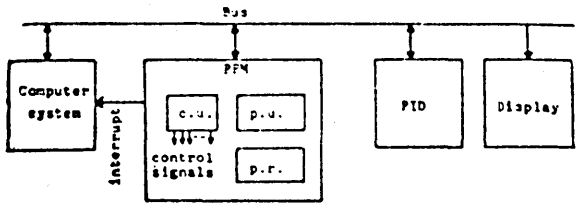

Figure 8(a)—Block diagram of parallel picture processing machine

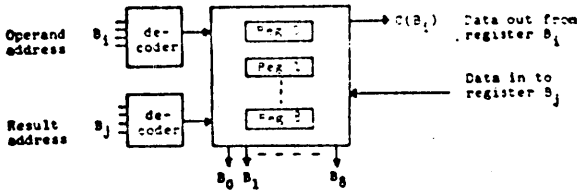

Figure 8(b)—Picture registers

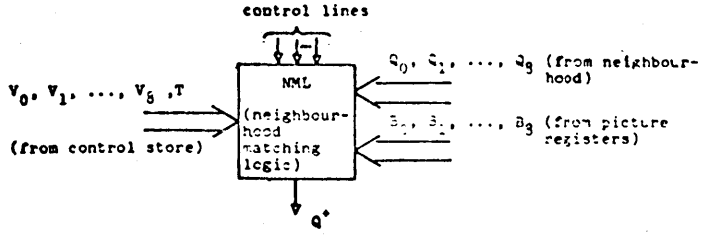

Figure 8(c)—Neighborhood matching logic

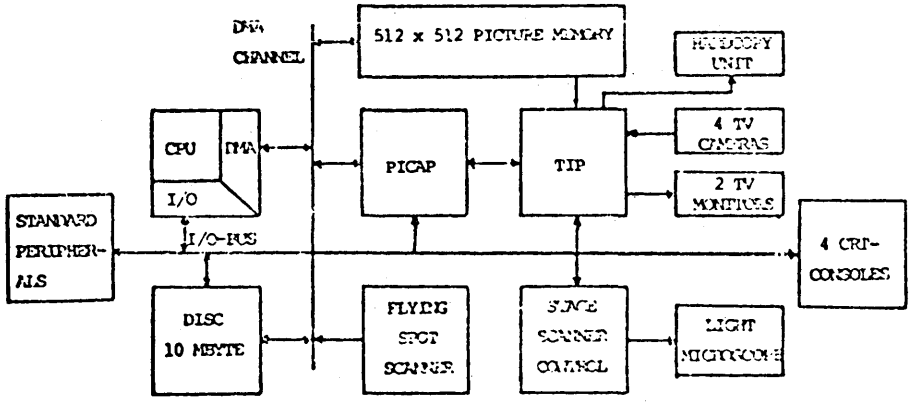

Figure 8(d)—Block diagram of PICAP computer system

capable of storing a picture. The main parts of the processing unit are the neighborhood matching logic (NML), shown in Figure 8(c), the line buffers (LB's) and neighborhood counting register (NCR) and coordinate register (COR). The demand for LB's stems from the fact that when a picture is stored in a picture register, only one picture point at a time is accessible. To be able to perform the local neighborhood operations, all nine neighborhood units must be accessed simultaneously. Therefore, two LB's are added. Note that the speed improvement is accomplished mainly at the expense of NML. The control unit is conventional in all respects except for the writable memory where the templates of an operation to be performed are stored. The parallel picture processor in Reference 9 has been linked with an ordinary minicomputer as part of the computation facilities of the PICAP picture processing laboratory[10] at the University of Linkoping, Sweden. The block diagram of the system is shown in Figure 8(d). The function of the minicomputer is twofold: (1) it controls the other devices and (2) it performs all nonpictorial data processing. PICAP which is a modified version of PPM is dedicated to the several tasks of the picture processing, such as fingerprint coding and malaria parasite detection. An important modification of PICAP has been the addition of a set of registers for the collection of measurements. The most important task of the picture processor is to produce measurements of application-dependent features. That is, to reduce the often enormous amount of information in an image to a set of feature measurements that can be handled by a conventional computer.

Each module in PPM is a synchronous sequential circuit with inputs from the 8 neighbors and the controller. All modules change states simultaneously.

STATE TRANSITION FUNCTION—Q(i,j)+=d(V,Q(i,j), Q(i,j+1), . . . , Q(i+1,j))
OUTPUT FUNCTION—U(i,j)=Q(i,j) [Moore model]

Since a Moore model is assumed, signal propagation through many layers of combinational logic is avoided and results in faster execution.

The system possesses gray scale capability since Q(i,j) can be many bits wide (say n) and can represent 2**n gray levels. This permits arithmetic operations on pictures. (Digital filtering, thresholding, image enhancement, etc.) In order to avoid long control words to fully specify the desired state transition function (extremely large number of state transition functions are possible, but few are useful in practice) a template matching scheme is proposed. Each module is capable of storing a list of templates, against which the current state vector is compared, and if a match is found a state change to the specified state occurs.

It is also possible to define arithmetic operations on pictures. For example:

$$f(P) = \begin{matrix} 0 & 1 & 0 \\ 1 & -4 & 1 \\ 0 & 1 & 0 \end{matrix}$$

can be used as the template to find the discrete Laplacian of a picture. Here Q(i, j)+=−4*Q(i, j)+Q(i−1, j)+Q(i, j−1)+Q(i+1, j)+Q(i, j+1). Operation on two or more pictures is possible by using multiple arrays with interarray communication. Conceptually this system can perform virtually any local operation. Unfortunately, hardware costs prohibit a fully parallel implementation of all features.

CDC flexible processor

Using the approach of distributed computation for designing a special purpose computer for image processing, the Control Data Corporation designed the Flexible Processor.[11] The Flexible Processor was developed for a large digital change detection system for concurrent processing of four channels of side-looking radar imagery. The Flexible Processor is a microprogrammable processor and uses random access memory up to 1024 words of 48 bits each for microprogram control. One special feature of the Flexible Processor is its data transmission which is shown in Figure 9. Four separate balanced party-line transmission channels are available. Each 32-bit channel can initiate and receive register-buffered transfers. A scanning system allows several Flexible Processors on a party-line to communicate with each other and with peripheral devices. For output transmission, a 32-bit output channel is provided which interfaces on balanced lines. A dual internal data bus system is used

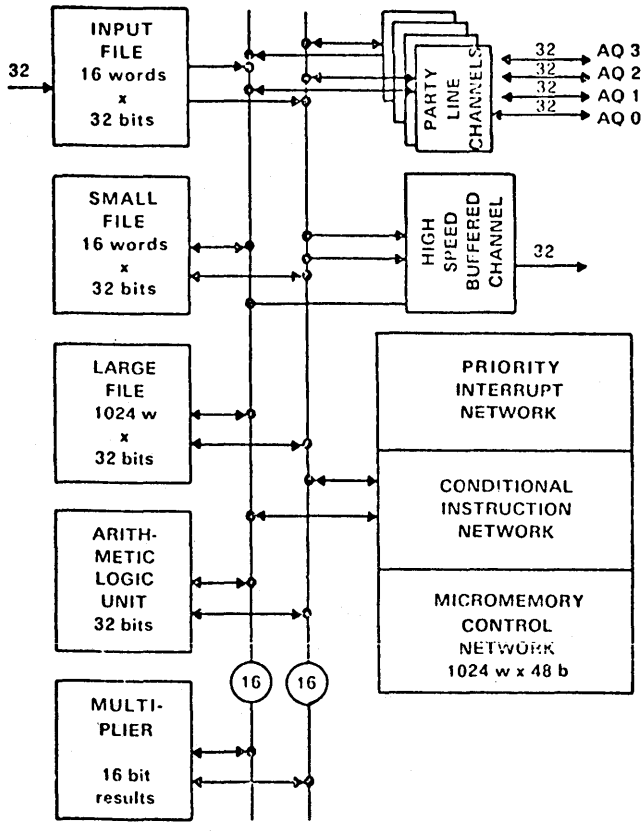

Figure 9—Block diagram of flexible processor by Control Data Corporation

to match data transfer speed to the speed of arithmetic logic. The arithmetic unit consists of an arithmetic logic unit, hardware network for conditional microinstruction execution, array hardware multiplier, specialized logic for square root and divide, and hardware priority interrupt mechanism.

TOSPICS

The TOSPICS, developed by Toshiba Company called Toshiba Image Processing System TOSPICS,[12,13] is an interactive image processing system which is a disk-based system and each operation is performed by the command input through a teletypewriter. The software system for the image processing system consists of the permanent and non-permanent resident system programs, the picture processors, the block common area, and a package of image processing programs. The system diagram of TOSPICS is shown in Figure 10. The special features of TOSPICS for image processing are that the image memory is commonly used in order to reduce the amount of data transmission and the parallel picture processor is constructed to perform certain

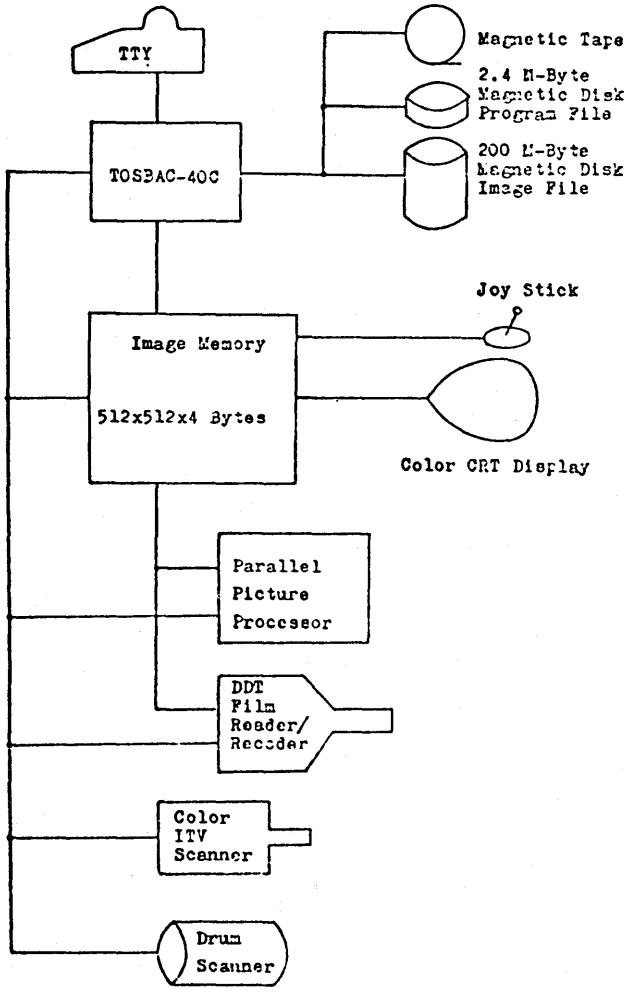

Figure 10—Block diagram of TOSPICS computer

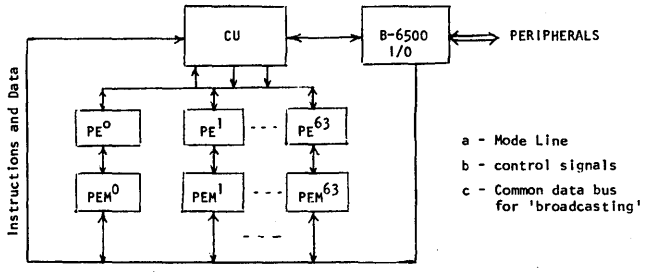

Figure 11—Functional block diagram of ILLIAC IV

programs at high speed. The parallel picture processor performs the program of spatial filtering at a speed of 1 pixel/1 μsec. The I/O devices of TOSPICS include a unique high precision flying spot scanner by a Double Deflection Tube (DDT) with 4096×4096 resolvable points and 32,000×32,000 addressable points.

Comparing the systems of Flexible Processors and TOSPICS, the basic ideas of parallel processing for image processing by the distributed computing approach are the same for these two systems. The difference between these two computer systems are the ways of utilizing processing elements. The TOSPICS uses the minicomputer, TOSBAC-40C, as an image processor and a parallel picture processor is attached to it. The parallel picture processor is used for certain programs, such as spatial filtering, affine transformations, histogram calculation, and density conversions.[12] The computer system of Flexible Processors uses the Flexible Processors as the processing elements. Each Flexible Processor is assigned for one task and several Flexible Processors are organized as the computer system.

ILLIAC IV

The ILLIAC IV[14,15] is a large array processor designed in the mid 60's to solve complex scientific problems involving arrays (matrices). The system was designed to have 256 processing elements (PE's) divided into four quadrants to achieve a total throughput rate of 1000 MIPS. However, due to cost overrun, only one quadrant has been built so far. The ILLIAC IV is patterned after the SOLOMON computer and employs one master control unit (CU) for instruction fetching, decoding and scalar operations. All processors in the array execute the same command (Figure 11).

Each processing element (PE) may be in one of the two modes: active/inactive, thus permitting some modules to be selectively disabled. Each PE has access to its own 2048 words of 64 bit memory called a PE memory (PEM). Each PE is a sophisticated arithmetic and logic unit capable of performing a wide range of operations. The PE's have been specially designed to perform floating point operations on 64 and 32 bit words very fast. The CU is also capable of executing its own instructions in parallel with the PE's. The CU has access to all the PEM's and fetches instructions from them. A broadcast facility permits common operands to be fetched by the C and 'broadcast' to all the PE's. Each PE has communication paths to nearest left and right neigh-

bors as well as to PE's at distance 8 on each side. The ILLIAC IV is under control of a Burroughs B-6500 processor which handles all I/O and operating system tasks in a conventional manner.

The ILLIAC IV is a powerful array processor for operations on matrices, vectors, etc. However, since most instructions on this system are geared toward 64 or 32 bit floating point operations while most image processing is done on integer arrays of 8 or 12 bit length, there is considerable mismatch and results in many problems. If only one pixel value is stored per ILLIAC word, most of the memory is wasted whereas packing results in execution time inefficiencies. (Eight-bit arithmetic has been recently incorporated in its hardware.[25])

The ILLIAC IV is organized as a linear array rather than as a two-dimensional array. The only routing signals being to the nearest neighbors much of the spatial connectivity relations have to be established by software.

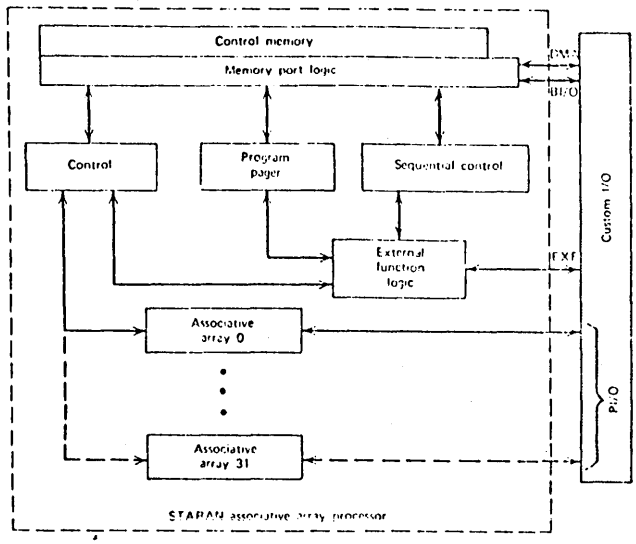

Figure 12—Block diagram of STARAN computer

STARAN

The STARAN[16] computer is a parallel processing computer built by Goodyear Aerospace Company in 1972. STARAN was not designed as a special purpose computer for image processing. But this computer was utilized for the task of resampling in the field of image processing in 1977.[17,18] The STARAN parallel processor is a *single instruction* stream *multiple data* stream (SIMD) processor.[19] The previously reviewed computers, such as, ILLIAC III, CIP 4, PICAP, and TOSPICS are also SIMD processors. The Flexible Processor is a SISD processor. The single most important element of STARAN is the associative array, which provides content addressability and parallel instruction execution capabilities. Most STARAN computing is done within a word of associative array memory. An associative array word is normally divided into fields of varying lengths by the programmer to suit the requirements of specific programs. The values of these fields then can be added, subtracted, multiplied, and divided within the word. The STARAN can perform the same operations as a sequential processor but with the added capability of performing these operations simultaneously on literally thousands of words in the associative processor arrays. A basic STARAN configuration contains an associative array. However, up to 32 associative arrays can be included in a single STARAN system. The block diagram of the STARAN computer is shown in Figure 12. The sequential controller provides off-line capabilities for assembling and debugging STARAN programs and control of STARAN error processing, diagnostic, and maintenance programs. Buffered I/O is available for tying different types of peripherals into the STARAN control memory. Also BI/O can be used to transfer blocks of data and/or programs between the STARAN control memory and host memory. The external function (EXF) logic facilitates coordination between the different elements of STARAN for special functions and simplifies housekeeping, maintenance, and test functions. By issuing external function codes to the EXF logic, elements of STARAN can control and interrogate the status of other elements. In general, the STARAN computer is powerful compared with the Flexible Processor and TOSPICS. However, only one kind of image processing task (resampling) has been carried out on this computer. Therefore, the effectiveness and efficiency of STARAN for all types of image processing and pattern recognition is still an open question.

Each STARAN array consists of 256 processing elements connected to a (256×256) bit multidimensional access memory. The array is controlled by a conventional sequential processor. The array memory and routing system permit memory access in many different modes. For example, it is possible to access in either column mode or row mode. Hence, we can process either all bits within a word in parallel or the same field of all desired words in parallel. Shifting capability has also been provided for various data manipulations such as the familiar butterfly computation for evaluating Fast Fourier transforms.

It is possible to use an associative processor as a parallel processor to operate on pixels simultaneously. For this the associative nature of the processor is not utilized but rather the parallel processing capability of the associative processor array. On the other hand it is possible to utilize the content addressibility of associative processors to simplify certain problems in image processing. Several illustrative examples can be found in Reference 22.

REMARKS

Consider the attributes of the bit-plane processing approach and the distributed computing approach. The bit-plane approach mostly uses Boolean operators as processors. Boolean operators work only on binary images which are not common in the real world. One way to get around this is to use several binary picture planes to represent the grey scale values of picture points. But, the complex software and additional memory requirement cause another problem and this problem limits the processing power of the

processor. The distributed computing approach appears to be more feasible considering the present state-of-the-art with respect to both software and hardware. Almost all the special computers discussed are only designed and tested in terms of signal-level processing[21] (such as image filtering, thresholding, thinning, and edge detection). There has been very little attention at the symbolic level, such as syntactic and semantic processing. A major drawback of previous computers is that the system's processors are not reconfigurable. The vast varieties of sensor types, applications, and image processing techniques, require that the image processing system (especially the parallel processor) be reconfigurable. Therefore, a generalized computer architecture which is reconfigurable under software control appears to be appropriate for the many applications of image processing. One of such a system has recently been proposed.[23] In the proposed computer architecture parallelism with the task is exploited by a multi-microprocessor parallel processor. In the meantime the operations of the sequential arithmetic processor are pipelined with the parallel processor under programmer control in certain tasks which can be decomposed into pipelined processing. Therefore, parallelism and pipelining are exploited at the same time in the proposed computer architecture.

In some special applications, the use of an auxiliary memory for image processing has been implemented in conventional computer facilities for image processing and pattern recognition research. One example is described in Reference 24. The computing facility is organized around a DEC PDP 11/45 digital computer with 32K core memory and 96K fast secondary memory, two disk drives, a magnetic tape drive, two cassette tape drives, a line printer, and a CRT monitor. The computer is not a special purpose computer, but the auxiliary memory is a special feature for image processing. The auxiliary memory was developed for image processing mainly because of the limited addressing range of the 16-bit minicomputer. Therefore, the limited addressable memory is difficult to use for implementing large programs. A memory controller has been built which can access up to 2^{32} bytes of memory and which now controls 64K 16-bit words of core memory. The controller is interfaced to the PDP 11/45 unibus through essentially three 16-bit registers. Two registers form an effective address of 32 bits, and the third register contains the data to be written into the memory or the data read from memory. Once the address is loaded on the two registers, data can be written into or read from memory in less than one microsecond. Since large arrays of data can be addressed without I/O to the disks, execution times improve. Also, computer programs become simpler since no sophisticated disk-core swapping software is needed. An experiment on rib identification in chest x-ray images was programmed once without using the auxiliary memory and once using this memory. On the average, the execution time improved a factor of five. Other software shows comparable execution time.

Experience with a picture processor in pattern recognition processing*

by BJÖRN KRUSE
Linköping University
Sweden

INTRODUCTION

In recent years much effort has been devoted to the study of picture processing algorithms and pictorial pattern recognition. The efforts have resulted in both theoretical understanding of and practical approaches to some of the basic problems involved.

Common to the areas of picture processing is the great need for processing power. One picture may contain as much as several million picture elements (pixels). A scene viewed through a common television camera for example, represents approximately two megabits of data renewed 25 times per second. To produce or analyze data at such rates is completely beyond the capacity of the general purpose computer. Even if the speed is increased by a factor of ten, which may be anticipated in the future, the GPC will fall short when faced with real-time applications. The problems stem from the fact that pictures represent a new type of data, orders of magnitude richer in information than that for which the GPCs architecture was designed.

Many attempts have been made to design a computer architecture that is more suited for picture processing[1–7] and in some cases the machines have also been constructed.

The design of the PICAP processor has evolved through a number of generations. Starting with a simulation study in 1971,[8] the first version of the processor was built in 1973.[4] Gradually as experience with the processor accumulated new features were incorporated such as automatic histogramming and collection of various measurements made on the picture. The final version of PICAP which will be described here has been operational since the beginning of 1975.

PICAP AND ITS ENVIRONMENT

The following paragraphs give a brief presentation of the PICAP Picture Processing Laboratory as a background to the description of PICAP's architecture. For a complete description of the laboratory see Reference 9.

PICAP operates in close connection with a conventional minicomputer of quite standard configuration. Standard peripherals, such as alphanumeric and graphical displays, and a multi-user disc operating system are the main features. PICAP and the computer are also connected to an advanced television input/output interface, TIP[15] (see Figure 1). Both PICAP and TIP are controlled by the computer which besides its controlling function performs all computations of non-pictorial nature.

Through TIP PICAP has access to an entire TV field of 512×640 pixels from which a randomly positioned window of 64×64 4-bit pixels may be extracted at full video rate. Both the sampling density and gray-level range in the digitization process are controlled by a set of programmable parameters. Thus the window may in one frame represent the entire field coarsely sampled with the full dynamic video range mapped onto the 16 level gray-scale and in another frame it may represent a small subpicture densly sampled in a certain slice of the video range. Consequently a scene may be analyzed on many levels starting with a coarse overview and ending with a detailed analysis in full resolution. These features correspond in a way to the vision systems found in nature where only a limited retinal area, the fovea, have high spatial resolution and where a scene is sequentially scanned by mechanical eye movements.

There are four video channels available in TIP of which two are used for the present. One camera is permanently mounted on a light microscope which is supplied with a computer controlled stage scanner and the other is mounted on an optical bench so that ordinary slides may be read.

THE ARCHITECTURE OF PICAP

PICAP belongs to the category of "single-instruction-stream multiple-data-stream" (SIMD) processors. Unlike many processors used for pattern recognition, it is fully programmable with an instruction set especially tailored for efficient processing of both gray-level and binary pictures. Equally important as the feature of programmable picture into picture transformations is PICAP's capability to extract measurements. In all pattern recognition tasks the (often very redundant) input data has to be reduced into a set of adequate descriptors that describe its relevant features, such as gray-scale distribution, object position and shape. It is very important that this can be done efficiently since these

* This work is supported by the Swedish National Board for Technical Development (STU).

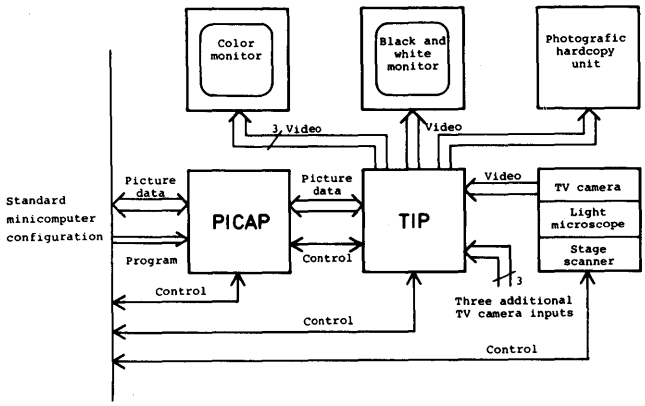

Figure 1—Processor environment

descriptors, measurements, form the basis for a subsequent classification. From the processor's point of view the measurements constitute the final result. The picture transformations only serve to enhance the features that finally are to be measured.

The 64×64 4-bit window mentioned in the preceding section constitutes the basic data unit that PICAP operates on much in the same way as the 16-bit word is the data unit for common minicomputers. Figure 2 shows schematically the two main types of processor action on the picture data, *multiple* picture processing and *neighborhood* processing. In the multiple processing mode two, X and Y, or more (up to nine) pictures are operands giving a result Z, the pixels of which are determined by the corresponding pixels in X and Y and the actual operation. Thus

$$Z_{ij}=F_C(x_{ij}, Y_{ij}, \ldots)\ i,j=1, 2, \ldots, 64$$

The mapping function F_C is defined by C, a set of parameters which is supplied by the instruction. Typical multiple mode instructions are weighted summation (e.g., subtraction) of pictures and masking.

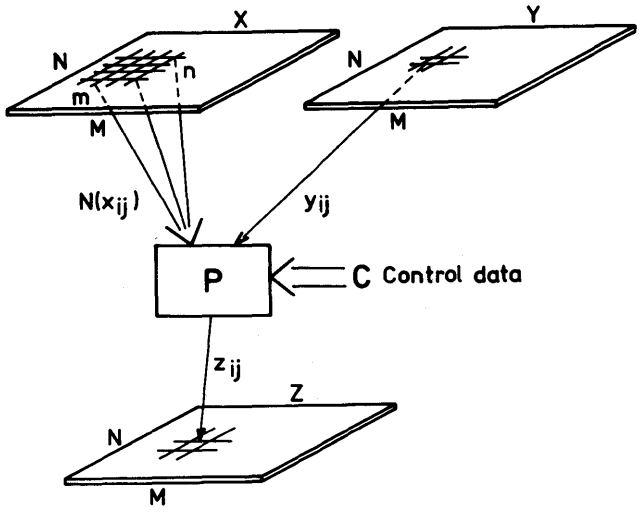

Figure 2—Schematic operation of the processor

The neighborhood operation mode applies to a single picture, X, at a time. In this case the output pixels of array Z are determined by corresponding pixels in X and their immediate surrounds, the 3×3 neighborhoods $N(x_{ij})$.

$$Z_{ij}=F_C(N(x_{ij}))\ i,j=1, 2, \ldots, 64$$

The actual neighborhood operation is determined by the parameter set C and it is performed identically on all neighborhoods of X. Convolutions, shrinking and labelling of pictures are typical examples.

Note that the actual mapping, symbolized by F_C, is identical in the two modes. It is only the operands that differ.

In addition to the instructions belonging to the categories above there are trivial instructions, such as input/output and shift of pictures, that will not be discussed here.

The main units of the processor are shown in Figure 3. The picture memory PM is a set of nine separate picture registers $R_0, R_1, \ldots, R_8$ into which any window of the input TV field may be loaded. The registers are also used for intermediate results much in the same way as the registers of common CPUs are. The MLA unit in which the actual processing is performed takes its operands either from the nine picture registers (multiple mode) or from the neighborhood registers $Q_0, Q_1, \ldots, Q_8$ of the LB unit (neighborhood mode). The parameter that determines the actual processing resides in CTM which essentially is an extension of the instruction register not shown in the figure.

Simultaneously to the processing of pictures the MLA unit collects instruction dependent measurements that are stored in a set of thirty-three registers, MR. To enable conditional branches in the instruction flow to the processor the contents of these registers are made available to the controlling computer at the end of each executed instruction. In a way the measurement registers are the analogue of the status register in conventional computers in that they describe the outcome of an instruction.

As has been stated above PICAP is a SIMD processor since a single instruction determines the operation performed on a large set of operands, the pixels. Physically, SIMD processors may be designed with different degrees of hardware parallelism and this is especially apparent for picture processors where there are three distinct levels on which the parallelism may be introduced, the pixel, the neighborhood and the picture levels. On the pixel level there is a choice on the number of bits that can be processed in parallel. In PICAP this is four, contrary to most existing picture processors that are binary. On the neighborhood level the degree of parallelism is equal to the number of neighborhood pixels that may be accessed and processed simultaneously which in most existing processors including PICAP is nine, a 3×3 neighborhood. Finally on the picture level the choice is on the number of neighborhood processing units. In PICAP there is one, the MLA unit, which means that the neighborhoods are processed sequentially. The level on which the great hardware effort should be made is a controversial question which will be commented on in the last section.

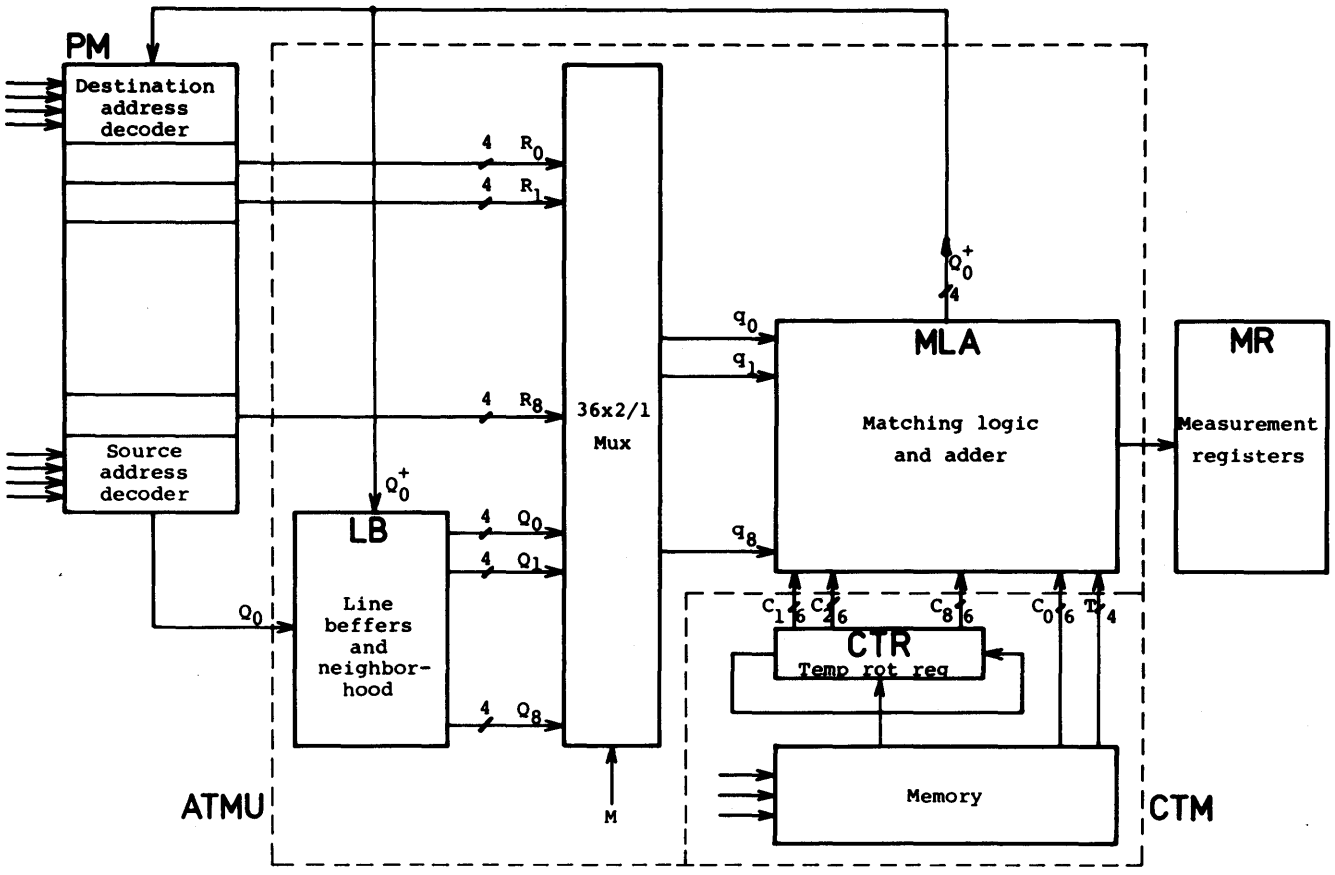

Figure 3—Matching logic, adder and line buffers

THE INSTRUCTION SET

There are two main PICAP instruction categories: the logical and the arithmetical instructions. The instructions are described in detail in References 9 and 10 and only a summary will be given here. Their characteristics will be described as applied in the neighborhood operation mode. The implications for the multiple mode operation are obvious.

The logical neighborhood instructions are based on generalized 3×3 templates called *condition templates* consisting of nine subconditions one for each of the neighborhood elements. Each instruction may contain up to eight such condition templates. In the course of execution the picture neighborhoods are all subjected to a test whether they do or do not belong to the class of neighborhoods defined by the set of condition templates of the instruction. If a neighborhood matches a certain template its center pixel is given a new value, T, that is supplied by the instruction. *All other pixels remain unaffected.* In case of multiple hits a simple precedence rule determines the new value. The entire transformation may be thought of as an associative multiple search in two dimensions for pixels whose neighborhoods correspond to certain features as defined by the templates.

The subconditions C_K are composed of a relation R_K and a number n_K, $C_K=\langle R_K, n_K\rangle$. The condition is fulfilled iff the pixel q_K is related to n_K by R_K. Four different relations may be used: equal to (E), less than (L), greater than (G) and the universal relation (X=don't-care). The subconditions are defined over the 3×3 neighborhood forming a condition template

$$C \equiv \begin{matrix} C_4 & C_3 & C_2 \\ C_5 & C_0 & C_1 \\ C_6 & C_7 & C_8 \end{matrix} \quad T$$

A certain neighborhood matches a condition template iff all its element fulfill their corresponding subconditions. To each condition template there is associated a transition value T, the value into which the center pixel is transformed in case of a match.

The format of the instruction is shown in Figure 4. It is a variable length format as the number of condition template is not fixed. The instruction-head contains a modifier field and the addresses of the source and destination registers besides the operation code. A number of variations to the instruction's basic properties as described above may be specified in the modifier field (see Figure 5). For example,

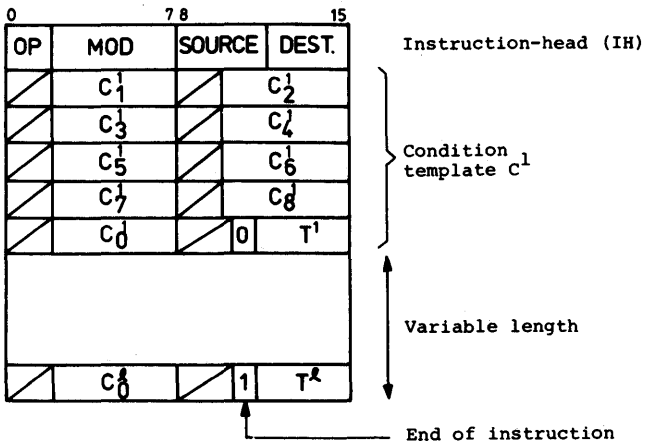

Figure 4—Format of logical instructions

the modifier M determines the mode of operation, multiple or neighborhood mode. The other modifiers apply to isotropic application of the templates ($R4$ and $R8$), loop operations (It), extraction of the first matching neighborhood (In) and sequential picture operations (S). A full descriptions of these are given in Reference 10 which also contains a number of typical operations. A trivial example is given below.

Example 1: Neighborhood dependent thresholding.

X	Gn	X			X	X	X	
Gn	Gn	Gn	1		X	X	X	0
X	Gn	X			X	X	X	

The first template of the instruction covers the class of five element neighborhoods whose elements have a value greater than n (Gn). Due to the precedence rule, center points that belong to such neighborhoods will aquire the value 1 irrespective of the second template. As the latter covers all possible neighborhoods the remaining pixels will get the value 0. (End of example.)

Compared to the logical instructions the arithmetical ones are conceptually much simpler. They have the form of a convolution between an array of coefficients defined over a 3×3 neighborhood and the picture array. The computations are followed by normalization with a factor 2^{-n} so that the result will not overflow. Hence the center pixel of the neighborhood is replaced by the value of the expression

$$\left(\sum_{i=0}^{8} m_i q_i\right) 2^{-n}$$

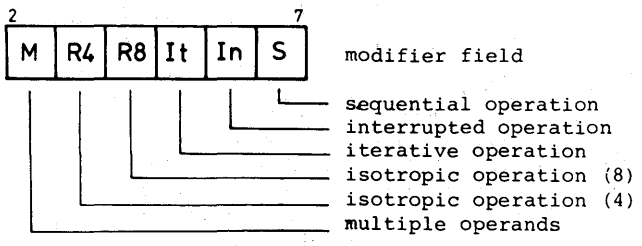

Figure 5—The modifier field

The coefficients $\{m_i\}$ and the normalizing exponent n have eight and four bits precision respectively. The instruction format is similar to the logical instruction format.

The following example shows a simple contrast enhancement operator.

Example 2: Contrast enhancement.

Coefficient array:			Normalizing factor:
−1	−1	−1	
−1	40	−1	2^{-5} (1/32)
−1	−1	−1	

The operator has unit again for low spatial frequencies and enhances high frequencies.

MEASUREMENT EXTRACTION

The picture transformations described in the preceding section are accompanied by a fairly large set of automatically performed measurements.

- Neighborhood counting
- X-Y extent determination
- Gray-scale maximum, minimum and average
- Histogram collection

Neighborhood counting

To each condition template of a logical instruction is associated a counter which is incremented for each occurrence of a matching neighborhood. Hence locally countable properties such as Euler number, area and perimeter are easily extracted.

X-Y extent determination

To provide for extraction of positional information there is a set of four registers $X_{\min}$, $X_{\max}$, $Y_{\min}$ and $Y_{\max}$ that gives the maximum and minimum coordinates on both axes for the occurrence of a matching neighborhood. The set of coordinates defines the minimum rectangle aligned with the axes that enclose a set of features which is described by the templates.

Gray-scale maximum, minimum and average and histogram collection

The gray-level distribution and its maximum, minimum and average are collected in a set of 19 registers HC_0, HCl, . . . , HC_{15}, $G_{\max}$, $G_{\min}$ and G_{av}. Any transformation of a picture results in an updated set of gray-scale measurement.

It should be noted that the inclusion of automatic measurements is especially simple in a processor where the pic-

ture is sequentially processed since it amounts to little more than a straightforward counting procedure.

EVALUATION AND PERFORMANCE

During the years that PICAP has been operational it has been employed in many different pattern recognition projects. A subset of these form the basis for the following evaluation of the instruction set. The subset is chosen to contain quite dissimilar applications in order to reflect the operational use of PICAP in different contexts. The evaluation is based on three programs: printed circuit board inspection, malaria parasite detection and fingerprint coding. The object of the statistical analysis below has been to quantify the use of the instruction categories, modifiers etc. and most of all to see how often the controlling minicomputer has been used for picture processing.

The printed circuit inspection program tests the circuits with respect to the minimum tolerable conductor widths and separation. It incorporates necessary adaptive thresholding of the gray-level input pictures[11] and generation of a pseudo color output picture that indicates the defects. The nominal width of the conductors and insulators is checked by an appropriate number of erosion and swelling operations. The statistics are shown in Figure 6.

The statistic material shown in Figure 7 is the pooled statistics from two separate programs for classification of and core location in fingerprints. For a complete description of these programs see References 12 and 13. The fingerprints are read by a TV camera. Through the use of appropriate direction sensitive filter operators the ridge and valley pattern is extracted. Then syntactical methods are used to compute the category assignment and the location of the fingerprint core.

The malaria parasite detection program[14] is the most advanced of the application programs. Biological specimens of malaria-contaminated blood cells in a thin smear on a microscope slide are analyzed. During the scanning procedure the infected blood cells are located and the parasites are classified according to their stage of evolution. One test evolves the analysis of 5000-6000 red blood cells which takes approximately five minutes for a skilled microscopist whereas the automatic program takes eight minutes. Figure 8 shows the statistics. The descriptions above are of course very schematic and do not at all give full credit to the actual sophistication of the programs.

It is apparent from the pooled statistics in Figure 9 that the predominant instruction category is the logical instruction. This category accounts for over 70 percent of all executed instructions. It is less dominant in the case of the malaria parasite program (55 percent) presumably because the source data is inherently non-binary. The picture transfer and arithmetical instruction types are equally frequent, accounting for approximately 15 percent each, whereas the shift instruction is virtually never used. As a shole the malaria parasite program exhibits greater balance between instruction types, reflecting the general type of processing required.

The modifiers of the logical instructions are used in approximately 50 percent of the cases which means that the nonmodified, i.e., the one-operand local, logical instruction accounts for 50 percent. Among the modifiers the isotropic ($R8$), and the multiple operand modifiers are used most frequently. Of the eight available templates in the instruction format only one or two are needed in nearly 90 percent of the cases. The one- and two-template instructions account for 44 percent each.

The picture transfer instructions, of which the input type is predominant, are second-most-frequently used. It is an interesting fact that of all executed instructions input from the TV field to PICAP accounts for over 10 percent which means that on the average every tenth instruction inputs a new picture. This emphasizes the need for fast transducers. Loading of a picture should not be slower than the execution of one instruction if the processor is to be kept busy 90 percent of the time which seems to be a reasonable figure. Another interesting fact is that transfers of pictures to the host computer's memory are virtually nonexistent (less than 1 percent) which means that essentially *all picture processing operations are performed in PICAP*. As PICAP programmers always have the option of processing the pictures in the host computer this indicates that the chosen instruction and measurement sets are very well adapted to the task set.

The arithmetical instructions are used to approximately the same extent as the transfer instructions, 14 percent. Multiple operand instructions such as addition/subtraction of pictures are relatively infrequent, 12 percent.

Among the picture registers R_0 is most frequently used. In 68 percent of the instructions R_0 appears as either source or destination register. R_0 and R_1 together account for over 80 percent of the cases which indicates that the number of nine registers is more than sufficient.

To measure the performance in terms of the execution time for the basic instructions is always unsatisfactory since it obviously depends on many other factors such as the speed and versatility of the picture transducer, the host computer and its operating system. The best figure of merit for the PICAP system is given by the malaria parasite program which, as has been stated above, has a performance of a skilled microscopist. The processing speed including input, feature extraction and classification of the parasites is 10-15 blood cells per second.

Finally, for the sake of completeness the execution time for the basic one-template and two-template logical instructions are 1.2 and 1.5 μs/pixel respectively. The execution time for arithmetical instructions are 1.2 and 3.6 μs/pixel for a smoothing and an arbitrary convolution respectively.

CONCLUSIONS

The PICAP architecture and instruction set has been shown to cover the needs for solving typical pictorial pattern rec-

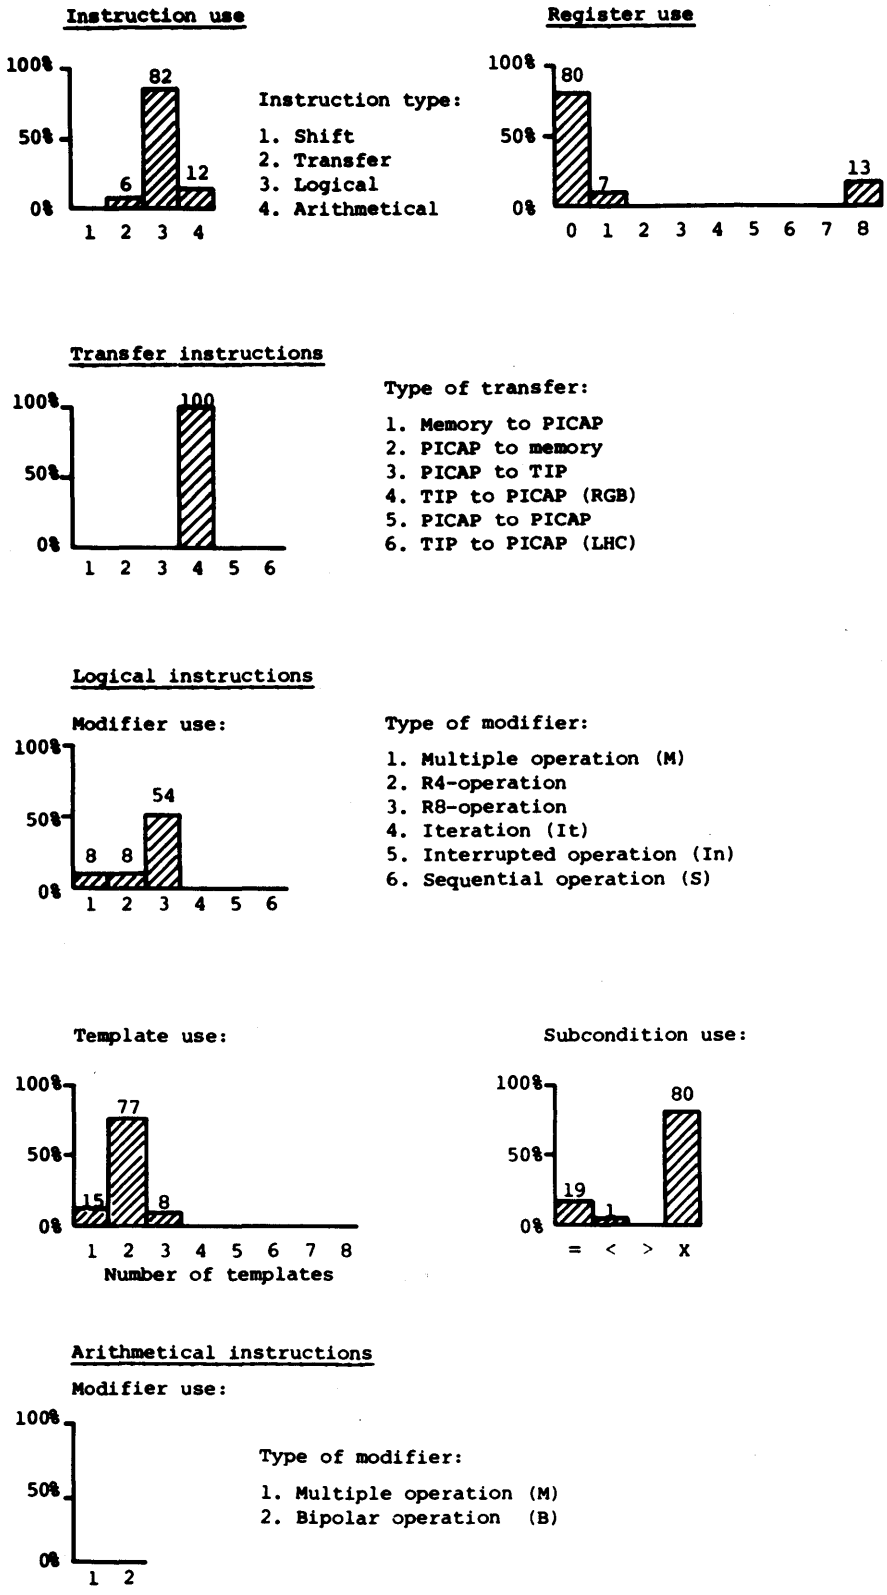

Figure 6—Statistics of the PC-board inspection program

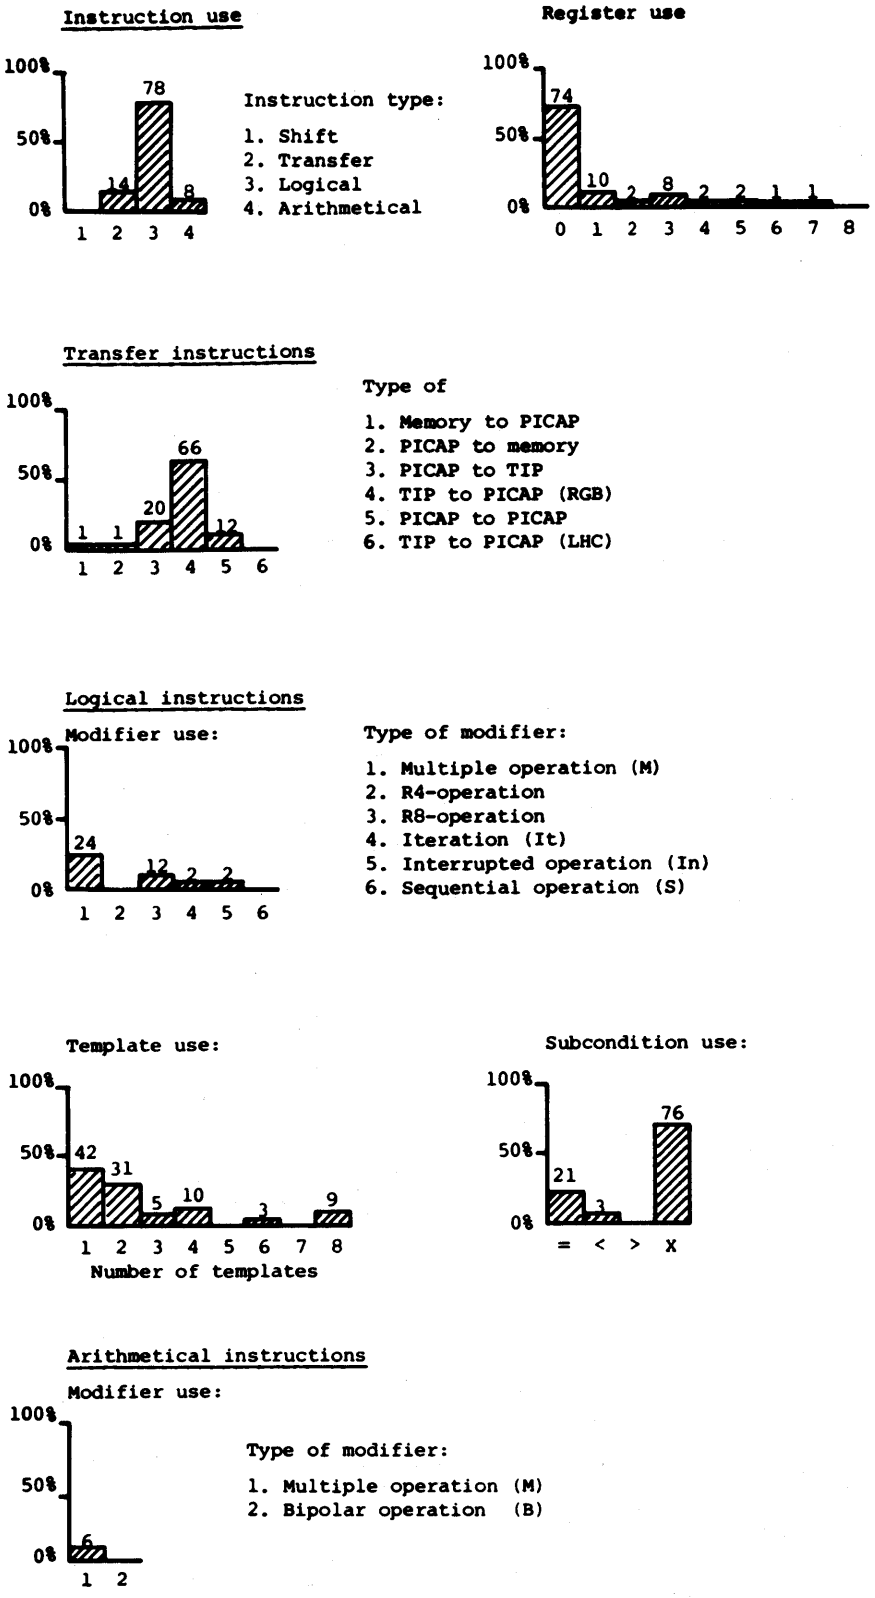

Figure 7—Statistics of the combined fingerprint classification

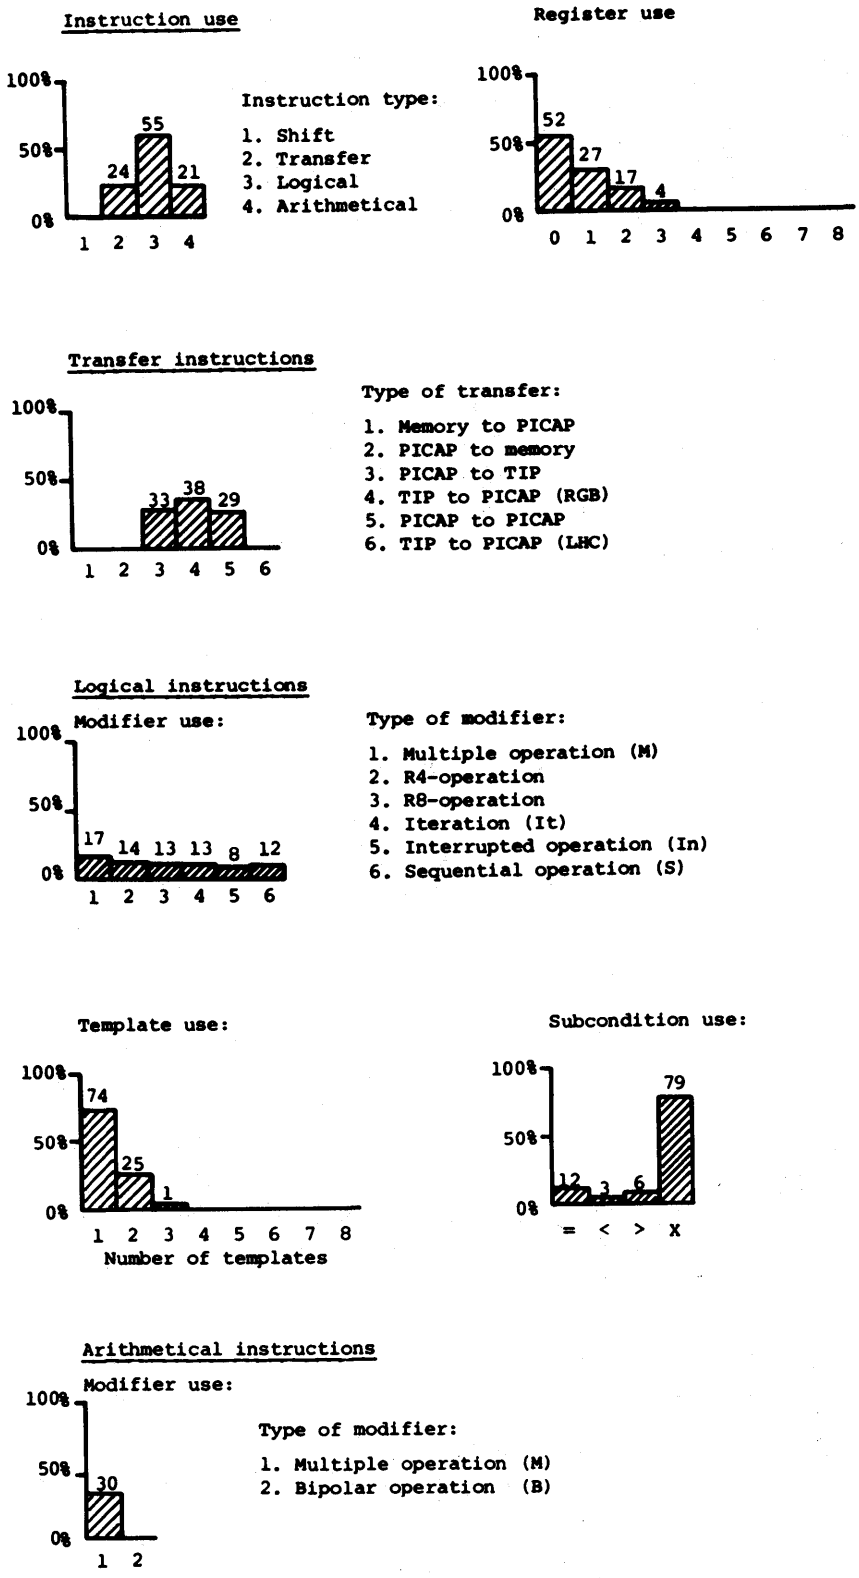

Figure 8—Statistics of the malaria parasite detection program

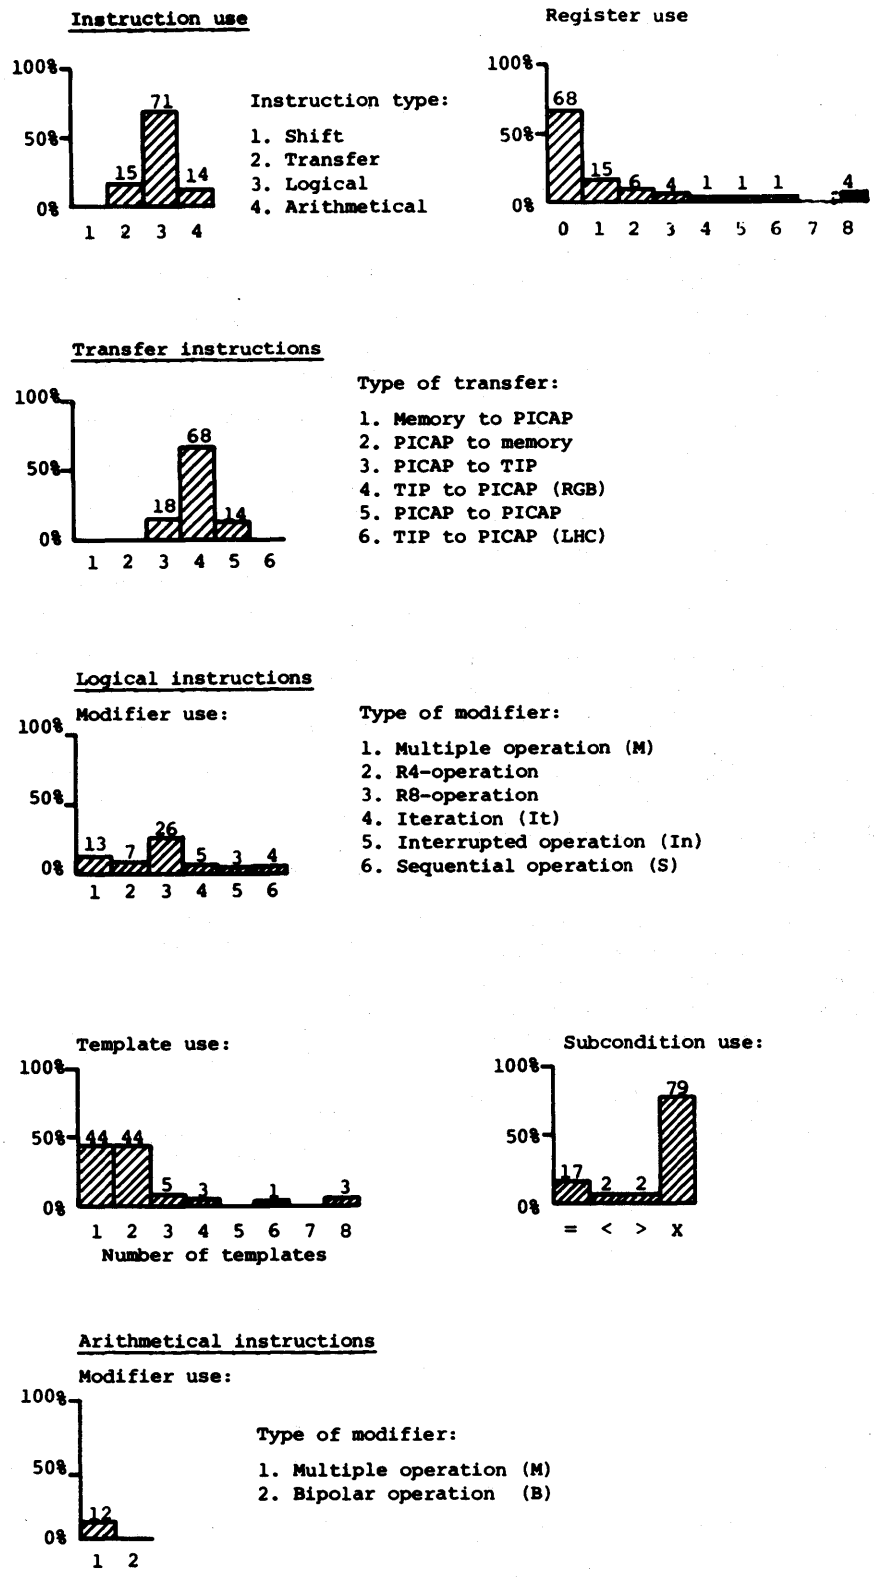

Figure 9—Pooled statistics

ognition applications very well. The performance in an advanced task like malaria parasite detection, equals that of a skilled microscopist.

The fact that on the average only nine operations are performed on each input picture is not explained by the well-adapted instruction set alone. It is also a consequence of the frequent use of several levels of sampling density. This means that featureless parts of the input scene often may be located in a coarse survey at an early stage of the recognition procedure. Since such parts need not be further processed the average number of operations per picture is lowered.

The high frequency of input instructions stresses the need for fast picture transducers. On the other hand, the speed requirements of a processor with PICAP's characteristics is limited to not much more than nine times the speed of the system's transducer.

The ability for fast collection of various measurements is very important. The ease with which such facilities are incorporated in PICAP, using not much more than a simple counter for each measurement, speaks strongly in favor of physically sequential machines.

In processors where parallelism on the picture level is used, corresponding measurements have to be extracted by a cumbersome programmed procedure. The number of program steps for such an extraction may be several orders of magnitude larger than the initial number of processing steps that produced the feature to be extracted. Therefore the high inherent speed of truely parallel machines in picture-picture transformations is very much impaired in pattern recognition applications.

In fact, PICAP with its low order of complexity can in several cases compete with more elaborate parallel designs. Another reason for this is that the sole neighborhood processing unit of a sequential processor may easily be made more powerful than the corresponding multiple units in a parallel design.

Finally, the continuing advance of IC manufacturing makes the future look bright for practical, high-performance picture processors.

ACKNOWLEDGMENTS

The author wishes to thank Dr. K. Rao, K. Balck and P. Rowa for the application programs and Prof. P. E. Danielsson for suggestions and support during this work.

Design of local parallel pattern processor for image processing

by KEN-ICHI MORI, MASATSUGU KIDODE, HIDENORI SHINODA, and HARUO ASADA

Toshiba Research and Development Center
Kawasaki, Japan

INTRODUCTION

Several image processing machines have been designed and some of them already implemented. The Illiac III by McCormick,[1] hexagonal processor GLOPR by Golay,[2] and binary image processor BIP by Gray[3] are examples. The idea of parallel processing hardware has proved its feasibility, appealing to a number of industrial applications. Special purpose image processors, such as the optical character reader,[4] the white blood cell differential count analyzer,[5] the remotely sensed data analyzer[6,7,19] and the computer tomography machine[8] have their characteristic architectures according to their purpose. General purpose image processors have been proposed by several research groups[9–11,18] and are demonstrating their ability.

The problem now to be solved is determining what architecture of image processing machines is superior in the cost performance ratio. Trade offs in various aspects like speed, generality and economy, should be discussed. Our approach is a microprogrammable local parallel pattern processor (PPP) which has several basic image processing functions in a simple hardware. In the second section, major concepts considered for the design of the PPP will be discussed, and in the third section, the details of the implementation of the basic image processing functions are described. Some simple examples of programming the PPP will be shown in the fourth section, but the details of command formats, application softwares for remotely sensed data analysis, medical image processing, etc. can be found in other papers.[12–14]

DESIGN CONCEPTS

The PPP has several features in design concepts for improving the image processing cost performance ratio. These features contribute to speeding up major calculations in image processing to approximately 100 times faster than by the conventional digital computers, and to reducing the hardware cost and complexity.

Image memory

The PPP is directly connected to the image memory unit of the interactive image processing system TOSPICS (**TO**Shiba Pattern Information Cognitive System) shown in Figure 1. In the TOSPICS, the image memory unit plays five roles, as high speed buffer memory for image input/output devices, refresh memory for color display monitors, working memory for the PPP, buffer memory for a magnetic disk unit and external bulk memory for the host mini-computer. This configuration minimizes the "idle" data transfers among hierarchical levels of the memory. The time for those data transfers generally share a large fraction of the total throughput time by conventional computer configurations, which are not necessary for the essential calculations in the image processing.

Basic image processing functions

There are several types of computation that are frequently used in image processing. Most of such operations take a large amount of time. The parallel image processing machine should be fast enough to execute those basic operations for improvement in the cost performance ratio.

Those basic image processing functions are listed as follows:[15]

(1) Two Dimensional Convolution

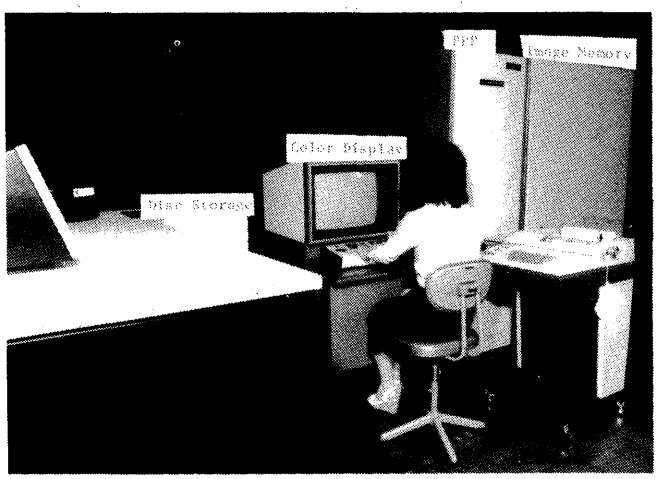
$$G(X,Y)=\sum_{i=1}^{m}\sum_{j=1}^{n} W_{ij}F_{ij}(X,Y) \tag{1}$$

where $F_{ij}(X,Y)$ is a neighboring pixel of input image data around the coordinate value (X,Y), and W_{ij} is an element of weighting matrix of size $m\times n$. This computation is used in such image processing operations as: convolution, spatial filtering, general linear algebra computations, correlation, template matching, texture analysis, K-L transformation of image,[13] and scene classification by matched filter or maximum likelihood method. Many operations used in spatial frequency domain analysis, such as restoration, enhancement, reconstruction from projections can be similarly expressed by Eq. (1).[16]

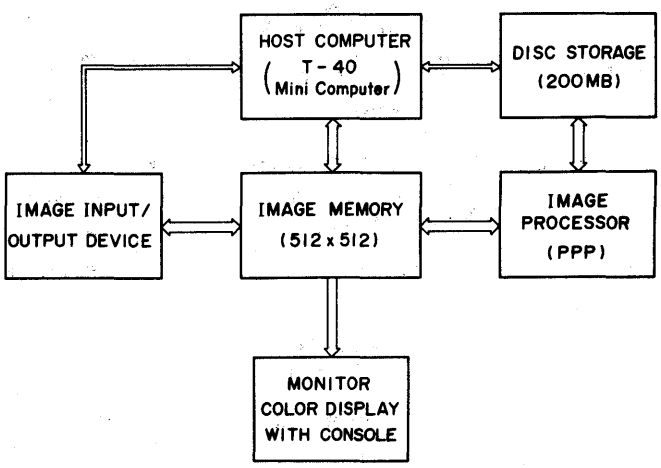
(2) Point Mapping

$$G(X,Y)=\phi\{F(X,Y)\} \tag{2}$$

where ϕ is a single-valued (usually nonlinear) function. Point mappings are used for such operations as: enhancement,



(a) TOSPICS Overall View



(b) TOSPICS Blockdiagram

Figure 1—Overview and blockdiagram of TOSPICS

nonlinear filtering, gray scale mappings, multilevel thresholding, pseudo-color generation, correction of intensity nonlinearity of image sensors and displays.

(3) Linear Coordinate Transformation

$$\begin{cases} G(X,Y)=AF(X,Y) \\ A:\begin{pmatrix} X' \\ Y' \end{pmatrix}=\begin{pmatrix} a & b \\ c & d \end{pmatrix}\begin{pmatrix} X \\ Y \end{pmatrix}+\begin{pmatrix} e \\ f \end{pmatrix} \end{cases} \quad (3)$$

where A is affine transformation specified by a linear coordinate transformation matrix and shift values. This operation is used for rotation, size change and registration of image.

In addition, logical filtering, region labeling, histogram generation and pixel operations are frequently used. These basic image processing functions are greatly speeded up by the use of specially designed circuits.

Local parallel vs. fully-parallel

There are two types of parallelism in image processing. The most popular idea is a two dimensional array of identical pixel processing elements, which works simultaneously on independent data stream per processing element. However, the image processors on the fully-parallel basis using a large number of LSI calculation elements[17] have restricted data communication between only adjacent neighboring pixels. This architecture will limit the applicability of the image processing operation of Eqs. (1) and (3), or will need excessive time to access neighboring image data, which cancels the speed-up effects brought about by the fully-parallel basis.

A pixel generally has stronger dependency to neighboring pixels than to those in the distance. The range of neighboring pixels depends on the nature of operations, but it falls between 3×3 and 32×32 pixels surrounding the center pixel. In the PPP, the local parallel processing, i.e., parallel accessing and calculation within local dependency up to $n\times n$ neighboring image data, is carried out in the specially designed circuits. Then, the center position of local parallel operation is shifted sequentially to the next position. The combination of local parallel processing and the sequential processing fits the serial data transfer characteristics of image data input/output devices and image memory.

Dynamic microprogramming

The PPP includes seven special purpose modules for two dimensional convolution, point mapping, linear coordinate transformation, logical filtering, histogram generation, region labeling and pixel operations. These functions can be combined for more global and complex functions such as texture analysis, shape identification, region separation and so on. By using dynamically rewritable microprogram architecture, powerful and flexible programs of image processing were designed and demonstrated in the interactive image processing system TOSPICS.[12,13]

IMPLEMENTATION

System configuration

An overall blockdiagram of the PPP is depicted in Figure 2. The host computer in TOSPICS is a minicomputer TOSBAC-40C with 64 K bytes memory. The image memory, the TOSPICS pivot, consists of four layers of 512×512 pixels, 8 bit per pixel, and four planes of 512×512 binary graphic memory. The two dimensional convolution module includes a buffer memory of a shift register and a weighting matrix memory. The shift register storing the image data of n lines enables a parallel accessing of $n\times n$ image data for the local parallel calculations. The 512 byte scratch-pad memory is needed for table look-up operations in logical filtering, point mapping and region labeling. It is also used as 256 registers of 16 bit length in histogram generation.

The image memory is connected to the high speed bus in the PPP, which has a transfer rate of 4 M bytes per second. The interface to the image memory has two address controllers which independently calculate the input and output memory addresses and transfer image data simultaneously to or from any image memory layer or graphic plane. Those address controllers are used for the linear coordinate transformation of image data. They are capable of calculating

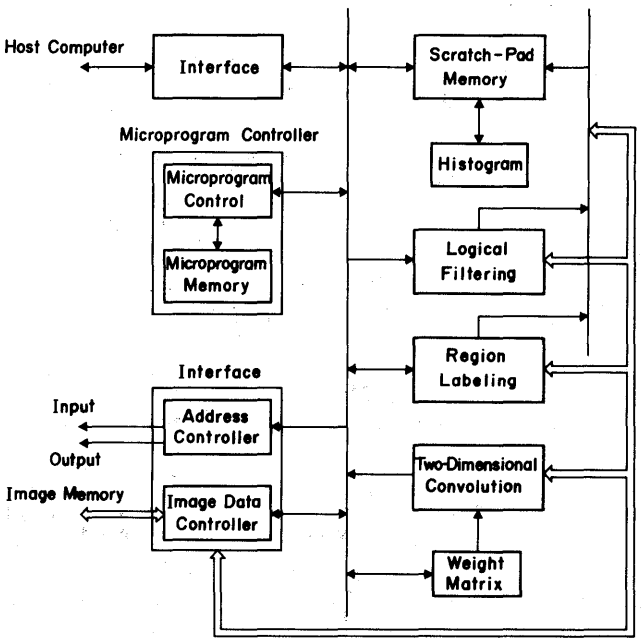


Figure 2—Local parallel pattern processor blockdiagram

next memory addresses automatically, and checking the boundary of image data.

The microprograms and execution commands are transferred through the interface from the host computer with a set of parameters to execute those programs and commands. The processed image data are usually transferred to an image output device, but data can be also stored in the disk memory for the higher level processing, such as image understanding.

Table I shows a repertoire of execution commands. They are grouped in three categories: initialization commands, parameter transfer commands and function execution commands. Initialization commands initiate the internal status of the PPP and transfer any user's microprograms into a random access program memory. Some of the frequently used microprograms, such as enhancement, pixel operations and maximum likelihood decision can be stored in the read-only program memory. Parameter transfer commands permit parameter data communication between the host computer and the PPP. Function execution commands start image processing functions. At the end of operations, an interrupt signal is generated to the host computer.

TABLE I.—Command Repertoire

Mnemonic Code	Function
CLR	PPP Initialization
LMP	Load microprogram in the program memory
LDT	Load data in the scratch-pad memory or in the weight table
SAR	Set parameters in address registers
ASM	Assign memory for processing
TDT	Transfer data from the table memory
FLT	Two-dimensional convolution
AFN	Affine coordinate transformation
HST	Histogram computation
DCV	Data conversion
LFL	Logical filtering
LBL	Region labeling
PIX	Pixel operation

Details of the basic function modulus

Two dimensional convolution module

Figure 3 shows a mechanism for two dimensional convolution function by Eq. (1). It includes m^2 multiplications and (m^2-1) additions for the weighting matrix W_{ij} whose size is $m \times m$. It is obvious that the more parallel arithmetic elements are used, the faster the computation will be performed and the more circuit cost and complexity increase exponentially. To reduce the number of required arithmetic elements, a time-shared pipeline control technique is adopted. The principle of the control is as follows: Eq. (1) is expanded as

$$G(X,Y)=\sum_{j=1}^{m} W_{ij}\,F(X+n-1,Y+n-j) + \cdots + \sum_{j=1}^{m} W_{mj}\,F(X+n-m,Y+n-j) \quad (4)$$

where m is the size of the weight matrix w_{ij}, $F(X,Y)$ is a pixel of input image data at the coordinate values (X,Y), and $n=\left[\frac{m+1}{2}\right]$. By the use of the circuit shown in Figure 4, each term of Eq. (4), a partial sum of products, is calculated by m multipliers and $(m-1)$ adders in parallel, while m terms in Eq. (4) are calculated successively and summed up by the last adder. This configuration of two dimensional convolution module reduces the number of multipliers and adders from m^2 to m, while the total calculation time increases m times, compared with the fully-parallel base configuration.

In practice, the weighting matrix size was determined to be eight as a result of a trade-off between speed and econ-

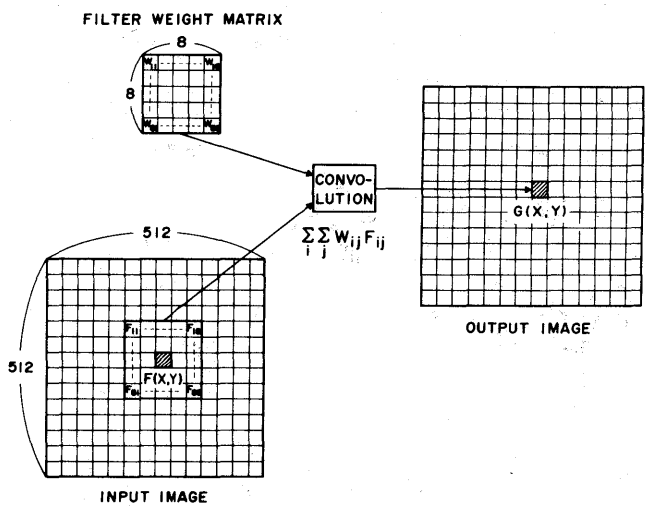

Figure 3—Two-dimensional convolution mechanism

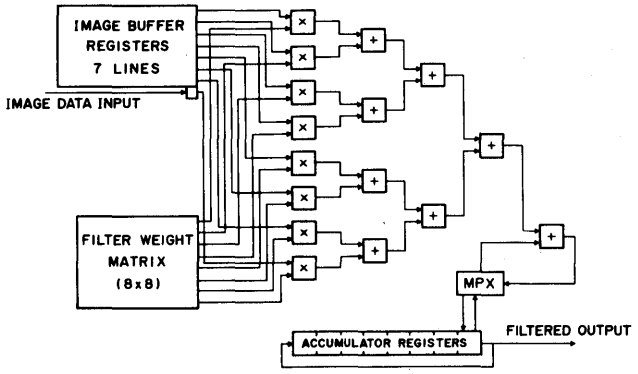

Figure 4—Two-dimensional convolution circuit blockdiagram

omy. Every partial sum of products is calculated at the clock rate of 125 nanoseconds, therefore one micro second is needed to complete the calculation of Eq. (1) for output pixel $G(X,Y)$. This local parallel calculation accomplishes 64 multiplications, 64 additions, and 256 data accesses within 1 micro second. Thus, the input and output data transfer rate between image memory and the PPP is 1 M bytes per second.

In addition, for simplifying data access, a long shift register, which buffers seven lines of image data is used in the two dimensional convolution module, as in Figure 4. A partial column of input image data $F(X+n-1,Y+n-j)$, $j=1,2,\ldots,m$ is used for the calculations of $G(X,Y)$, $G(X+1,Y)$, . . . , $G(X+m,Y)$. If the partial sums of products for those partial column image data in $G(X,Y)$, . . . , $G(X+m,Y)$ are calculated when the column data are shifted at the end of the buffer shift register simultaneously, then the data access time to fetch image data to the arithmetic units can be made nil. Partial sums are sequentially accumulated into the accumulator registers to complete the calculation for output image data.

Logical filtering module

Logical filtering is an operator applied to binary image data for thinning, shrinking, swelling, boundary detection, topological feature extraction operation etc. Figure 5 depicts a result of the logical filtering operation that extracts simultaneously from a thinned binary image, end points (E), branching points (X or Y), line segment directions (1,2,. . . ,8), isolated points (I), and small loop points (0). A logical filtering module takes up every 3×3 submatrix in the image data, and then converts the 9 bit binary data to corresponding output code, consulting the conversion table stored in the scratch-pad memory. The 9-bit binary data are used as a binary address for table look-up of the scratch-pad memory with a 512 byte capacity.

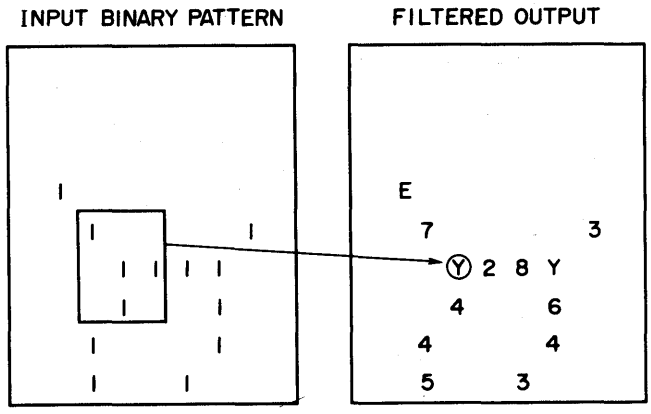

Figure 5—Logical filtering operation result

Linear coordinate transformation module

Two dimensional linear coordinate transformation (affine transformation) is performed by the address control module. Eq. (3) in the earlier section can be rewritten as

$$\begin{cases} X=pX'+qY'+Xo \\ Y=rX'+sY'+Yo \end{cases} \tag{5}$$

where X and Y are the input image coordinates and X' and Y' are the output image coordinates. In digital image processing, image data are expressed in the form of positionally sampled data, so X, Y, X' and Y' are to be integer values. All values in the address control module are expressed in 20 bits with 9-bit fraction. In practice, as the values of X' and Y' change in raster mode, input image coordinates X and Y are calculated by Eq. (5). Since the computed values of X and Y are not always integer, the address control module should interpolate the approximated gray level at coordinates (X,Y) from several surrounding image data, which have integer coordinate values near (X,Y).

Three interpolation algorithms are built in the PPP: nearest neighbor method, bilinear interpolation method and cubic spline function method. The address control module has additional registers to calculate the addresses of neighboring image data points at high speed. Other interpolation algorithms, such as raised cosine method and two dimensional sinc function method, can easily be microprogrammed. Moreover, nonlinear coordinate transformation can be attained by the algorithm using linear approximations for segmented image regions.

The speed of the affine transformation for 512×512 pixels was 0.26 second by the nearest neighbor method, 1.04 second by the bilinear interpolation, and 4.16 second by the cubic spline function method, which uses sixteen neighboring image data points.

Scratch-pad memory and histogram counter

Point mapping of Eq. (2) is done with the scratch-pad memory in Figure 2, where function ϕ is stored in tabular form to be looked up. Because the gray levels of input image data are expressed by 8 bits, the output value corresponding to any input gray level can be stored in the 256 byte capacity scratch-pad memory.

The scratch-pad memory is also used for histogram counting registers for image data. In this case, it sums up registers to count the frequency of points with the same gray level in the input image data specified area. From limitation of the

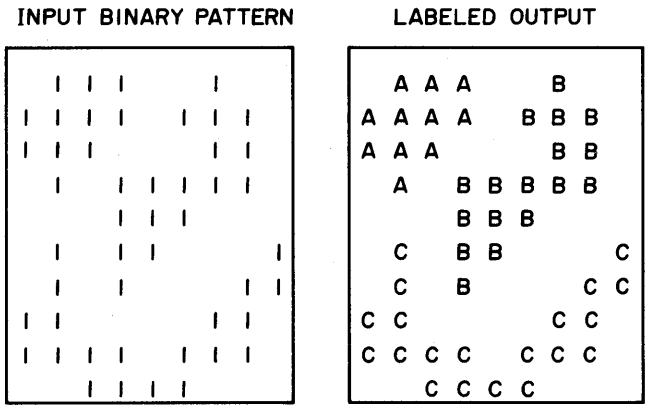

Figure 6—Region labeling operation result

scratch-pad memory capacity (256×2 bytes), HST (Histogram) command is applied to 256×256 image data at a time for a monotonous image. However, it can be applied to 512×512 image data when they are full of variety in gray levels.

Region labeling module

The region labeling module partitions a binary image data into several disjointed blocks by testing the connectivity in a 3×2 submatrix as shown in Figure 6. It is possible to select one of two definitions of connectivity: (a) four direction connectivity, such that if any two "1" points are horizontally or vertically adjacent in image data, after which they are decided to be connected, and (b) eight direction connectivity. In the example of Figure 6, a four direction connectivity mode is applied. If the eight direction connectivity mode is used, regions *A* and *B* would be decided to be connected and assigned by the same label.

Pixel operation module

Beside the most frequently used image processing functions mentioned above, the other problem-oriented operations, such as nonlinear coordinate transformation, maximum likelihood classification and texture analysis are dynamically microprogrammable. Microprograms are transferred from the host computer to the microprogram memory in Figure 2 by LMP command and executed by PIX command. Any arithmetic and logical operations for each pixel are interpreted by the microprogrammable controller (μC). The μC functional roles are as follows:

(1) Pixelwise operation for image data
(2) Communication to the host computer
(3) Interface control to the image memory
(4) Internal data bus control
(5) Control of each functional module.

The word length of a microprogram instruction is 40 bits. The μC cycle time is 250 nanoseconds.

TABLE II.—Applicable image processing repertoire

Basic Function	Applications
Two-Dimensional Convolution	Smoothing, Noise averaging, Enhancement, Differentiation, Restoration, ·····

APPLICATIONS

The PPP has been proved to be a powerful and economical tool for research and experiments in image processing, especially when it is used in an interactive image processing system. It should be emphasized that the PPP not only has the ability of gray level image processing but also of binary image processing.

A number of subprograms and application programs, using the PPP in TOSPICS, have already been developed for medical image processing, remote sensing and industrial image processing. Table II shows a list of repertoire of applicable image processings by PPP's basic functions. Each basic image processing function can be carried out at the rate of 1 microsecond per pixel. Some examples of execution time required for image data of 512×512 pixels are shown in Table III.

A typical program sequence, using the PPP, would have the following steps in the host computer:

Step 1. Assign image memory for input and output
Step 2. Set parameters in the address controllers

TABLE III.—Some examples of execution time for 512×512 Pixels

Function	Applications	Execution Time
Two-Dimensional Convolution	Laplacian, Smoothing, etc	262mS

Gradient Operation	Edge Detection	2.36S

1) W is maximum line width
2) No of separated regions is less than 254
3) Region separation and area counting

Step 3. Specify the basic function or transfer the microprogram string
Step 4. Command execution start
Step 5. Sense the end of execution from the PPP.

The gradient operation to image data, which calculates the magnitude and direction of gradient vectors, is one of the suitable application examples to show an assortment of the basic functions.

If the input image is denoted by $F(X,Y)$, then the magnitude $G(X,Y)$ and direction code $D(X,Y)$ of the gradient vector at point (X,Y) can be obtained as,

$$\begin{cases} G(X,Y)=\sqrt{\left\{\dfrac{\partial F(X,Y)}{\partial X}\right\}^2+\left\{\dfrac{\partial F(X,Y)}{\partial Y}\right\}^2} \\ D(X,Y)=\Theta\left[\tan^{-1}\left\{\dfrac{\partial F(X,Y)}{\partial Y}\Big/\dfrac{\partial F(X,Y)}{\partial X}\right\}\right] \end{cases} \tag{6}$$

where $\partial F(X,Y)/\partial X$ and $\partial F(X,Y)/\partial Y$ are output values of the two dimensional convolution with X-derivative filtering and Y-derivative filtering, respectively. $\Theta(\theta)$ indicates a multilevel thresholding function which encodes an angle θ into one of 16 direction codes.

Let the input image be stored in M1 memory layer, the main stream of subprogram to calculate $G(X,Y)$ and $D(X,Y)$ is as follows:

(a) Execute spatial filtering with X-derivative weighting matrix, and store the results in M2
(b) Execute Y-derivative operation for M1 image data and store the results in M3
(c) Using the point mapping function of x^2, calculate the square of M2 and M3, and add these values to M4
(d) Using pixelwise operation of division, calculate M2/M3 and store the results in M3. Then, execute two point mapping operations, $\tan^{-1}x$ and $\Theta(\theta)$, successively for M3. The direction code $D(X,Y)$ is obtained in M3.
(e) Using point mapping operation of $\sqrt{x}$ for M4, calculate the magnitude of gradient vector $G(X,Y)$ and store results in M2.

The concepts and algorithms of an image processing program for the parallel image processing machine may differ from those of conventional programs implemented in serial digital computers. It is an open problem to develop image processing, such as the relaxation method by Rosenfeld[20] and the primal sketch by Marr.[21]

CONCLUSIONS

A microprogrammable local parallel pattern processor (PPP) has been proposed and realized. The PPP has capabilities of programming local parallel basic operations, coordinate transformations and pixel operations. The processing time is a quarter second for 512×512 pixel image, which is about two orders of magnitude faster than conventional serial computers.

More global image processing functions, such as texture analysis, shape detection, region separation, etc., can be microprogrammed in combination with these basic functions.

Some experimental results have been demonstrated for remotely sensed data and medical image data. These demonstrations indicate that the PPP is sufficiently powerful and economical enough to explore novel applications and quick analysis in the image understanding studies.

A further expansion of the PPP, which is currently being developed, is to realize the fast Fourier transformation and some vector operations in a simple hardware.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Dr. H. Nishino of the Electrotechnical Laboratory and Dr. K. Kakizaki who directed the major phase of this development and encouraged authors, and to Dr. H. Genchi, Dr. S. Watanabe and Mr. T. Kondou who contributed many significant concepts to improving system design. They wish to extend their appreciation to Prof. K. S. Fu of Purdue University for his invitation and encouragement to this session. The research and development are under contract with the Ministry of International Trade and Industry on the Pattern Information Processing System (PIPS) Project.

INTRODUCTION

Recent progress in architecture technology has had a great impact on the study of pattern recognition problems. The increase in processing power is bringing a new concept of "understanding" into recognition areas. Recognition objectives have been greatly extended to meet real social requirements. As observed in the speech recognition system developed at Carnegie-Mellon University, for example, efforts have been shifted from attaining higher recognition of isolated words to the implementation of a system which provides reasonable understanding of the more natural utterances of connected speech.

This system called HEARSAY[1] provides multi-leveled knowledge sources ranging from parametric representations of the physical features of speech measured every 10ms to the conceptual level of common acceptance. Reliable performances for understanding speech are then attained by the hypothesize-and-test processes at these various levels where these knowledge sources are dynamically related to each other through a general structured global data base.

Concerning images, the University of Massachusetts is developing an image understanding system called VISIONS.[2,3] The system transforms visual sensory numeric data to a symbolic structure representing a model of the image. Conceptual models which are not image-specific are stored as a knowledge source in the semantic data base and serve to specify the observed model by communicating with various levels of features hierarchically extracted through spatial windows of various sizes.

Both of the understanding systems (HEARSAY & VISIONS) are based on the principle of model construction (hypothesizing) and the deductive processing (testing) of conceptual models by the incorporation of a semantic data base (knowledge sources). Thus the associative search of all possible conceptual models on a semantic data base plays an important role in advanced pattern recognition systems, and the efficiency of the search becomes the dominant factor in attaining high performance.

An associative processor ARES proposed by the authors before[4] also provides a powerful tool for associative search on semantic data bases in general because of the ability to associate data items on their deep structures. In the present paper, the association principle of ARES which is based on coding theory is generalized. The association capability is extended by the hierarchical use of a set of different codes. Following the overview of the generalized association mechanism is an architectural description of ARES which is now being developed. By adopting a multi-microprocessor organization, ARES has gained greater adaptability because of the functional flexibility provided by microprogramming.

In conclusion, the multi-microprocessor ARES provides an advanced pattern recognition facility partially bridging the gap between human cognitive behavior and logical processing by computers.

ADVANCED ASSOCIATION FACILITY

A semantic data base is defined generally as a collection of data items which are symbolic representations of speech or image. Data items D's are coded segmentally or categorically as shown in (1) in such a manner that the relatedness of the symbolic partial representations for each segmental or categorical block d_{si} is measured in terms of the distance of the code vectors associated with them.

$$D = (d_{s1}, d_{s2}, \ldots, d_{si}, \ldots, d_{sp}), \quad 1 \leq i \leq p. \quad (1)$$

The length of each segmental or categorical block d_{si} is not necessarily the same depending upon the application.

The association mechanism

Let's divide D into several blocks of equal length n as shown in (2), and apply an error correction scheme of the

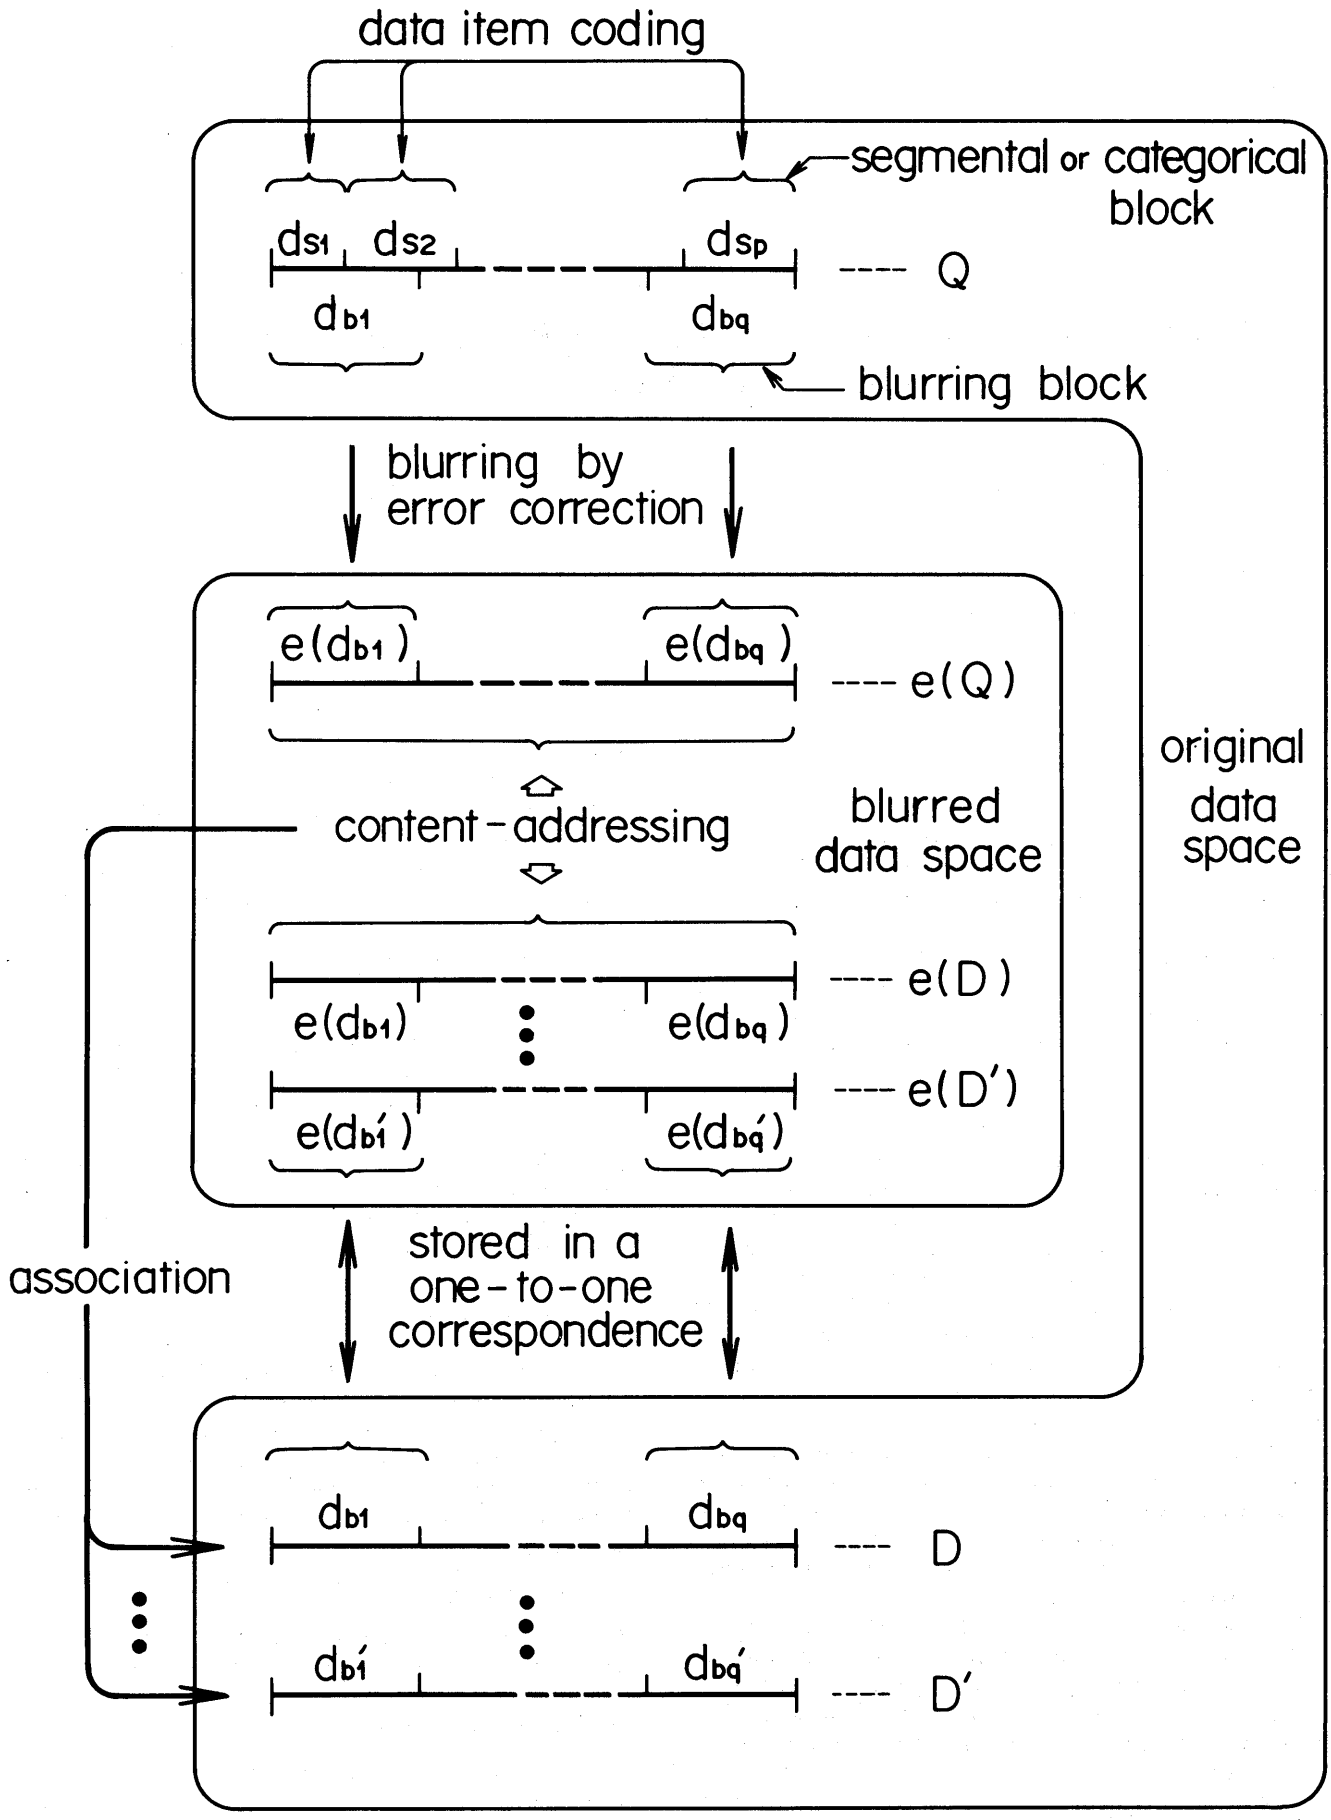

Figure 1—Association process

code of length n with t-error correction capability for each block d_{bj}.

$$D=(d_{b1}, d_{b2}, \ldots, d_{bj}, \ldots, d_{bq}), \quad 1\leq j\leq q. \tag{2}$$

The data representation thus derived is denoted as (3).

$$e(D)=(e(d_{b1}), e(d_{b2}), \ldots, e(d_{bj}), \ldots, e(d_{bq})), \quad 1\leq j\leq q. \tag{3}$$

Each error corrected code vector $e(d_{bj})$ represents a blurred feature of d_{bj}. The d_{bj} is then called a blurring block, and n is normally selected to cover several segmental or categorical blocks d_{si}'s so as to also blur the influence of artificial segmentation or categorization of semantic data items. Thus the $e(D)$ sustains a global structure of data items which are inherently related to each other with equal to or less than t distance.

Now let us apply the content-addressing scheme to $e(D)$'s. When Q is given as a query item, the content-addressing by $e(Q)$ is accomplished by checking the number of blurring blocks which coincide with each other for all $e(D)$'s in parallel, and then $e(D)$'s which coincide with $e(Q)$ in equal to or greater than $\theta(0\leq\theta\leq q)$ number of blurring blocks are selected. Assuming that both D and $e(D)$ are stored as a pair, D's which are strongly related to Q are then specified as associated data items without executing the complex calculations of relatedness.

The space where $e(D)$'s are accommodated is called a blurred data space. Specifying D's through the content-addressing on $e(D)$'s in the blurred data space is referred to as "association". The association process is illustrated in Figure 1.

As explained above, the intuitiveness and ambiguity observed in human cognitive behavior are brought into the association performance of ARES to some extent by connecting the conventional content-addressing and error-correcting technologies, and controlled systematically by the length n and the correctable error distance t of the code applied. Following is a generalization of the blurring by error corrections to reach the more global structure of data items before the association.

Hierarchical process of blurring

Let (n, k, t) denote a code of length n which has k number of information digits with a t-error correction capability, and let the blurred data item derived from D by (n_1, k_1, t_1)-code be represented as $D_1=e_1(D_0)$ where $D_0=D$. Suppose we want to have more general structure of data items, then we apply (n_2, k_2, t_2)-code to D_1 by dividing it into the blurring blocks of length n_2. Thus we can proceed the blurring as indicated in (4) until we reach the blurredness required for the association, where the relation $t_s\geq 2t_{s-1}+1$ should necessarily be satisfied when $n_s\geq n_{s-1}$.

$$D_0\rightarrow D_1=e_1(D_0)\rightarrow D_2=e_2(D_1)\rightarrow\cdots \rightarrow D_s=e_s(D_{s-1})\rightarrow\cdots. \tag{4}$$

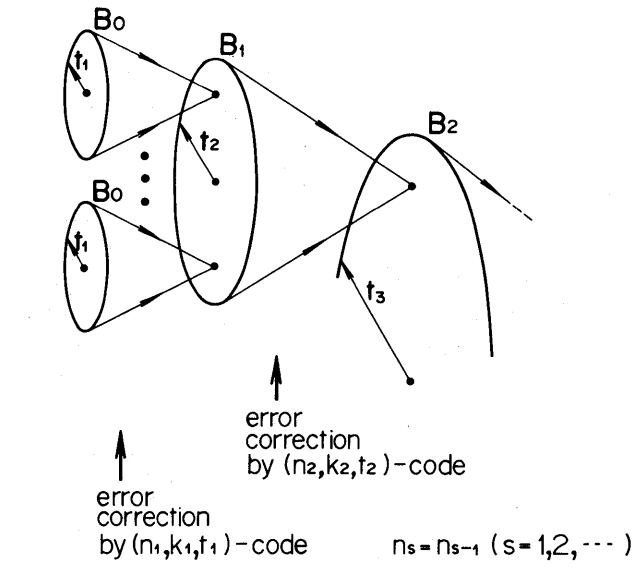

Figure 2—Blurring process

Let the original data space and blurred data space of level s be denoted as B_0 and B_s, respectively. Data items in B_0 are strongly dependent on physical features directly measurable at B_0. Data items in B_s, however, represent more general features commonly possessed by a larger class of data items, and the features go up to the conceptual or semantic level as the blurring proceeds under the hierarchical application of error corrections.

Perfect codes are desirably selected for the blurring. Figure 2 illustrates schematically the hierarchical blurring of a single block of coded data items for the case of $n_s=n_{s-1}$ $(s=1, 2, \ldots)$. Blocks of length n_s located in a circle of radius t_s in B_{s-1} are merged into one in B_s since they must have been strongly related to each other.

Association based on a deep structured relatedness

Content-addressing for the association can be applied at any level of blurring when the feature provided is satisfactorily general to meet the requirements. Let s^* denote the blurring level where content-addressing is applied. Then D_0's in B_0 to be associated are directly specified together with the related D_s's $(0<s<s^*)$ when necessary, without tracing back the blurring processes to B_0 since D_s $(0\leq s<s^*)$ and D_{s^*} are stored in a one-to-one correspondence.

Figure 3 is a schematic diagram explaining how the content-addressing and hierarchical blurring are connected for performing association. The query item Q_0 (ϵB_0) might in some cases be applied externally. The hit marks indicate the D_{s^*}'s which are content-addressed in B_{s^*}. When we have a restriction on the number of associated data items, the

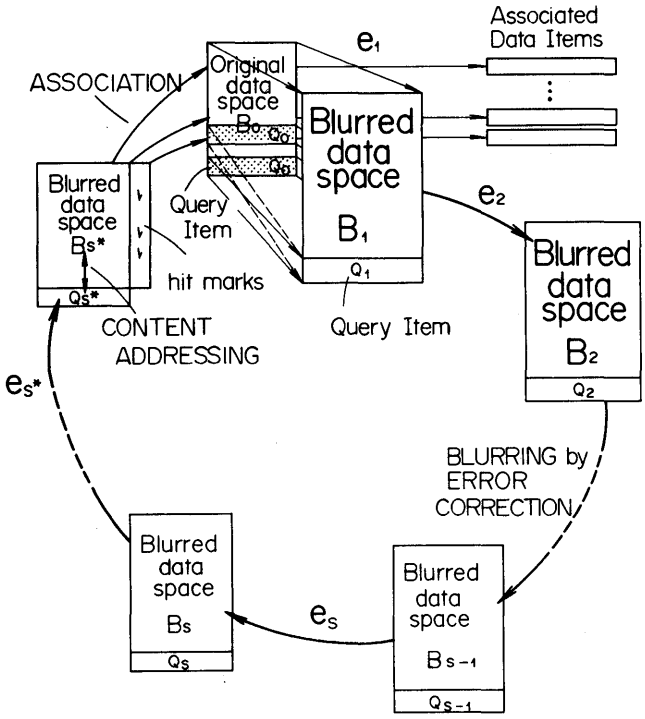

Figure 3—Association through blurring and content-addressing

threshold θ for content-addressing is heuristically selected so that hit marks do not exceed a certain limit δ.

ARES has data modification facility. Suppose Q_0 (ϵB_0) is given as a query item. If some D_0's in B_0 are specified by Q_0 through the content-addressing at the blurring level s^*, these D_0's and related D_s's ($0<s\leq s^*$) are replaced by Q_0 and its blurred expressions, respectively. Otherwise, Q_s ($0\leq s\leq s^*$) is registered, unmodified, to B_s ($0\leq s\leq s^*$). Q_0 might be given as a weighted average of two data items previously stored in B_0.

A MULTI-MICROPROCESSOR IMPLEMENTATION OF ARES

In order to effectively carry out the associative search on a semantic data base described in the previous sections, the following functions should be provided at the computer architecture level:

(1) A hierarchical blurring capability.
(2) The fundamental content-addressing capability.
(3) A heuristic control mechanism to obtain a reasonable number of associated data items.

For the hierarchical blurring capability, a control logic is

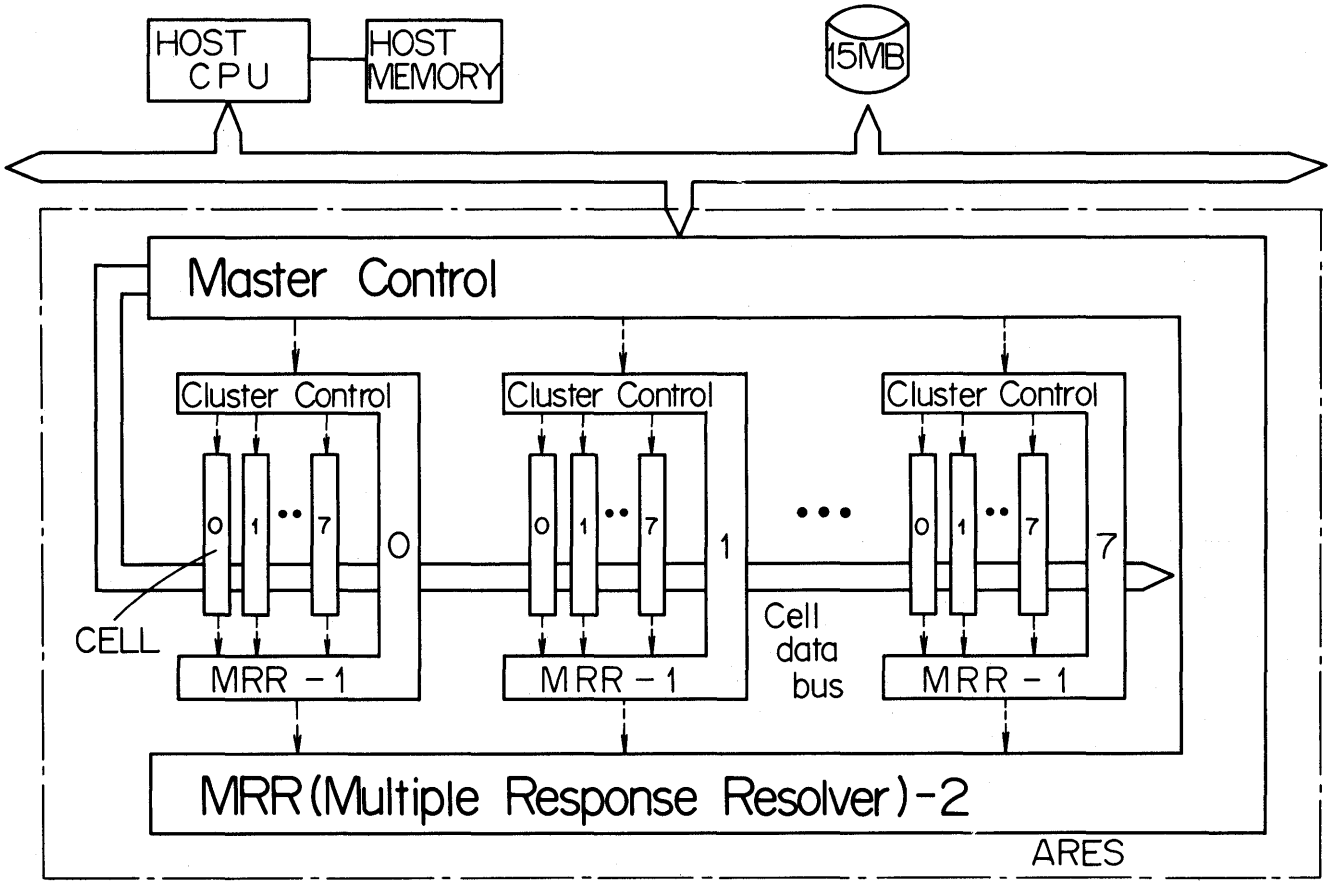

Figure 4—ARES main block diagram

necessary which offers an efficient access to the multiple blurred data spaces and executes the error correction schemes applied for the blurring. Binary cyclic codes are useful for a variety of applications because of the flexibility of selecting proper length and the easiness of implementing the error correction procedure.

As shown before in Figure 3, the content-addressing is accomplished in the blurred data space B_{s*} taking each blurring block of the final stage of blurring as a unit, and for all units in parallel. The number of blocks which coincide with each other is counted over all the blocks unmasked, and compared with a certain predefined threshold value θ. When it is equal to or greater than θ, the corresponding hit mark is set to 1, and the value of θ is gradually adjusted by the heuristic control mechanism embodied in ARES so that a greater number of associated data items as possible are obtained within the limit δ.

In principle, these functions associated with the content-addressing can be accomplished by the mechanism which is incorporated in the uniprocessor ARES originally designed for the recognition of handwritten characters.[4] However, in order to facilitate the blurring time after time and to effectively create the blurred data spaces, it is extremely desirable to provide a logic which works over many sets of blocks in data words simultaneously. Furthermore, a blurred data space should be spatially distributed again in order to execute the blurring and content-addressing for all data words in parallel. These concepts lead to a conclusion that a multiprocessor organization is the best of possible approaches to attain the advanced association facility described above.

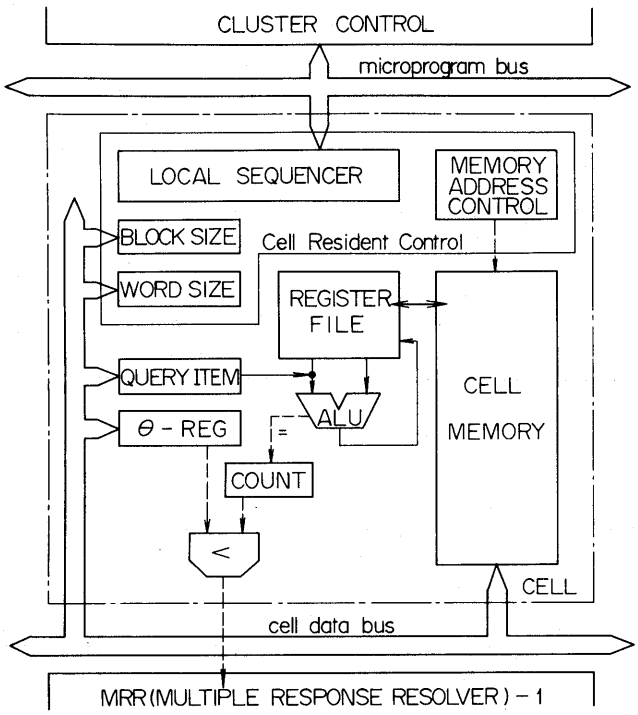

Figure 5—Cell diagram

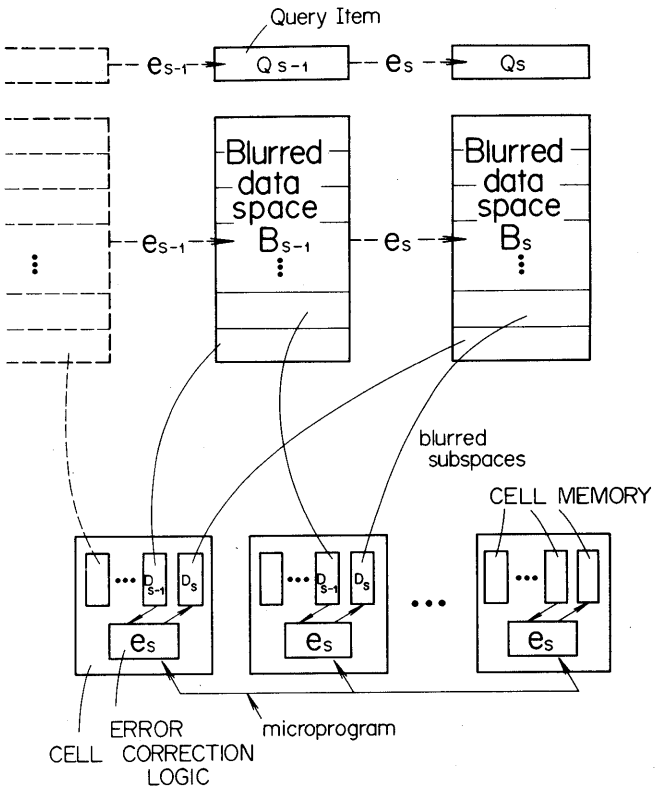

Figure 6—ARES in blurring mode

Architecture of ARES

Figure 4 shows the block diagram of multiprocessor organization of ARES. The distributed processing requests the Master Control to synchronize the whole logic units. As the logic unit, a functionally flexible logic, for instance, a microprocessor (TI-SN74S481; 16Kbytes memory) is used since the data structure of semantic data bases might be considerably complicated depending upon the problems to be solved. Hereafter, the logic unit is referred to as a cell.

The Cluster Control controls eight cells all together, and the master control governs eight cluster controls. Therefore, up to eight different programs may be processed in eight different clusters of cells in parallel. On the other hand, in the case that all the cluster controls are assigned to process the same program, sixty-four parallel operations can be performed in the whole cells.

The Multiple Response Resolver (MRR) which is a unique facility in ARES is made up of a parallel counter with multiple inputs. Each MRR-1 receives the hit marks from the cells attached to it, and the contents of MRR-1's are collected by MRR-2. The master control compares the content of MRR-2 with the predefined value of δ and adjusts the value of θ when necessary for further content-addressing. The design of MRR is basically made clear in Reference 4.

Figure 5 shows the internal structure of a cell which is the nucleus of the association logic. A data item and its blurred

representations are accommodated in a cell together with the logic encountered in a conventional associative memory. The block size and the word size indicate the length of a blurring block at each stage of blurring and the length of a data item, respectively.

We may conclude that the clustering of cells supplies high reliability and functional flexibility; the loss of a single cell function or MRR-1 results in a slight decrease of processing power but no complete breakdown of the system, and each cluster of cells can perform its own function individually.

Functional behavior of ARES

The functional behavior of ARES for manipulating a semantic data base is explained as follows: The mini-computer HP-21MX is used as a Host Computer, and recognizes ARES as an associative memory with extremely high intelligence. The operation is initiated when the host computer issues a global command to the master control. The master control analyzes the command and gives the related subcommands to the cluster controls. This implies the function of pointing out the start addresses of the microprograms to be performed, which are previously stored in the cluster controls. Then each cluster control carries out the specified operation individually.

Figure 6 shows the relationship between the blurred data spaces and the corresponding cells in the blurring mode.

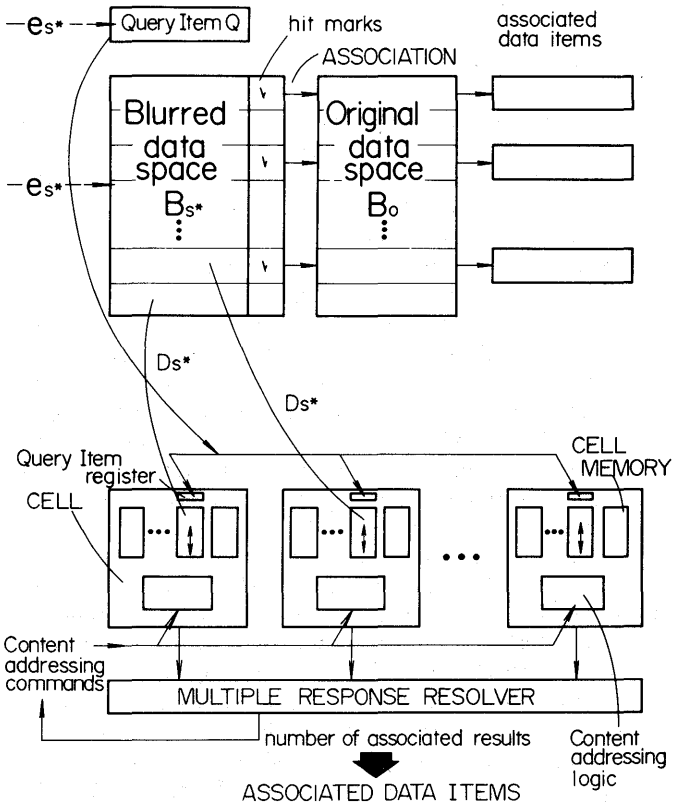

Figure 7—ARES in content-addressing mode

Each blurred data space is divided into subspaces and data items contained in a space are distributed to the cell memories so that they can be processed in parallel. The error correction for the blurring is accomplished through ALU shown in Figure 5, and controlled by the microprograms in the cluster control.

Figure 7 indicates the same relationship in the content-addressing mode. A query item and the value of δ are sent to each cell in parallel by the master control. The content-addressing is then performed in the blurred data space B_{s^*} which are distributed in cell memories, with θ heuristically controlled by MRR under the parameter δ. The control of θ is implemented in hardware because the very fast multiple associations are required repeatedly. The hardware is designed in consideration of the trade-off between the functional requirements imposed and the cost of implementation.

CONCLUSION

In this paper, the association principle presented before[4] is extensively developed in order to be applied to the associative search on semantic data bases for speech or image understanding. Data items are coded in such a manner that the relatedness of the symbolic partial representations of segmental or categorical blocks of data items is measured in terms of the distance of the code vectors associated with them, and they are blurred by the hierarchical application of error correction schemes. Thus, by simply applying conventional content-addressing schemes to the blurred data items, the associative search of original data items is accomplished on their deep structured relatedness without executing the complex calculations of relatedness on original data representation.

Following the overview of the generalized association mechanism, we presented an architectural description of ARES which is now being developed. From the viewpoint of computer architecture, ARES has the following characteristic features: A multi-microprocessor organization is adopted using HP-21MX mini-computer and TI-SN74S481 Schottky I^2L bipolar microprocessors as a host computer and cell components, respectively. This provides both the structural extendibility and functional flexibility supported by microprogramming to adapt to a variety of applications in the field of artificial intelligence. Furthermore, ARES facilitates heuristic control of the number of associated data items, which is useful to solve pattern recognition problems.

So far we have discussed the associative search on semantic data bases for speech or image understanding. However, ARES can be well applied to natural language processing. For example, the associative-categorical model proposed by Haralick and Ripken[5] for semantic word retrieving is dealt with by means of representing categorical relatedness of data items by code distances.[6]

In conclusion, a multi-microprocessor ARES provides an advanced pattern recognition facility bridging the gap between human cognitive behavior and the logical processing by computers.

ACKNOWLEDGMENT

The authors wish to thank Professor C. V. Ramamoorthy of UC, Berkeley for his encouragement.

The STARAN architecture and its application to image processing and pattern recognition algorithms

by J. L. POTTER
Goodyear Aerospace Corporation
Akron, Ohio

INTRODUCTION

The STARAN E is a general purpose parallel computer. However, certain aspects of the STARAN E's architecture, specifically, a single instruction stream-multiple data stream organization, high speed I/O, a flip (permutation) network and a conditional operation capability on each parallel processing element, are particularly pertinent to the areas of image processing and pattern recognition.

Some of the characteristics of image processing and pattern recognition which provide a good fit to the STARAN's architecture are repetitiveness, spatial dependencies, complex parallel decision making and high I/O to computation ratios. These characteristics and their corresponding STARAN E architectural accommodations are described in detail. The other aspects of STARAN's architecture are described in only enough detail to provide a basis for discussion.*

BACKGROUND

The STARAN E consists of an associative processor (AP) control module and a number (1 to 32) of associative arrays. The AP module consists of the AP control circuitry itself and bulk core. Figure 1 shows the basic STARAN architecture.

The arrays can be thought of as consisting of high speed memory, low speed memory and a bank of processing elements. Each array is organized into 256 "words." Associated with each "word" is a processing element (PE). Each word is 9K bits long with 1024 bits of high speed memory and 8192 bits of lower speed memory. Figure 2 illustrates the conceptual array organization and a general purpose layout for a 512×512 8 bit/pixel image.

Arithmetic operations are performed in parallel on every (enabled) word of memory, one bit at a time. That is, the least significant bit of every word in a field (a bit column vector) is added (multiplied, etc.) to the corresponding least significant bit of every word in a second field and stored in the least significant bits of the sum (product, etc.) field. The carry bits are saved and added into the second bit slices of the arguments. This process is repeated until the entire fields have been processed.

ARCHITECTURE—ALGORITHM PARINGS

Certain characteristics of image processing and pattern recognition mesh perfectly with some of the architectural features of the STARAN E. In the following paragraphs,

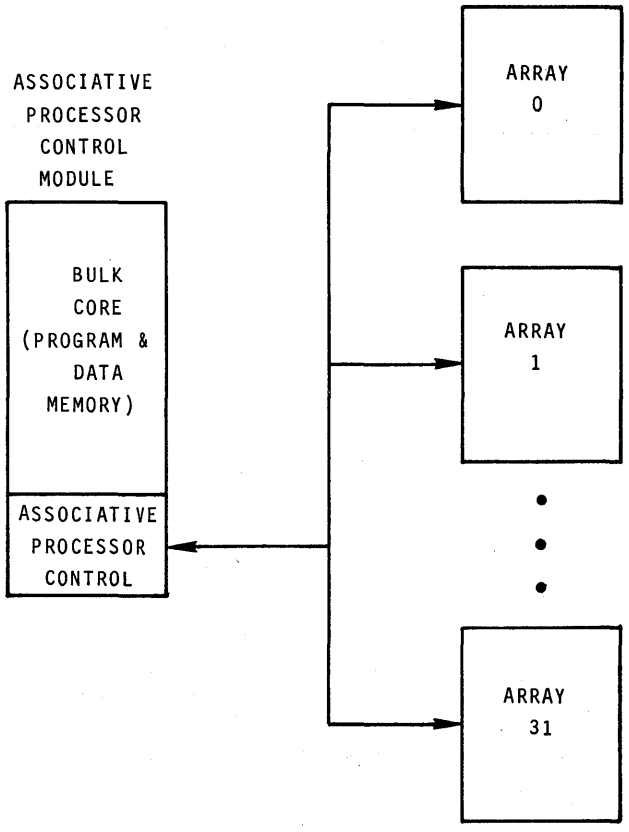

Figure 1—Basic STARAN architecture

* For a detailed description of the STARAN line of computers see References 1, 2 and 3.

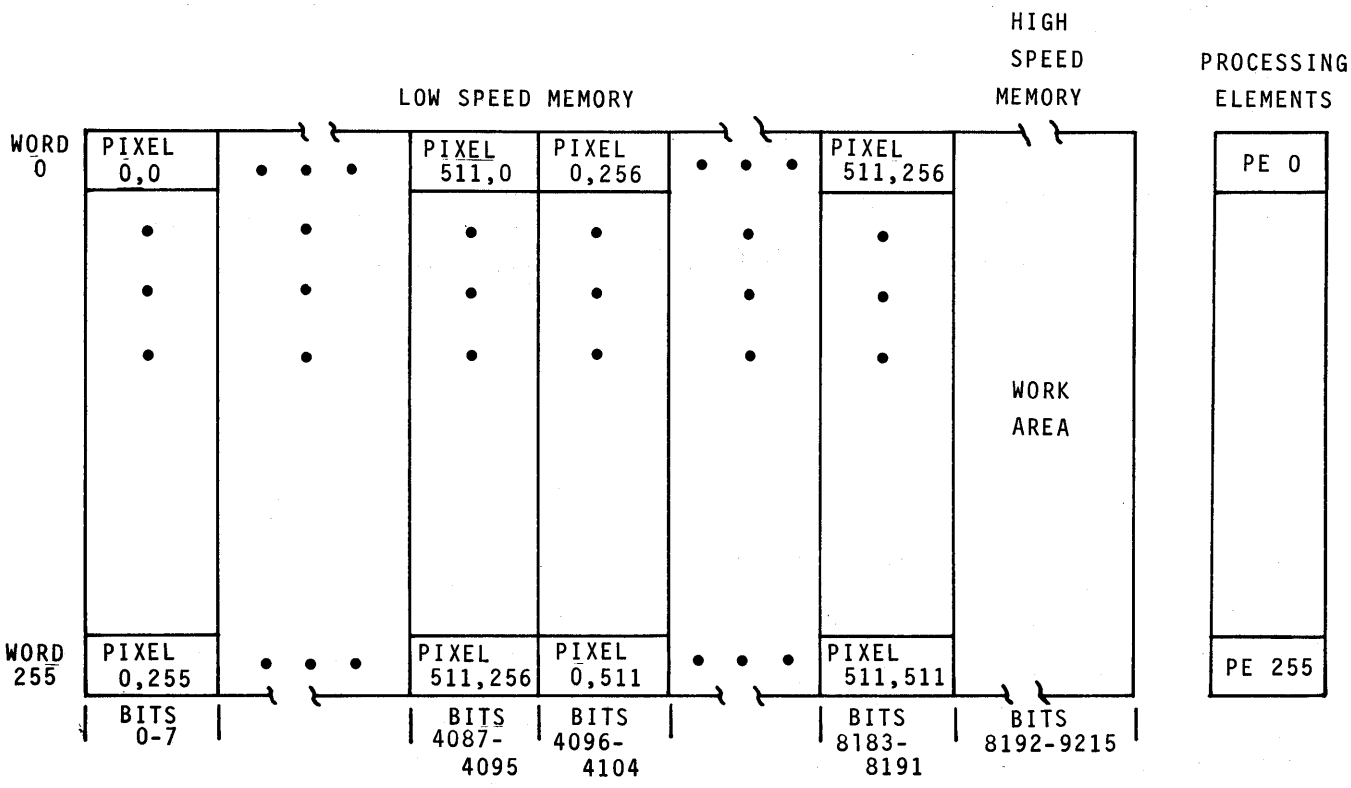

Figure 2—General purpose array organization

some characteristics of image processing and pattern recognition algorithms will be identified and described. Then the corresponding architectural feature of the STARAN E will be discussed and shown how it facilitates implementation of the algorithms.

REPETITIVENESS

Images consist of large volumes of data. A standard TV monitor size image contains over a quarter of a million pixels (picture elements). The images obtained from satellites may contain many millions of pixels. Almost all image processing and pattern recognition algorithms consist of performing the same sequence of operations for every pixel in an image. This aspect of image processing fits perfectly with the single instruction stream-multiple data stream organization of the STARAN.

The associative processor (AP) control portion of the STARAN computer provides a single sequential instruction stream to the associative arrays. Each associative array contains 256 processing elements (PE's) and a fully equipped STARAN E may have up to 32 arrays. Thus the single instruction stream can control from 256 to 8192 PE's resulting in a processing capability of from 11 to 356 million 32-bit adds per second (MIPS). Figure 1 illustrates the single instruction stream-multiple data stream organization of STARAN.

"Inherently serial" algorithms such as classical Maximum Likelihood classification are easily implemented in parallel with the above organization. This is because the algorithm is still executed in serial for every pixel, but from 256 to 8192 pixels can be handled with one pass of the algorithm. With the large number of pixels that need to be processed in a typical image, parallel application of the algorithm is the only practical answer.

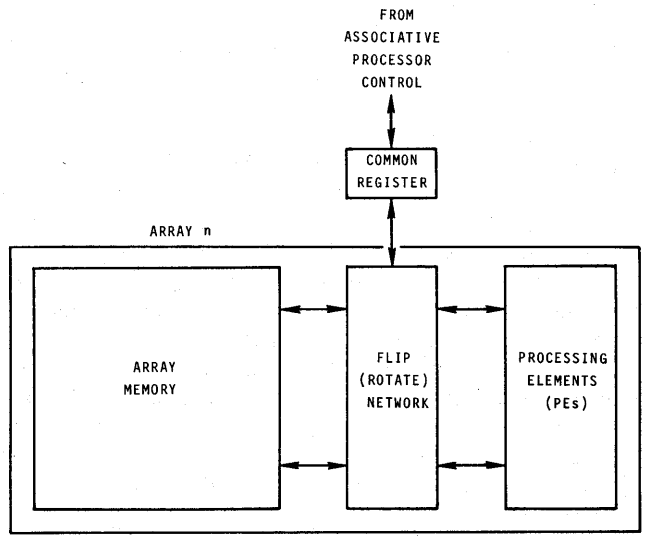

Figure 3—Flip network

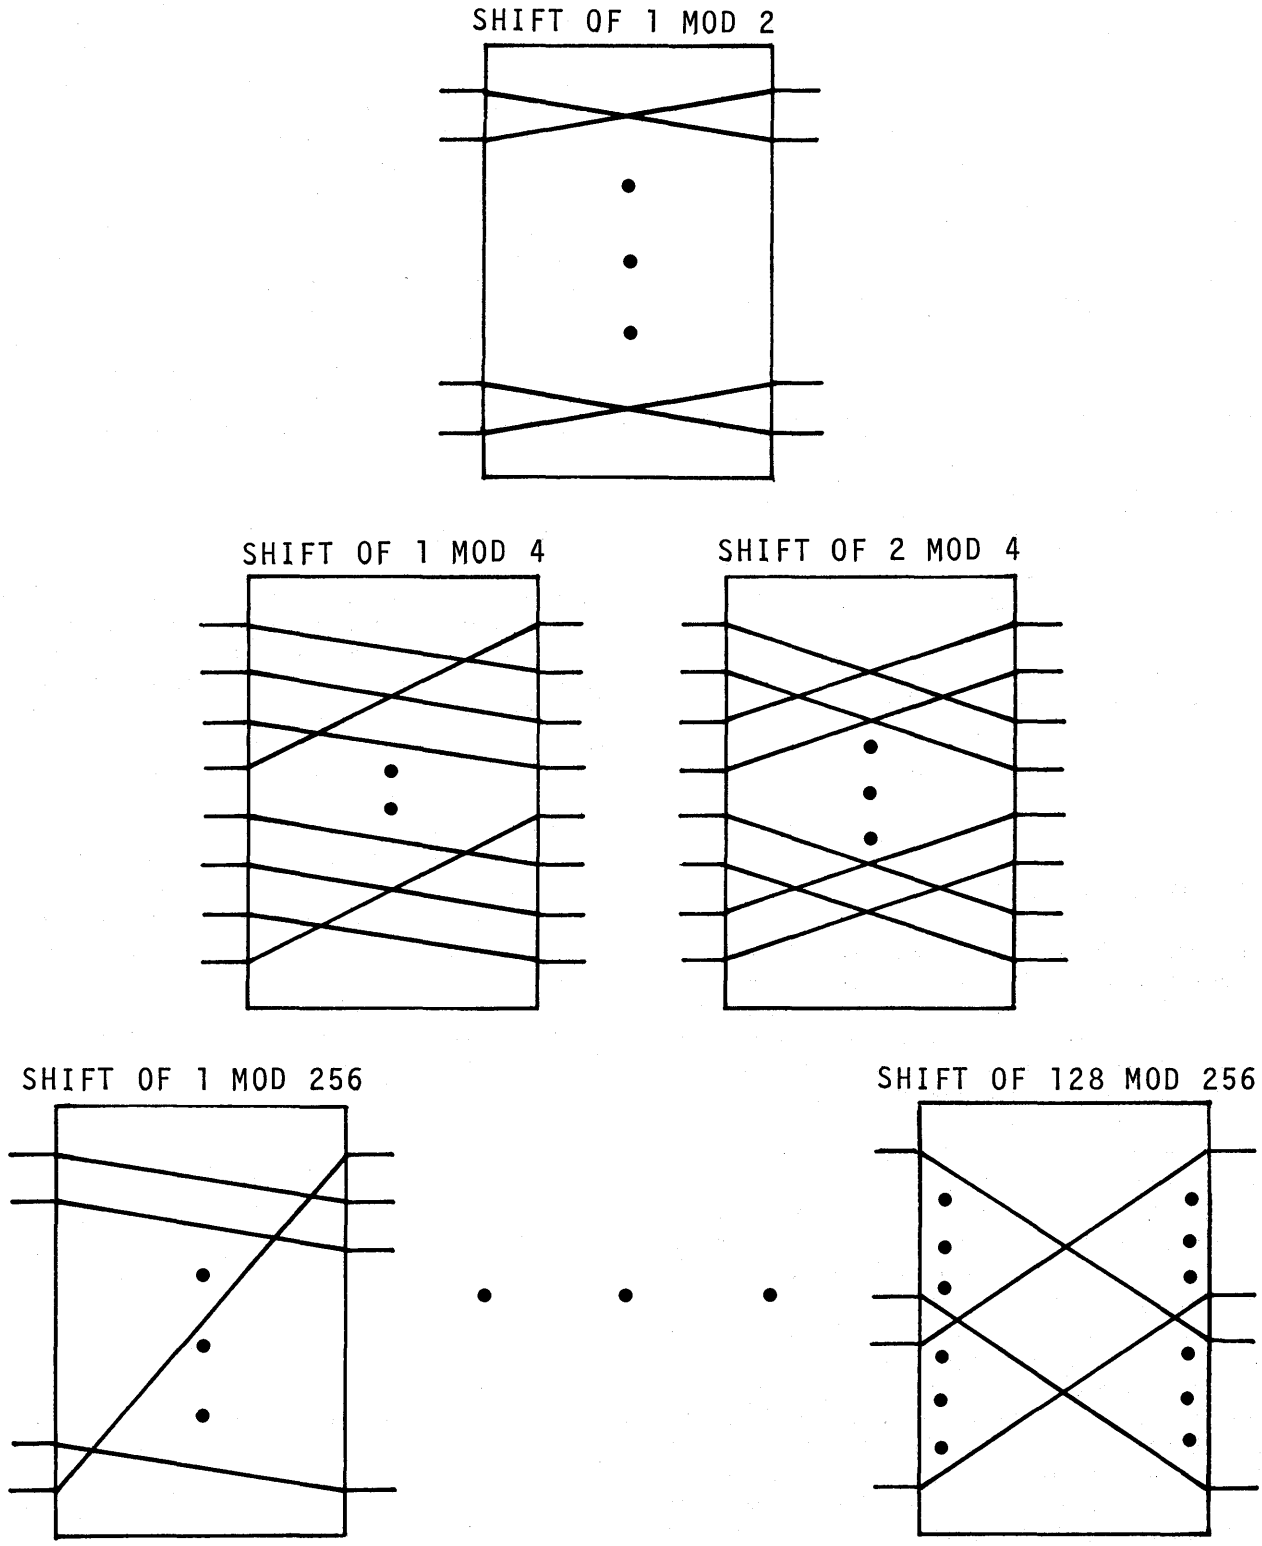

Figure 4—Flip network rotations

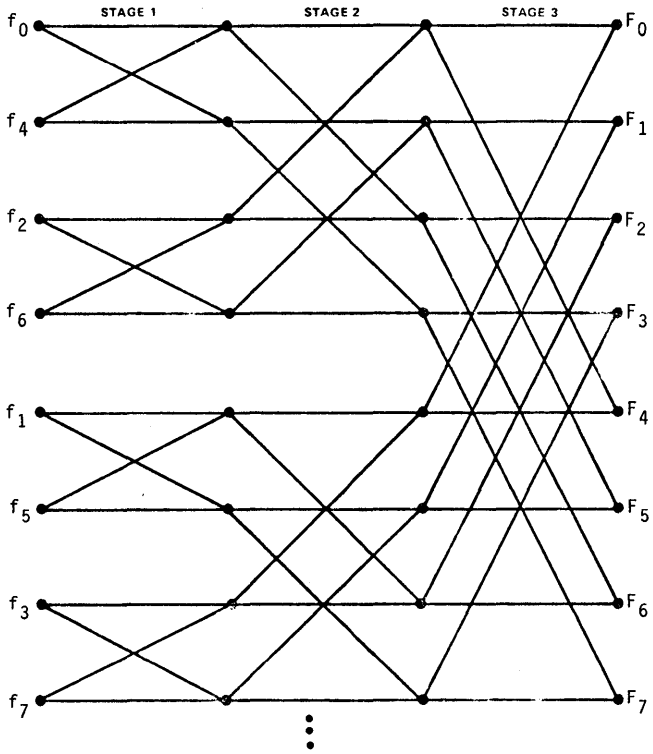

Figure 5—Butterfly diagram for FFT

SPATIAL DEPENDENCIES

Image data is inherently two dimensional and processing algorithms often must deal with this "built in" organization. In general, there are two different types of relationships. The neighborhood relationship requires that pixel neighbors in the two dimensional plane be readily accessible. The second type of relationship is normally spatially more extensive and is typified by the Fourier Transform where the pixel and its neighbors at power of two intervals for an entire row or column are related.

The STARAN associative arrays are well suited for accommodating both types of dependencies. Each array, as shown in Figure 3, has a flip network located between the memory and PE portions. This network performs as a specialized shift register and provides great flexibility in accessing pixels which are spatially related.

In particular, the flip network can accomplish power of two rotates within power of two sized fields with no time penalty. That is, a 1 bit rotate in 128 2 bit fields; 1 and 2 bit rotates in 64 4 bit fields; 1, 2 and 4 bit rotates in 32 8 bit fields; on up to 1, 2, 4, 8, 16, 32, 64 and 128 bit rotates in one 256 bit field. (See Figure 4) This means that inter-word operations at these intervals can be performed in parallel at the same rate as intra-word operations. Moreover, all inter-word operations can be performed with only a slight penalty.

The flip network then provides a very efficient method of implementing algorithms such as the Fast Fourier transform which utilize the spatial power of two interrelationships between pixels. This power of two spatial relationships is frequently expressed in the butterfly diagram shown in Figure 5. A detailed discussion of how the FFT can be implemented in the STARAN in log N steps of 1 add, 1 subtract, 2 real multiples and 2 exchanges has been published elsewhere.[4]

Template matching and spatial convolution are two algorithms which require the neighborhood type of pixel access. These processes can be implemented with little or no time penalty for the required spatial relationships. In particular, 2×2, 3×3, 5×5, 9×9 and 17×17 displacements require no time penalty. Other displacement amounts up to 16×16 require at most one extra shift except for 12×12 and 14×14 which require two shifts. In general, the required shifting for processing *any* window or template size within the 256 word array (i.e. 255×255 or less) is insignificant in overall algorithm time.

PARALLEL DECISION MAKING

An important aspect of image processing and pattern recognition is decision making. Many algorithms perform different operations as a function of the data. The complexity of the process is typified best perhaps by scene analysis techniques. In these situations it is essential to be able to record the exact state of each individual datum in the image.

Each STARAN array contains a special register which can be set as the result of searches (LE, GT, etc.) and arithmetic operations. This mask (or M) register can be used to select a subset of the words in an array to participate in subsequent operations. The results of tests, conditions and states can be stored, retrieved and operated on to achieve any desired logical combination of tests. Figure 6 indicates the physical location of this register.

Two examples of how the M register can be used are template matching and hierarchical structuring. To start a 3×3 template match, the M registers are set to all ones so

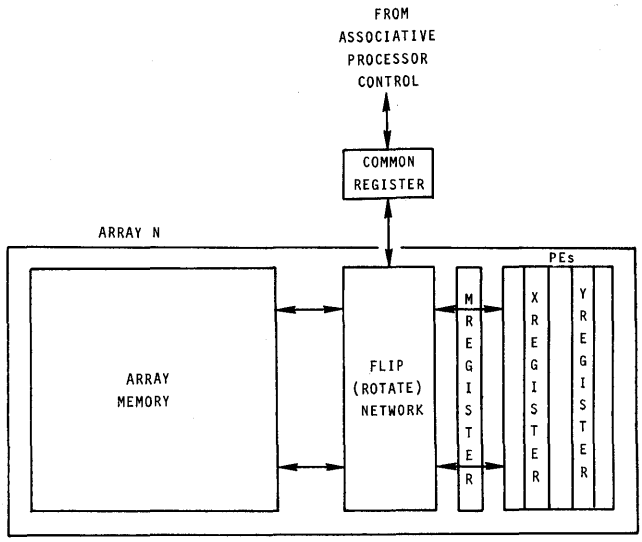

Figure 6—M register configuration

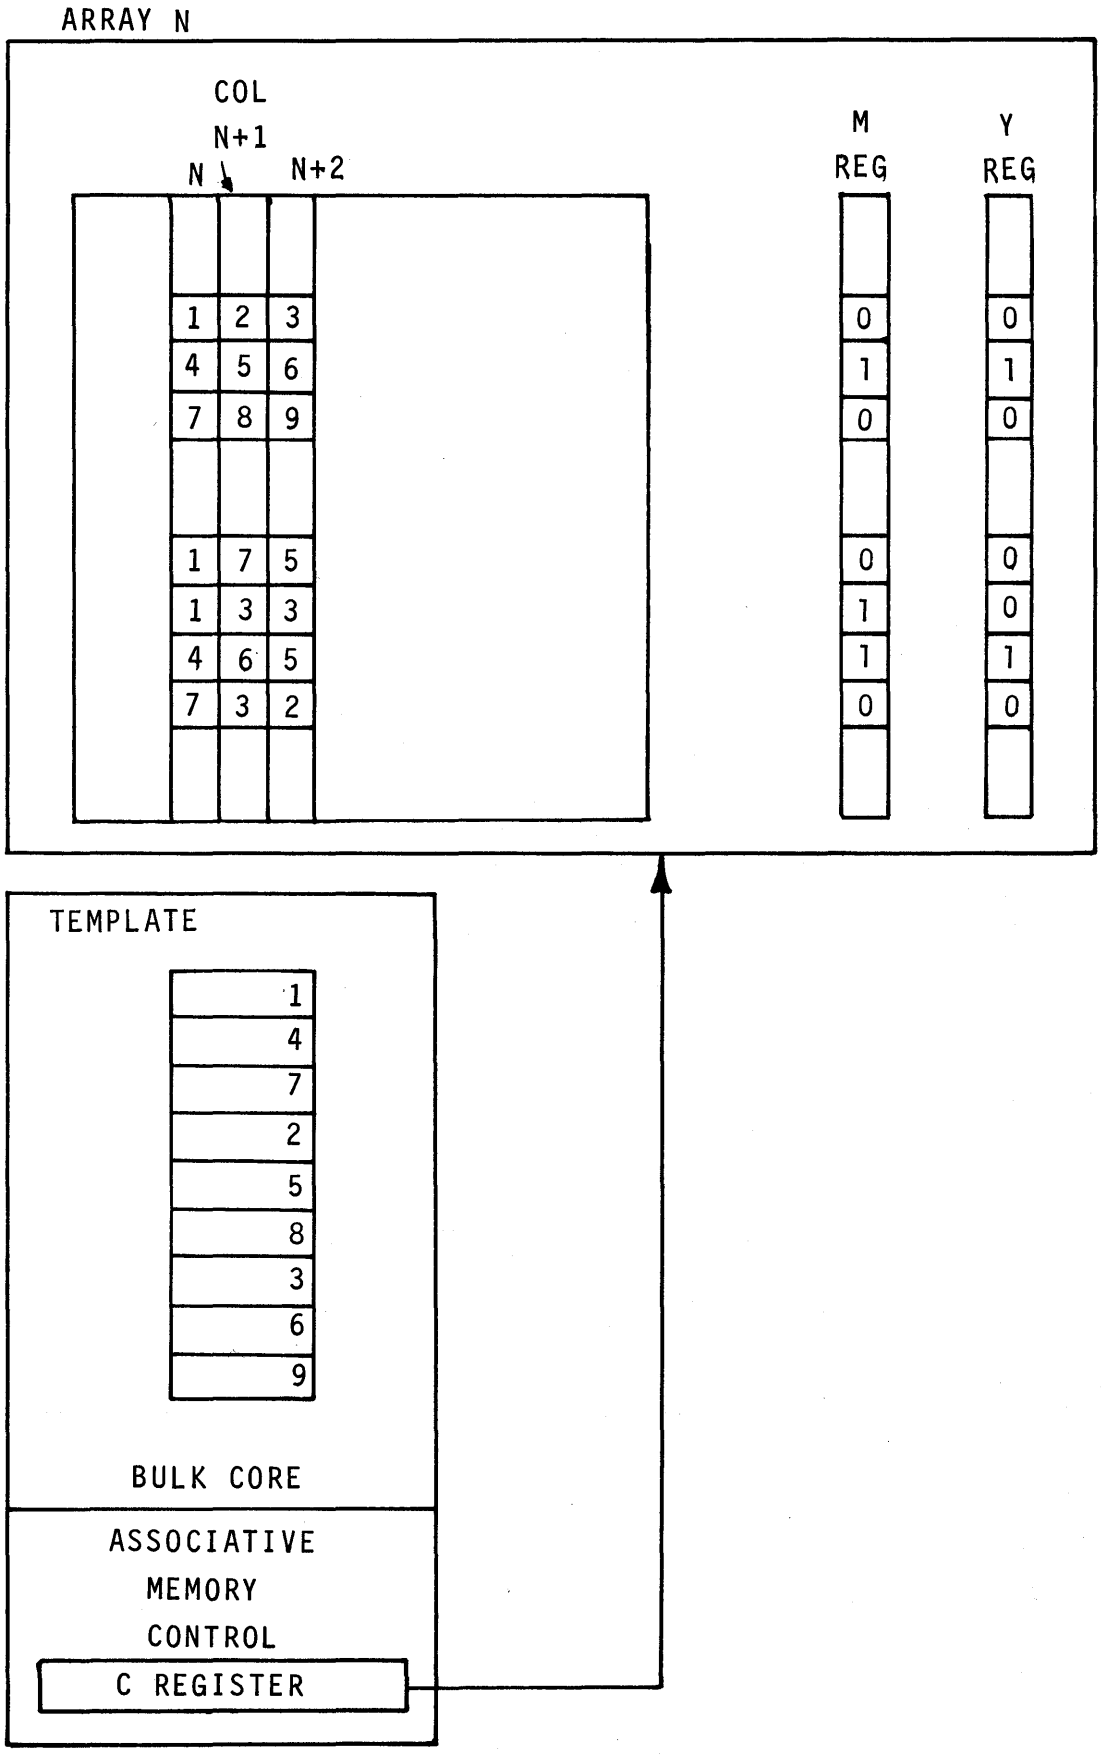

Figure 7—Template matching

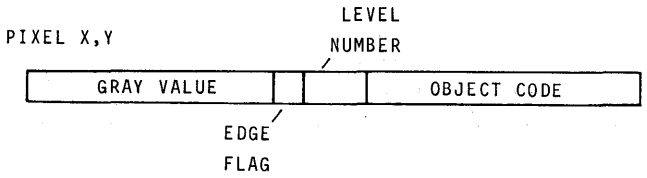

Figure 8—"Typical" scene analysis configuration

that every word participates in the search. The first value of the template is loaded into the common register and the first columns of all the arrays are matched against it. Every successful match is recorded in the Y register. The Y register is shifted down one and moved to the M register, the second template value is moved to the C register and the column is searched for a match of the second template value but on only those words with a corresponding one in the M register (i.e., only those which successfully matched the first value). Consequently at the end of the second search the Y register contains a one for every word and only those words which successfully matched both the first and second template values (the state shown in the M and Y registers in Figure 7). The procedure is repeated for each of the template values with an upward shift and column increment after searching for the third and sixth values. At the end of this process, the M register of all enabled arrays will contain a one (shifted down by two) corresponding to every successful template match covering columns 1, 2 and 3. The process is repeated for every set of columns to be searched.

Note that the columns need not be contiguous to be searched. Thus two situations can be easily handled. First, the columns can be organized in an order which facilitates another algorithm and/or input/output situations. Second, the template need not be contiguous but may cover essentially any size area in any desired manner. Both of these capabilities emphasize the flexibility of data processing in the STARAN arrays.

In a scene analysis application, each pixel might have a set of flags and auxiliary fields associated with it as shown in Figure 8. Then searches of the type "obtain the edges of object 5 on level 2" would be easily implemented in parallel by: first, searching all pixels in a column for object 5, then searching the matched words for level number 2 and then ANDing the edge flags with the Y register. The result is the answer to the search for the given pixel column. The process would then be repeated for each column under consideration. This example illustrates how easy it is to save the result of previous algorithms as flag vectors and codes in parallel and that this information is readily available for subsequent processing and analysis.

INPUT/OUTPUT VERSUS COMPUTATION

It has been established that in general, image processing involves large volumes of data. The algorithms vary quite markedly however in the degree of computation involved. Simple grayscale remapping is such a useful function that special hardware circuitry is often contained within the display devices. In order to make such changes permanent, however, a computer must be used. Operations such as changing (remapping) the grayscale values of images require only one operation per pixel but must be performed on every pixel. These algorithms represent the high I/O-low computation end of the spectrum. At the other end are such algorithms as the domain transforms. Frequently these procedures require numerous arithmetic operations on a per pixel basis. For example, a two dimensional Fast Fourier Transform for a 512×512 pixel image requires 54 multiples and 90 adds per pixel (for a serial computer).

The STARAN has three I/O paths. The common register path (shown in Figure 1 and at the top in Figure 9) operates at between 12-15 million bits per second (MBPS). It is most useful for "broadcasting" data such as constants and parameters to all arrays in parallel. It is a 32 bit wide path.

The most useful path for data I/O is the 32 bit wide multiplexed I/O bus into and out of each array. This bus is capable of operating at between 80 and 640 MBPS. Thus an entire 512×512 8 bit per pixel image can be input or output in from 26.2 to 3.3 milliseconds. This data path is connected to a crossbar switch so that it can be used to transmit data between arrays as well as to peripheral storage or image display devices.

The fastest bus is the 256 bit parallel I/O bus which can operate from 512 to 2560 MBPS. The data transfer rate on this bus is such that special peripheral configurations are

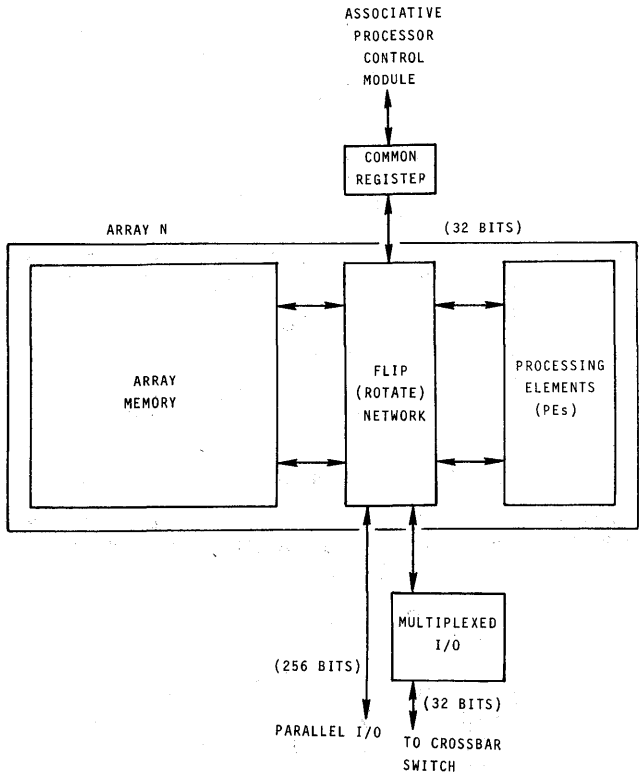

Figure 9—Array I/O paths

required. Consequently, it is best suited for special purpose applications.

Every array module is capable of being connected to either of two controllers. Thus in those applications where the equivalent of double buffering is desirable, some of the arrays can be switched to an I/O controller while the remainder are used for computation.

SUMMARY

The multiple data stream parallelism of the STARAN allows it to perform a "serial" algorithm on up to 8192 data elements simultaneously. This is important in image processing where large volumes of data are processed. Images are inherently two dimensional, but the large array size of the STARAN E, readily allows an entire 512×512 8 bit/pixel image to be stored in one array with essentially its two dimensional topography intact. The array addressing structure and the array flip network provides easy access to every pixel and its neighbors in a simple efficient manner. The mask (M) register operation in an array enables complex decision processes to be made on any subset of pixels in an array. All of the above aspects of the STARAN's architecture would not be valuable if it could not be efficiently used. The three I/O paths into every array provide the capability to efficiently broadcast parameters and constants as well as loading and unloading image data in an expeditious manner. Thus it is apparent that many of the architectural features of STARAN are ideally united for image processing and pattern recognition. This conclusion is confirmed by the execution times shown in Table I.

TABLE 1.—Sample Algorithm Processing Times

Function	Description	Image Size	Speed*
Magnification	2.5× cubic convolution interpolation	512×512 8 bit/pixel	588 milliseconds
Convolution	3×3 window	512×512 8 bit/pixel	700 milliseconds
FFT	1 Dimension	512 16 bit/pixel	2.7 milliseconds

* Measured times in the STARAN B machine exclusive of I/O. The STARAN E instruction execution time is approximately 20 percent faster.

The criterion COBOL system

by MICHAEL D. SHAPIRO
NCR Corporation
San Diego, California

INTRODUCTION

Higher level programming languages provide problem solvers an access to computers without requiring them to become computer experts. In the traditional environment, compilers perform the relatively complex translation from the higher level language statements into the machine instructions. The differences between the complex data structures and operations of languages and typical simple structures of machines makes this a wide chasm to bridge.

The mismatch between data and operations of the languages and machines appears clearly when one considers a language such as Cobol, APL, PL/I or Snobol4. In each of these, the fundamental operations and even basic data types do not translate easily because the language design depends on no one machine. The implementor must build mechanisms ranging from full software interpreters to elaborate subroutine libraries to perform the higher level language operations on higher level language data.

Despite the costs, the payoffs of using higher level languages make them worthwhile. And with the widespread use of microprogrammable processors as the base of computing systems, designers can realize the once primarily theoretical higher level language machines.[1] An interpreter for the operations of a higher level language, written in firmware rather than software becomes a higher level language machine.

The NCR Criterion Cobol System implements an indirect higher level language machine for 1974 ANSI Cobol in a conventional microprogrammed environment, permitting execution of a single run unit composed of both Cobol and other language modules in a highly efficient manner.

The system consists of a microprogrammed hardware processor supporting both conventional and Cobol machine firmware in a multiple virtual machine environment, a multiprogramming virtual resources operating system, a 1974 ANSI Cobol compiler designed to run in a virtual storage environment, the necessary execution time support subsystems and routines, and Cobol symbolic debug and runtime tuning subsystems.

The discussion focuses on the characteristics of the system as a Cobol environment and the structure of the Cobol virtual machine, the compiler, and the support subsystems.

THE CRITERION SYSTEM

NCR system architects chose a higher level language approach as part of the basic design of the Criterion, a new family of computers to replace the aging Century line. The other part of the design fully supports, without modification, existing NCR Century application programs, no matter what their programming language.

Cobol, probably the most widely used data processing applications language and hence of most interest to the company, serves as the base of the higher level language system. The new virtual resources executive (VRX) operating system design includes support of multiple virtual machines. Cobol Virtual Machine (CVM) firmware, a new American National Standard Cobol[2] compiler, and a set of Cobol execution time support subsystems form the resulting Criterion Cobol System (CCS).

A very fast (56 nsec) pipelined microprogrammable processing element forms the base hardware of the Criterion system. Three storage units attach to it: register storage (RSU), instruction storage (ISU) and memory storage (MSU). The RSU holds temporary work areas for the element. Microcode executes primarily out of the ISU, although some low-speed instructions execute from the MSU. The MSU areas not used by firmware become the main storage used by the operating system and application programs.

The hardware supports a paged memory environment with a maximum addressing capability of 16 megabytes (MB). The processing element performs address translations with interrupts to the executive on page faults.

The customer can receive either of two sets of firmware and software for the Criterion: the real resources system (RS1) or the virtual resources system (VS1). RS1 emulates NCR Century computers and permits use of the Criterion as a direct replacement. VS1 supports the virtual resources, including virtual storage and the multiple virtual machines. The two current virtual machines provide an extended version of the Century instruction set and architecture, supporting the NEATVS assembly language (NVM) and the new CVM.

While these two machines co-reside in the system and support many similar elementary data types, they have sev-

eral fundamental differences in design orientation. NVM uses binary data extensively while CVM works best with decimal data. NVM uses an absolute addressing scheme, but with addressing a maximum of 32 kilobytes (KB) offset from a register, except in the first 64 KB. CVM uses bases, but allows offsets up the full virtual address space limit.

Both NVM and CVM share a common stack-oriented calling mechanism and a common virtual addressing scheme so that a program executing in either machine mode can invoke a module in the other. Each entry point to a module has an entry point control item (EPCI) indicating the virtual machine mode for execution of that module. Machine state can change on any call.

COBOL VIRTUAL MACHINE

The Cobol Virtual Machine (CVM) implements an indirect higher level language machine for the Cobol data types and structures and for a large subset of the Cobol operations. An object module generated for execution by the CVM contains three principal memory areas and some minor auxiliaries.

The data area contains all the data described in the program either explicitly or implicitly. Implicit data includes various file tables, collating sequence tables, debugging tables, and literals. Data definition entries in the Data Division describe explicit data.

The descriptor area contains an internal representation of the information contained in the data description entries. Each referenced data element has a descriptor. Each descriptor contains location, size, type, index, and editing information for the data element.

The code area contains the translated procedure division statements. The basic internal operations (for example, simple MOVE or ADD) translate to single machine instructions. More complicated statements, such as those having multiple receiving fields, decompose into simple Cobol statements for code generation. With operation codes generally typeless, automatic conversion and editing occur when required by the referenced descriptors.

Data types

The fundamental elementary data types in the CVM correspond to the variations on COMPUTATIONAL and DISPLAY types in Cobol.

Packed decimal items represent computational data internally. The requirement for frequent conversions makes packed decimal the most efficient format to use in CVM. Depending on the Cobol picture, the item may or may not have a sign. Computational data items may vary in precision from 1 to 18 digits and may have an implied decimal point at any position adjacent to a digit or may have scaling to a maximum of 18 positions from the farthest digit. An additional four-bit trailing half-byte represents the sign, when present.

Both numeric and nonnumeric data items occur. Numeric display items follow the same rules for computational items on precision and decimal point position. ASCII characters '0' through '9' represent the digits. If the programmer specifies a signed item with a "separate sign," an ASCII '+' or '−' represents the sign. The user specifies whether the sign goes before or after the digits. If the user requests a "zone sign," the sign indicator combines with the first or last digit to form an ASCII character according to this table:

no sign	0	1	2	3	4	5	6	7	8	9
+ sign	{	A	B	C	D	E	F	G	H	I
− sign	}	J	K	L	M	N	O	P	Q	R

Strings of ASCII characters form the nonnumeric data items, having the internal categories of alphanumeric, alphanumeric justified right, numeric edited, and alphanumeric edited, and the properties specified in the Cobol standard.

The CVM provides two additional data types. Signed binary (two, four, or eight bytes) provides data communications with the NVM. User documentation recommends against its use for other purposes. Special index-handling commands manipulate index data items for the table handling operations. The internal structure of these items remains transparent to the user.

Descriptors

The descriptor area may contain any combinations of four types of descriptors. Two of the descriptors, used for compact data descriptions, require four bytes each. Only certain elementary items use them. The other two descriptor types define the more complicated data structures. The long descriptors take eight bytes each.

Short nonnumeric descriptors describe alphanumeric or alphanumeric justified right data items whose length does not exceed 4095 characters. Short numeric descriptors describe decimal, packed decimal, or binary items. In both cases, the item must begin in the first 32768 bytes of the data area.

Long nonnumeric descriptors describe alphanumeric, alphanumeric justified right, or alphanumeric edited data items. They allow a maximum length of 65535 characters. Other fields describe the number of dimensions the item has, whether an edit information mask pointer follows, and the method of addressing used for the data. Long numeric descriptors vary from the long nonnumeric descriptors in that they have decimal position and length fields in place of character length fields.

Edited data items require edit information. An edit mask provides the description of the format of the result. The mask derives from the picture specified in the source program. For alphanumeric edited and numeric edited items, a flag in the descriptor indicates an extension to twelve bytes, with the additional four bytes pointing to the edit mask and containing the numeric length for numeric edited items.

Addressing

Addressing in the CVM uses the standard 24-bit Criterion virtual address mode. Within a program, the system com-

putes the effective virtual address as an offset from the start of the data, descriptor, or code area. A linkage table contains the three bases. On entry to a module, the XLINK register of the machine points to a table of bases. The first three entries contain bases for data, code, and descriptor areas. An additional eight entries point to various other control and debugging locations.

Effective data addresses for descriptored items come as direct offsets for the data area or compute from addresses passed through parameters. Automatic computation of indices for tables occurs when table references appear.

Code

The CVM instructions, as indicated earlier, closely match Cobol statements for their operations. The common statement options form part of the instructions, where appropriate: numeric operations have rounded and size-error flags.

Each operation contains a bit indicating whether it begins a paragraph. The debugging system, described later, uses this information.

A few of the typical commands demonstrate the nature of the CVM instruction set:

MOVE commands act like simple move statements in Cobol, reformatting data as necessary from the source to the destination. A single instruction provides for all conversions and editing. The MOVE-BYTE commands allow movement of a single character literal.

COMPARE commands form the basic operations of the IF statements. The principal COMPARE command handles both numeric and nonnumeric data. Separate instructions provide IF-ALPHABETIC and IF-NUMERIC tests. Comparison tests use either native ASCII collating sequence or one derived from some table, such as EBCDIC. The user specifies the choice with a PROGRAM COLLATING SEQUENCE clause.

GOTO commands provide for internal branching, with Cobol GO TO and GO TO . . . DEPENDING statements as basic instructions. Others include a conditional GO TO for size error detection and an indirect GO TO for PERFORM handling.

Arithmetic commands mimic the Cobol arithmetic statements (except the COMPUTE statement). The commands require numeric source operands and numeric or numeric edited result items. Both two- and three-address operations occur, corresponding to statements of both forms:

```
ADD A TO B.
ADD A, B GIVING C.
```

Programmers request rounding and size error detection in the arithmetic commands by clauses in source:

```
ADD A, B GIVING C ROUNDED;
ON SIZE ERROR . . .
```

CALL commands invoke a standard Criterion calling sequence. The program sets up parameters in the standard parameter stack using a MOVE-VMA command to compute the virtual address. A state switch to NVM may occur during the call.

EXIT commands provide the Cobol EXIT PROGRAM statement for a called subprogram. On exit to the calling program, a state switch may occur to return to the NVM state if an NVM program invoked the CVM program.

THE COBOL COMPILER

The Cobol compiler (CBL) for the CCS converts 1974 ANSI Cobol programs to CVM object modules. Its logic design generally matches that of a typical textbook example Cobol compiler, but with the unique feature of its extensive use of the Criterion virtual address space.

The implementation team used contemporary software engineering techniques in constructing the compiler. They wrote the bulk in a subset of the NCR Software Writer's Language (SWL). NEATVS assembly language functions provide a few utility services, and Cobol coded modules (after bootstrapping) do the input-output. CBL contains more than 200 modules, linked together in a tree-structured manner.

The development process, which occurred concurrently with the development of the Criterion and the operating system, heavily used a variety of tools. A commercial time-sharing system served as the initial development engine. An earlier Cobol development project formed a base for about 30 percent of the code. Snobol4 encoded programs translated this code to the SWL syntax required by CBL. The compiler team coded the remainder of the compiler in the SWL subset. A tools group developed a compiler for the time-sharing system to match the subset of SWL used by CBL. The resulting object program for CBL executed under a simulated virtual storage test environment developed for the CBL project. The team debugged most of the compiler logic before the new hardware and operating system became available.

When the Criterion system could run with a rudimentary operating system, a modified remote entry system transmitted source modules to the NCR equipment for compilation and testing. This linkage remained in place throughout the development cycle. The master library remained on the time-sharing system until the Criterion system became fully stable.

User's view of CBL

To the Cobol programmer, CBL appears as an easy-to-use conventional compiler. Information provided at compilation time relates the execution time debugging output to the source program. The compiler can produce extensive diagnostics in clear English. The programmer specifies a

requested minimum level, from non-ANSI feature through serious errors only. Diagnostics refer to the source program by source line and column number.

Input to the compiler comes from source cards, from a Cobol source library, or (for compatibility with earlier systems) from NCR "SPUR" format files. Outputs include the source listing and a diagnostic summary, along with the object module on disc, if the compiler generates it. The user may specify optional cross-reference, object listing, and object map printed output. The Cobol library facility furnishes texts for the Cobol COPY statement.

Object modules produced by the compiler contain the code, data, and descriptor tables required by the CVM, the control tables used by the link editor, and optionally, debugging tables used by the execution time Cobol symbolic debugging and tuning systems.

Tables and texts

The structure of internal tables and texts gives CBL the properties which make it particularly well-suited for virtual storage operation. As used in this discussion, a table structure holds randomly accessed data and a text structure stores sequentially accessed data.

Tables in CBL contain the information usually associated with the compilation process: data names and attributes, procedure (label) names and attributes, file properties, literals, etc. In keeping with the rules for virtual storage programming, the design of tables makes them compact. A vector of data records forms a table. If a record requires eight or fewer bytes, the table consists of the collection of records. If the record size exceeds eight bytes, the table contains a vector of three-byte record pointers and a collection of records allocated, as required, from a storage pool. This approach permits CBL to compile the widest mix of Cobol programs, keeping the table storage as compact as possible.

A few principal internal tables hold most of the data passed between phases:

DATA TABLE. The data table contains the data name information and the attributes of the data name. The attributes include both external properties, such as line and column where defined, and internal properties, such as data type or level in structure. An auxiliary table entry holds less frequently used items which cannot fit into the data name attribute table.

PROCEDURE TABLE. The procedure table contains the procedure name (Cobol paragraph and section label) information. It uses the auxiliary table when necessary.

PICTURE AND LITERAL TABLE. The picture and literal table contains pictures and literals which appear in the source program, literal generated by the compiler, and edit masks generated from the pictures for numeric edited and alphanumeric edited data items.

FILE TABLE. The file table takes the information developed by the compiler from environment, data, and procedure division references to files. The file table links to the data table and to the auxiliary table to store additional information.

Texts in CBL store the information frequently associated with temporary scratch files. A text appears as a large vector of relatively small records. The compiler places entries into a text or retrieves entries from a text in a sequential manner. In this way the virtual storage paging mechanism moves the idle information to the page storage device and brings it back when referenced. The overhead associated with normal file input-output operations disappears and, for a small Cobol program in a relatively idle system, the text pages may never need paging out.

The principal internal texts used for passing information between phases in CBL are:

COBOL TEXT. The Cobol text (CTEXT) contains a regularized representation of the original source program with data names, procedure names, and reserved words, pictures, and literals represented by entry numbers in appropriate tables.

GENERATOR TEXT. The generator text (GTEXT) contains an intermediate form of the Cobol program, with references to table entries for data items, labels, literals and other items. The GTEXT contains a series of "packets" which correspond roughly to assembly language statements in a compiler which compiles to assembly language in the "front end."

OBJECT TEXT. The object text (OTEXT) contains the object information produced by the object generator, but before packaging into an external object module format.

ERROR TEXT. The error text (ETEXT) contains the information produced by the compiler analysis phases and used by the diagnostic formatter.

Compiler phases

CBL divides into from five to ten phases, depending on how one wishes to number them. If one chooses the minimum number, several of the phases divide into subphases.

A main driver initializes compiler work areas, opens source and listing files, processes user request options and then calls the first compiler phase. It proceeds through each compilation phase, checking for a possible compilation abandonment after each, until it reaches the object generation phase. It invokes generation only if:

a. the user has not suppressed it (an option), and
b. no serious error has suppressed it.

After object generation, the object formatter outputs the code, the main driver prints a compilation summary, closes

the files, and returns to the monitor to terminate compilation.

The source scanner, first phase of the compiler, converts the Cobol source lines read from input to the CTEXT. A hashing mechanism (buckets and chained entries) builds the symbol table through the data and procedure tables. Pictures, literals, and unknown symbols go into the picture and literal table. The scanner produces the source listing and places syntax diagnostics into the ETEXT.

The source scanner does all the Identification Division processing, principally recording the program name.

Three subphases handle the Environment and Data Division processing. One of these, the picture analyzer, scans the picture strings for meaning and errors, and sets up attributes for data associated with the picture. It also builds edit masks corresponding to specifications in the picture. Two subphases extract source from the CTEXT and parse and analyze other table information in the divisions, building and modifying the appropriate table entries. All three subphases can generate diagnostic requests into the ETEXT.

The Procedure Division processor takes the source text from the CTEXT and information from the tables and builds the GTEXT. It also makes entries, if necessary, in the ETEXT and other tables.

The final front-end phase, the literal pooler, moves entries from the picture and literal table into the literal pool, a small text.

Two back-end subphases generate the object module. An object generator analyzes the tables and literal pool to build the data and descriptor areas. It uses the results from these and the GTEXT to construct the code area, and also produces the required link editor tables. All of this information goes into the OTEXT, which passes to the object formatter. The object formatter writes the object module on disc and optionally produces an object map and listing.

The main program has two utility phases available when it needs them. A cross-referencer produces an alphabetic reference listing of all data and procedure names. The main program runs this procedure, on user request, immediately after the source scanner. The diagnostic formatter runs just before the end of compilation if any phase has emitted a diagnostic request to the ETEXT.

EXECUTION TIME SUPPORT

Criterion Cobol System execution time support includes a set of "global" routines for handling the operations required for input-output, sort-merge, communications, and operating system interface statements. It also contains software/firmware debugging and tuning subsystems, described in the next section.

Global routines in VRX, residing in a protected memory area accessible to all simultaneously executing programs, consist of reentrant code.

The input-output system, the Criterion Access Method (CAM), provides Cobol support for sequential, relative, and indexed files. Relative and indexed files may reside on any disc type supported on the machine. Other devices handle sequential files only.

The sort-merge system provides the Cobol support for sorting and merging magnetic tape and disc files.

The Message Control System (MCS) provides functions for the Cobol Communications functional module. The Network Description Language (NDL) processor sets up the communications paths according to user specifications.

An operating system interface module, invoked primarily for Cobol ACCEPT and DISPLAY statements, supports such actions as reading the clock or calendar, communicating with the operator, and reading control card parameter information.

COBOL SYMBOLIC DEBUG AND TUNING AIDS

The Cobol symbolic debug system (COBUG) provides the Cobol programmer with a variety of information for symbolically monitoring the program and data flow in an executing program.

The first instruction of each paragraph contains a special flag bit. Before executing the instruction, the firmware checks that bit and an internal symbolic debug switch. With both conditions *on*, the COBUG subsystem takes control. It displays information requested by the user. The user, through control statements, may request a variety of types of information:

DUMP of all or selective data items at specific places in the program. Options include specification of which time during execution the dump should occur, the number of times, and relational conditions:

```
DUMP ABC AT XYZ FOR 10 TIMES WHEN A
IS LESS THAN B
```

TRACE of all or selective paragraph flow. Options include ranges, and the number of times:

```
TRACE XYZ TO PDQ ON 5 FOR 12 TIMES
```

FLOW of program execution. If requested, the firmware records the execution of each instruction. At program termination time, the COBUG system formats and prints a listing of the data. The user, who must understand the CVM operation, can use this listing to detect problem points in the program.

The Cobol analysis routine for runtime tuning (CARTUNE) provides the Cobol programmer with a mechanism for collecting execution time statistics. The Cobol compiler, on request, builds a source line table and three activity tables in the object module. At execution time, the CVM firmware optionally maintains tables of the number of times each type of operation code executes, the number of references to each data item, and the number of times each instruction executes.

At the end of execution, CARTUNE gathers the information and prints an analysis. The user may request specific

reports: source line executions, data references, and object instruction execution history. These data assist the programmer in locating the inefficient portions of the program for improvement.

THE RESULT

The Criterion Cobol System provides the Cobol user with an integrated system optimized for highly efficient Cobol program development and execution.

Review of the CLIP image processing system

by M. J. B. DUFF
University College London
London, England

INTRODUCTION

In this paper, the terms "pattern recognition" and "image processing" will be considered only in relationship to optical or visual images, which will be expressed as two dimensional arrays of numbers, each number representing the image intensity in the corresponding picture element, or "pixel." The image will be assumed to be adequately reproduced by means of an n by n array of square picture elements whose intensities are chosen from a range of L discrete values which are uniformly spaced over a selected brightness range. Obviously, both n and L must be large enough to give acceptable spatial and grey-tone resolutions for the task to be performed on the image.

Many of the operations carried out during pattern recognition or image processing can be described as "local;" this implies that the new value of a pixel in the processed image is a function of the values of a limited and compact subset of pixels in the original image. A particularly useful subset is the immediate neighbourhood of each pixel, i.e. the three by three array of adjacent pixels surrounding and including each pixel. The implication of this statement is that extremely fast processing of images could be achieved by constructing an array of identical processors in one to one relationship with all the pixels of an image, each processor receiving inputs from its corresponding pixel and from the eight immediate neighbours of the pixel. The purpose of the CLIP (Cellular Logic Image Processor) programme of research has been to optimize a processor array structure for the range of operations commonly required in image processing, having due regard to the cost of implementing the system as an array of large scale integrated circuits. At the same time, it was recognized that, ideally, the array should be capable of executing all possible functions provided an appropriate sequence of allowed instructions is obeyed. In other words, the array should perform as a general purpose computer optimized for a typical range of image processing operations.

CLIP4 LOGIC

The basic unit of the array is the cell, being a combination of logic units (i.e., the processor) and memory. Details of the CLIP4 cell are shown in Figure 1(a) in which A, B and C are single bits of buffer memory and D is a 32 by 1 bit RAM. The boolean processor provides two program selected independent functions, D and N, of the two binary inputs A and P, one of which (N) is used to form an output to all neighbouring cells. Inputs from neighbouring cells are individually gated and then OR'ed together to form the binary function T which combines with B to produce P. A and B are each single bits of the pixels of two images in the array location corresponding with the cell concerned. Other gates are included which can be used to generate the exclusive OR (EXOR) of B and T at P and also the AND of B and T which is then OR'ed with the N output of the boolean processor to form the interconnection output N*. These additional gates are of use when the processor is performing arithmetic operations and are brought into use by special instructions which put 1's on the R and C control inputs.

Before considering the details of the operations in the CLIP4 cell, it will be helpful to examine the organisation of the data storage in the n by n cell array (see Figure 1(b)). Each address in the D memories can be visualised as a plane of single bit stores, d. If the location of each cell is given by its (x,y) coordinate in the array, then a bit plane will be the set of bit stores defined by:

$$D_j=\{d_{jxy}: x,y=1, 2, \ldots n\}$$

A pixel will be formed as a column of single bit stores passing through g bit planes. Thus the pixel at location (x,y) is defined by:

$$P_{xy}=\{d_{jxy}: j=k, k+1, \ldots k+g-1\}$$

D_k will contain all the least significant bits in the binary numbers representing the grey levels in each pixel; D_{k+g-1} will contain the most significant bits. Note also that

$$g=\log_2 L$$

implying g binary bit planes are needed to represent L grey levels. The ordering and addressing of the bit planes in the 32 available addresses in the D memories is arbitrary and may be varied to suit the needs of the program.

When numerical calculations are to be performed on data in which there is no longer an exact correspondence between the n^2 pixels and the n^2 processors, it is sometimes convenient to represent data in the binary column mode, in which n binary numbers are stored in the n columns of a

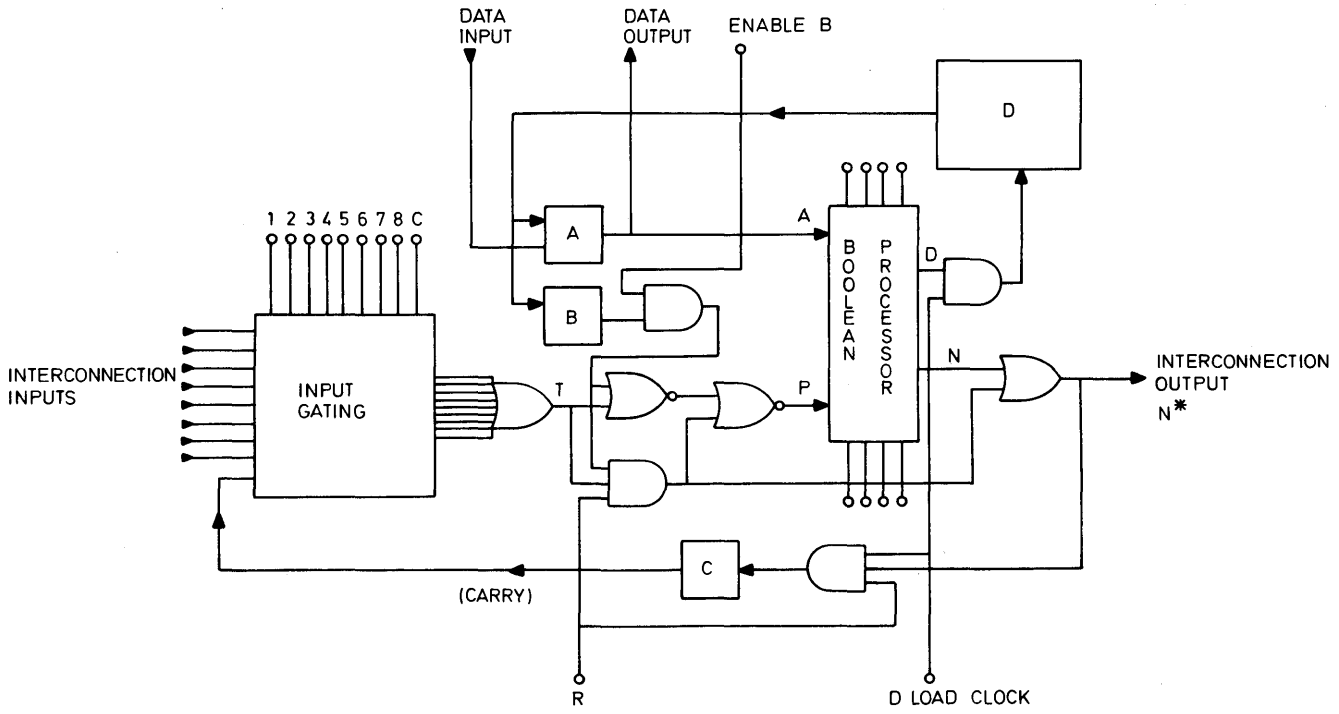

Figure 1(a)—The CLIP4 logic and memory structure

single bit plane. A binary number will be represented by the column:

$$\{d_{jxy}: y=1, 2, \ldots, n\}$$

Normally, the precision provided by n bits will be unnecessarily high for typical values of n. Methods have been devised for using the available storage more effectively.

A binary image is composed of elements which are either black or white so that pixels have values 0 or 1 respectively. Usually, binary images are produced by thresholding a grey tone image. Binary images are stored in a single bit plane of the D memories, at any convenient address.

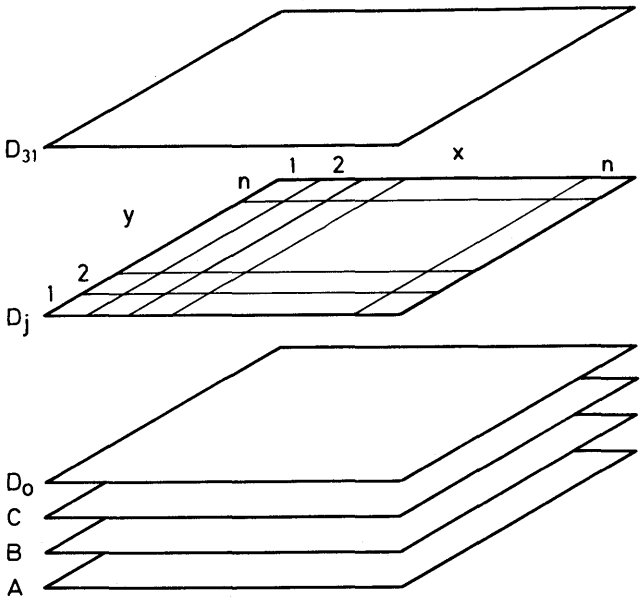

Figure 1(b)—Bit plane and binary column data organisation

USING THE CLIP4 CELL

The five principal ways in which the CLIP4 cell can be configured are illustrated in the simplified logic diagrams of Figure 2(a)-(e). In each case, the symbols A, B, C and D refer to bit planes.

Simple boolean operations (Figure 2(a))

Binary image I_1 is loaded into A and binary image I_2 loaded into B. The direction gates 1 to 8 and inputs R and C are disenabled. Any of the 16 possible boolean functions of the two images can be produced and loaded into a selected address of the D memories. If I_1 is in D_1, and I_2 in D_2, and if the result address is D_3, the coding for the operation of taking the exclusive OR of I_1 and I_2 is (in the CLIP4 language: CAP4):

```
SET  P @ A
LDA  1
LDB  2
PST  3
```

(Notes: @ implies EXOR; PST is a mnemonic for Process and Store)

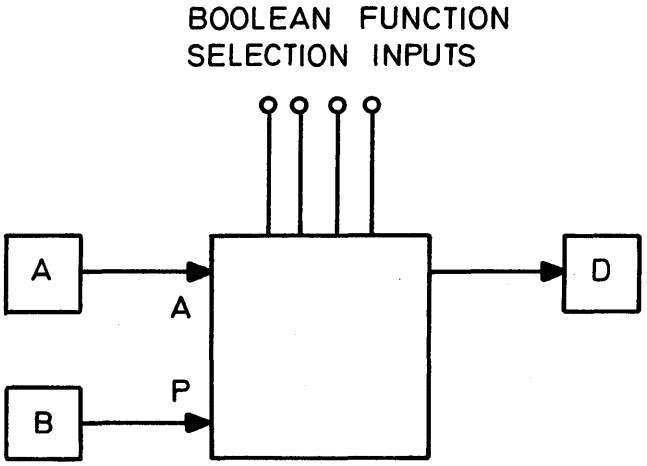

Figure 2(a)—Simplified logic for boolean operations

Simple propagating operations (Figure 2(b))

A binary image is loaded into A and an interconnection function set up (for example: N=A). A selection of interconnection gates are opened (for example: those in directions such that outputs from neighbouring cells to the North, East, South and West are admitted, i.e. directions 2, 4, 6 and 8) and a boolean function for the output D is chosen (say: P=$\bar{A}$). The coding is:

```
SET  P + − A, [2 4 6 8] A
LDA  1
PST  3
```

(Notes: the negative sign implies NOT; the B pattern does not affect the operation).

Labelled propagating operations (Figure 2(c))

In this case propagation can be started from any cell in which B has the value 1, i.e., from any white pixel in I_2. Using the same values as in the previous example, the coding becomes

```
SET  P+−A, [2468B] A
LDA  1
LDB  2
PST  3
```

(Notes: the connection to the B store is enabled by inserting the symbol B at the end of the direction list on the SET instruction).

Propagation can also be initiated at the edges of the array by adding an E at the end of the SET instruction. This has the effect of supplying a 1 to all interconnection inputs of array edge cells which cannot connect to missing neighbours lying outside the limits of the array.

Bit plane arithmetic operations (Figure 2(d))

If A is a particular digit of one binary number, B the corresponding digit of another binary number, and C the carry digit resulting from the addition of the previous digits of less significance, then the expressions for the sum digit and new carry digit are:

```
SUM=A.EXOR.B.EXOR.C
CARRY=(B.EXOR.C).OR.B.AND.C
```

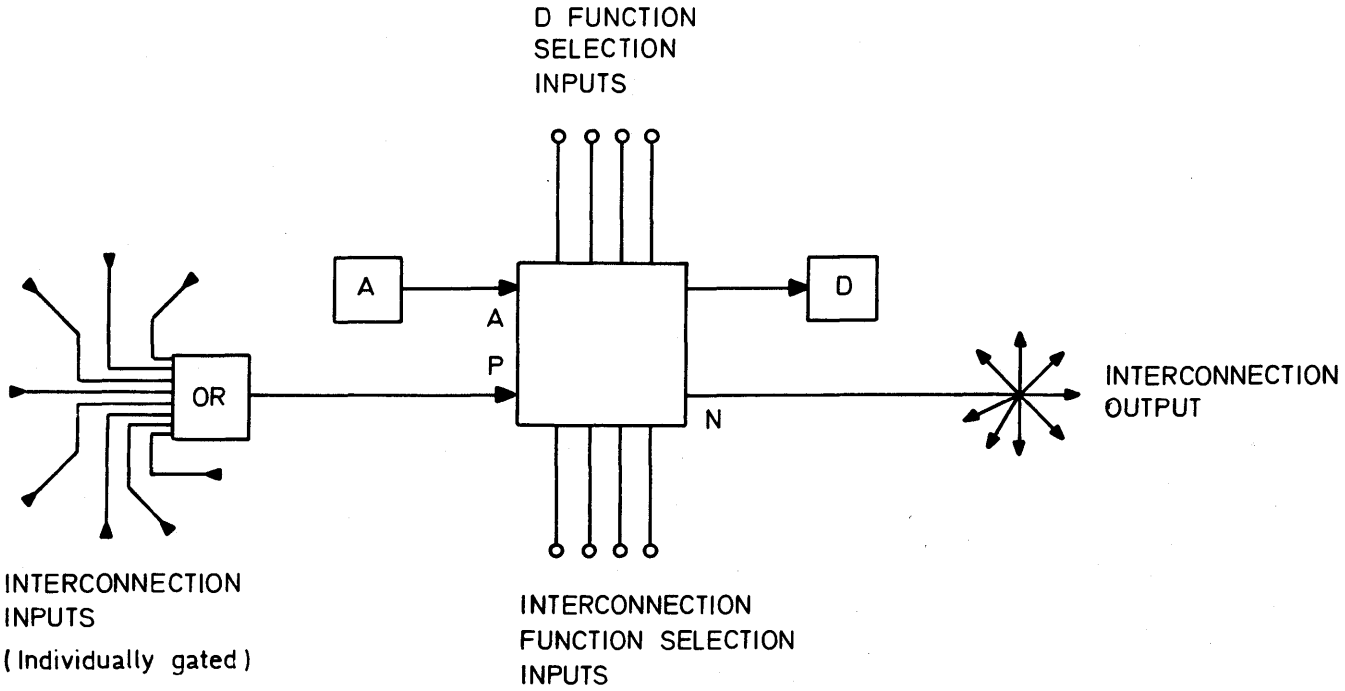

Figure 2(b)—Simplified logic for propagating operations

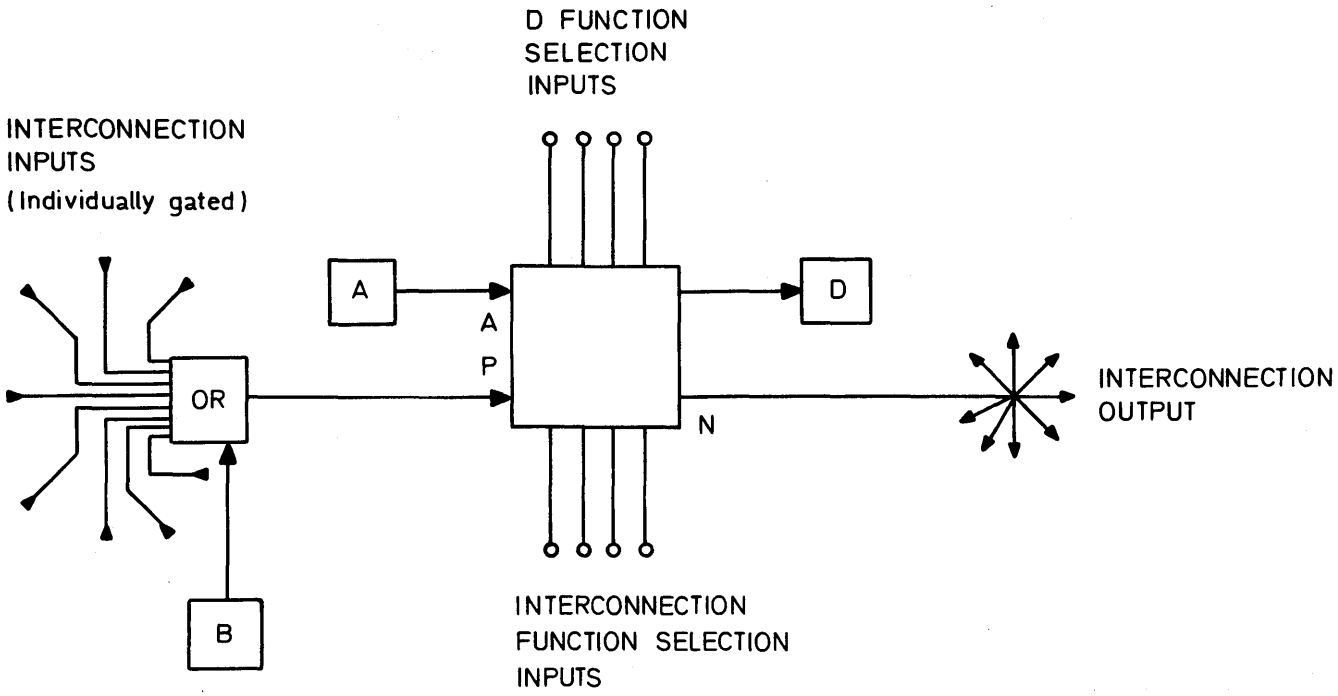

Figure 2(c)—Labelled propagation logic

When the inputs R and C are enabled, the CLIP4 cell will implement this arithmetic function for bit planes loaded into A and B, using the boolean processor to provide the operations N=P.A and D=P.EXOR.A. If two grey tone images are loaded into D_1 to D_6 and D_7 to D_{12} respectively, then the part of the coding which adds the second least significant digits is:

```
SET P@A, [B] P.A, RC
LDA 2
LDB 8
PST 14
```

Giving a summed image in D_{13} to D_{19}.

Binary column arithmetic operations (Figure 2(e))

Two planes of binary column numbers in D_1 and D_2 can be summed to form a new plane of binary column numbers in D_3 by writing the following short program:

```
SET P@A, [6B] P.A,R
LDA 1
LDB 2
PST 3
```

(Notes: the carry function is automatic when R is enabled; no use is made of the C plane stores; direction gate 6 is opened to allow carries to be propagated along the binary columns).

Other arithmetic functions can be developed from the summing operation in the usual way. In principle, floating point arithmetic can also be performed, although full details of the algorithms involved have still to be worked out.

OTHER HARDWARE FEATURES

In the CLIP4 system now being constructed, a 96 by 96 cell array is being assembled using custom-designed NMOS integrated circuits. Each circuit comprises eight cells arranged in two rows of four. The A elements are serially connected to form 96 shift registers, each of length 96 and lying along the array rows. Single bit planes of data are loaded serially into a 9216 bit shift register external to the array; this shift register can then be reconfigured into 96 short shift registers which then discharge their data into the A rows. The whole system interfaces to a television camera and monitor via two shift register memories, both of which can store a 96 by 96, six bit grey tone image. Analogue to digital conversion and digital to analogue conversion between these memories and the television camera and monitor respectively proceeds at the full video rate.

The array is operated by a controller which extracts the 16 or 32 bit instruction words from the controller memory, decodes them and drives the array and peripherals. Included in the controller are 14 general purpose 16-bit registers. A fifteenth register has a special additional function: a bit plane may be shifted from the array through a tree of parallel adders, thus permitting a rapid count of the 1-bits set in the A stores. This count appears in register 15. Furthermore, another instruction can be used to output the contents of

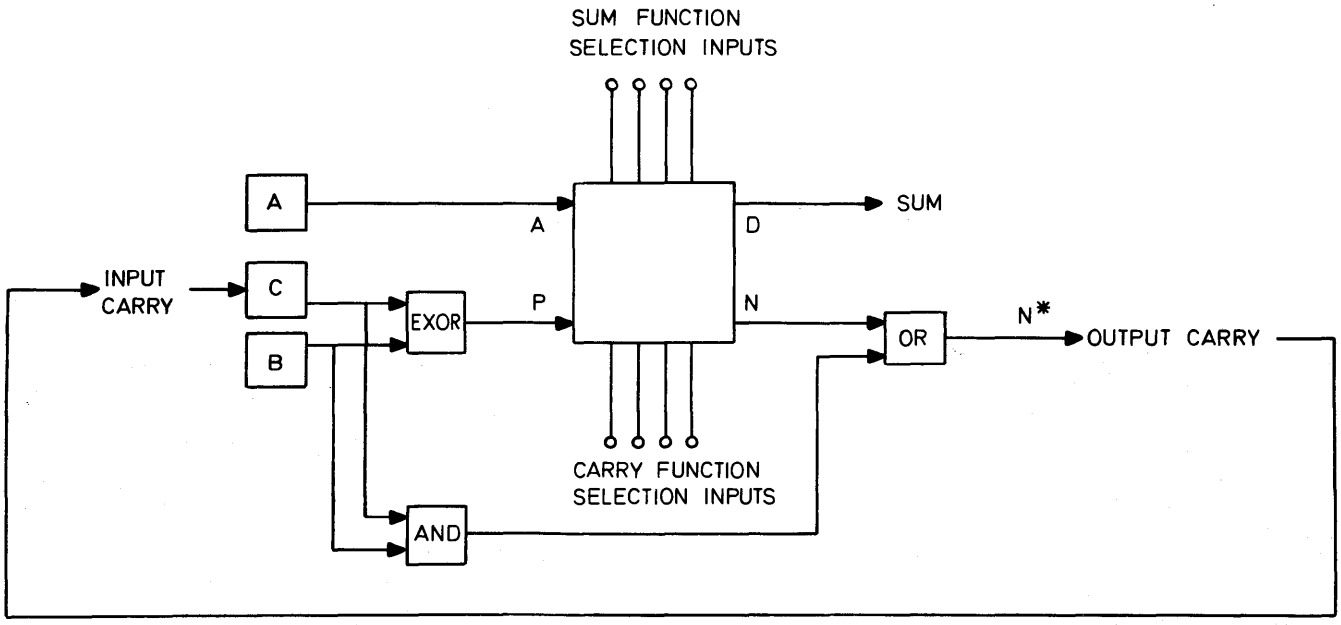

Figure 2(d)—Bit plan arithmetic logic

register 15 back into the array by means of an operation similar to the E instruction.

CLIP4 INSTRUCTION TIMES

CLIP4 is a Single Instruction, Multiple Data stream computer and performs image processing tasks at speeds which are quite unobtainable in conventional machines. The integrated circuit operates with a four phase, 400 ns clock cycle; load instructions require 8 cycles, PST instructions 10 cycles and SET instructions 12 cycles. A further 3 cycles are required for each propagation step through a cell when the selected boolean function is such as to cause propagation. Branch and register instruction require 4 or 8 cycles (the longer time being for memory reference register instructions).

Interleaving of these instructions is used to reduce complete array operations to just under 9 μs plus 1.2 μs/cell for propagation beyond the immediate neighbourhood of each

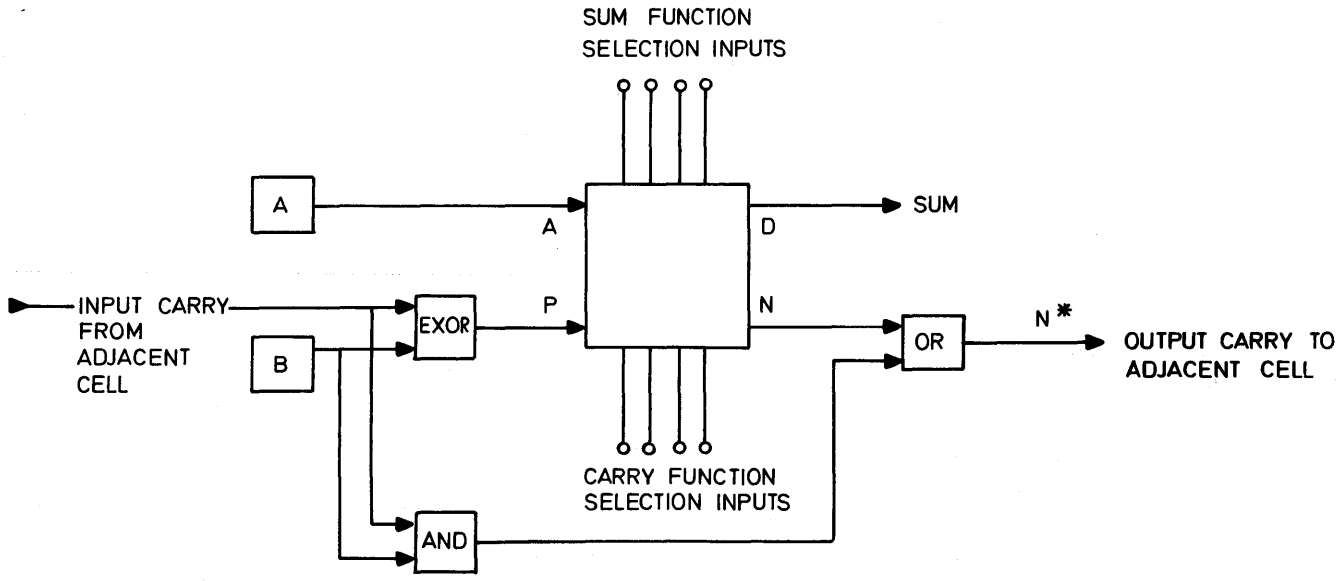

Figure 2(e)—Binary column arithmetic logic

cell. In general, the complete operation will comprise the instructions SET, LDA, LDB and PST. A bit plane of data can be entered into the array in under 4 ms. However, this may increase up to 10 ms since the operation is synchronised with the television scan cycle.

SYSTEM STATUS

A small scale pilot model of the system (CLIP3) has been in operation since 1973. The array comprises 16 by 12 cells and can be used on images of the same size or, by scanning the array across a 96 by 96 pixel image, can be used to simulate the larger CLIP4 array. Additional hardware and software is incorporated to handle sector to sector propagation when CLIP3 is used in the scanned mode. Details of the CLIP3 system are provided in References 1-5, which also include bibliographies of earlier studies both at University College and elsewhere.

At the time of writing (late January 1978), the CLIP4 chip design is complete and prototype chips are expected to be delivered before the end of March 1978. All other parts of the hardware and software for the image processing system are complete, although some modifications and improvements are being carried out. Negotiations are in hand to arrange for CLIP4 systems to be manufactured and made commercially available. Preliminary estimates suggest that the first systems will be ready during mid to late 1979. The University College prototype is scheduled for operation in Autumn 1978.

Evolution of new hardware technology

OVERVIEW

Evolution of new hardware computer technology continues at a rapid pace. Implications of developments in semiconductor LSI technology for logic and memories, new achievements in magnetic bubbles and disk storage and progress in computer printer technology for a modern computer system are far reaching. The impact of these developments has resulted in (i) significant cost reduction for a given function; (ii) increased complexity resulting in enhanced capability and performance; (iii) improved reliability; and, (iv) reduction in physical size. These trends can be expected to continue during the next decade and even though these technological changes are evolutionary, their impact on the computer organizaton and utilization is indeed revolutionary. Entire new areas of application will become available to the computer industry with the advent of inexpensive yet powerful and versatile hardware. The generic impact on the architecture and configuration of a computer will be as follows:

- Every type of terminal, control and data entry equipment, etc., will have a rather large amount of intelligence at the point of use.
- Dedicated small digital systems will be incorporated in computer subsystems, i.e., computer peripherals.
- System design will be determined by repetitive use of very inexpensive hardware.
- Archival mass storage will be available on line.
- Today's operating system features and other system software will be implemented in firmware.
- Performance measurement monitoring, maintenance and error logging accompanied with fail soft and fault tolerant design will be incorporated for increased hardware reliability and availability.

The three key areas of technical progress responsible for the developments projected above are: (1) semiconductor technology for LSI logic, microprocessors and RAMs/ROMs; (2) magnetic technology for bubble memories, and disk storage; and, (3) printer technology for data/information output. Present status and

projected developments in these areas will be described in the sessions on hardware evolution.

Semiconductor technology has been able to double the functional density on a single silicon chip every year since 1960. In the logic area, this progress has taken this technology from a single transistor to IC's and then to microprocessors and microcomputers. In complexity the microprocessors have evolved through 4 bit and 8 bit complexity to 16 bit complexity. By incorporating ever increasing RAM/ROM and control function powerful single chip microcomputers have become available for a price of about $10. Progress in the technology promises that by about the mid-eighties a 32 bit microcomputer with one million bits of memory could be made on a single silicon chip for a cost of about $20. With such inexpensive but powerful intelligence, no equipment would be permitted to stay dumb anymore.

In the area of semiconductor memory, the first challenge to the dominance of magnetic core memories occured in 1970 when the first 1K bit semiconductor memories became available. Since then the progress in this area has been rapid and now the technology stands on the threshold of the availability of 64K bit RAMs. This progression in complexity is likely to continue and reach a 1 million bits per chip by 1985.

CCD and magnetic bubble technologies provide solid state alternatives to rotating electromechanical mass storage devices. During the past year, significant technical advances have taken place in both of these areas. Both of these technologies have started to appear in the commercial products. CCD memories have faster access times than the bubble memories and will find a place in the memory hierarchy. Bubble memories, however, promise to reach the 1 million bit on a chip capability sooner than any semiconductor technology. The resulting low cost and high reliability when coupled with their inherent characteristics of non-volatility will permit this technology to fill the presently existing gap between semiconductor memories and moving magnetic mass storage.

Even as the CCD and bubble memories become more cost effective and attempt to replace magnetic disk technology, the moving head disk technology continues to improve. Disk technology progress has included not only the readwrite heads but media, source coding and error correction and improved system bus interfacing. These developments have improved the performance and reliability. Area density of storage has continuously increased and has been a key factor in achieving cost reductions.

Printer technology developments is another area of major activity. Both the impact and non-impact printing technologies using plain paper have progressed significantly. Ink Jet and xerographic printers are now commercially available. Progress in these technologies is radically changing the quality of the computer output as well as the cost of computer printing.

The technical developments in the areas discussed above will be described and projection of developments in the years to come will be made by experts who themselves have played a major role in making these developments possible.

One more aspect of this rapid evolution in hardware technologies is that wherever there is a significant technological change, there are opportunities for entrepreneur organizations to bring these technologies to the marketplace. A panel of distinguished speakers will address themselves to the proposition of "Opportunities for New High Technology Companies" as a part of the series of sessions on Evolution of New Hardware Technology."

Semiconductor rams of the future

by CHARLES BOETTCHER
National Semiconductor
Santa Clara, California

Semiconductor memories have, since 1970, been a significant factor in data storage. This has been especially true in Random Access memories and is becoming true of the slower serial access memories.

The manufacture of semiconductor memories takes place in two stages; the batch manufacture of the dice as wafers and the piece-by-piece assembly of the good dice into packages. It is the batch manufacturing of the dice that has led to the continuing trend of lower cost per bit. (Figure 1) With each new generation of memories, four factors have contributed to increased density of good bits per batch and therefore lower cost. These four factors are; decrease in storage cell complexity, decrease in feature size, increase in wafer size (thus batch size), and decrease in defect density.

Decrease in storage cell complexity has been the most significant factor in increasing batch density. (Figure 2) An appropriate comparison of cell complexity can be made by expressing cell area in units of f^2, where f is the minimum feature size allowed by the pattern-definition technology. Cell sizes in the last eight years have decreased from $200f^2$ for the first static flip-flops to a present range of $16f^2$ to $20f^2$. It is theoretically possible to reach a cell size of $4f^2$ where there are two features in both the X and Y directions, one to store the information and the other to isolate it from adjacent cells. If means can be found to isolate adjacent cells in less than a feature size, then a cell size of f^2 is possible.

Added to the decrease in cell size is an inherent increase in layout efficiency. When memory size increases by a factor of four, only twice as many decoders, sense amplifiers, etc., are required; only two more address buffer circuits and the same number or less bonding pads are needed.

A combination of design and process innovation has allowed this decrease in storage cell complexity, resulting in a 13.5 times increase in batch density.

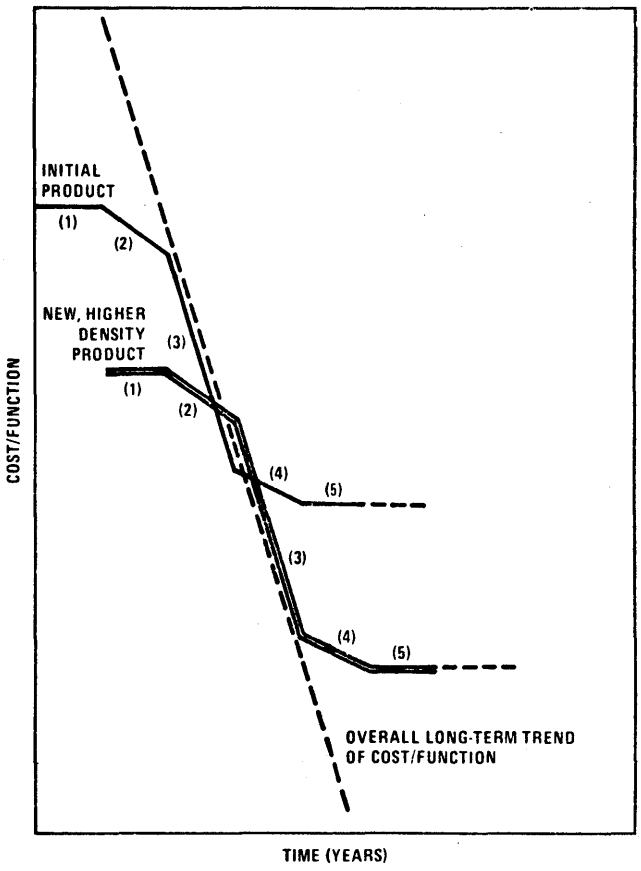
The second most significant of the four factors has been increased wafer size. As a result of a significant amount of development work on the equipment for manufacturing raw wafers and processing wafers, as well as developing processing techniques for handling larger wafers, the size of wafers has increased from two inches to four inches in diameter. This has resulted in a four times increase in wafer area and therefore a four times increase in batch density.

The remaining two factors, feature size and defect density have contributed the least to increasing the number of good bits per batch. Smaller minimum feature sizes have been possible as a result of improvements in mask making, mask aligning, and photoresist technology. Full utilization of improvements has been hampered by several factors. As feature sizes approach the film thicknesses and step heights present, dimensional control and feature integrity becomes increasingly difficult to maintain. In addition, as the feature size is reduced, the size of particle that will cause a defect in the masking is also reduced. Since smaller particles have a much higher probability of passing through the various forms of filtering used in semiconductor manufacturing facilities, the effective density of defects increases exponentially with decreasing feature size. (Figure 3) These factors have limited batch density improvements due to feature size reduction to a 2.2 times increase.

Overall, these four factors have resulted in a 120 times increase in batch density. With each new generation of memories, when a four times larger memory could be fabricated and packaged for the same cost as four smaller memory in four packages, the new generation was introduced. The packaging density increase of course offered an overall savings in system costs and users started switching to the new generation. As volume has increased and yields improved, costs have dropped and the cycle has repeated.

To what extent can we extrapolate and thereby predict the future?

With respect to decreasing cell complexity, there is little real room for progress. Present design and process technology is producing cells in the $16f^2$ to $20f^2$ size range. If we attain a $4f^2$ cell size, we will only realize a factor of four to five times density increase. In addition, in order to attain a $4f^2$ cell size, significantly new device types will have to be developed or adjacent storage cells will have to be built on separate layers. Increasing the number of layers affects yield in the same manner as a larger area. Therefore, achieving a $4f^2$ cell, with a corresponding increase in number of mask layers, may give no actual improvement in good bits per batch. Examples of new device types are Ovonic materials sandwiched between layers at the memory crosspoints or CCD devices which require changes in system architecture to cope with large percentages of their data base in serial access storage. In such cases the technology development required is significant.



NOTES:

(1) Product is introduced, very little or no competition.

(2) Product is multiple sourced but prices still hold up as production is limited.

(3) Production expands dramatically as yields improve, competition is fierce, prices tumble, marginal suppliers are beginning to drop out.

(4) Significant yield improvements are no longer available, new product is beginning to compete for the same market, competition is still intense, suppliers still drop out.

(5) Major market share is taken by new generation of product, market shrinks but prices hold up as competition is minimal.

Data courtesy of T. Klein, National Semiconductor.

Figure 1—Typical decrease of memory products' prices/costs during product life

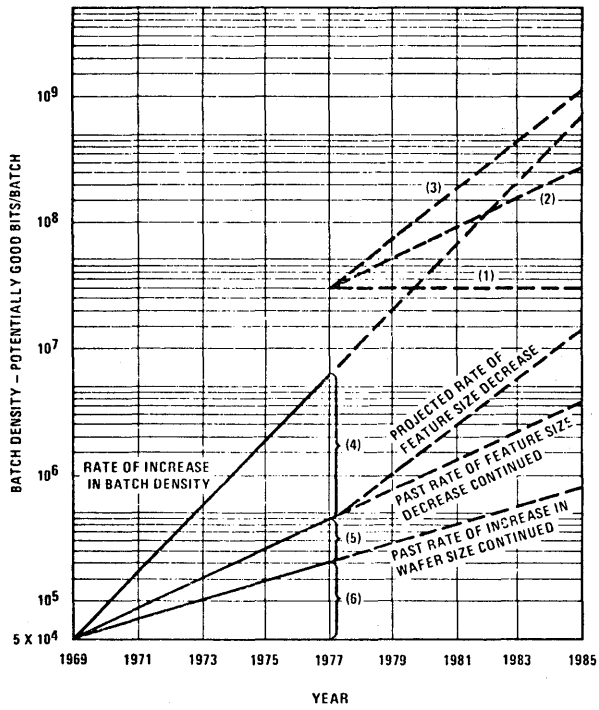
With respect to wafer size increase, the trend will continue, wafer area will double every four years. Each time manufacturers change wafer sizes, virtually all wafer processing equipment has to be replaced at a tremendous cost. Planning ahead and installing equipment that has a longer life is not really possible because of the ability with which equipment can be developed that will handle larger wafers with increasingly stringent control requirements.

Feature size reduction is the area where the industry is predicting the most improvement in batch density.

Projection aligners are already in use or being installed in most manufacturing lines. They have allowed the masks to become permanent tooling rather than production materials that must be discarded with every second or third run, and therefore, made it practical to invest in defect free masks with very tight tolerances. Projection aligners will allow feature sizes approaching one to two microns, a five times improvement over present practice. The lower defect densities possible with projection aligners will help offset the exponentially increasing effective defect density inherent with smaller feature size, but significant and costly improvements will also be needed to reduce other defect sources.

Electron Beam exposure systems are being developed, evaluated and purchased. Proponents of E.B. systems are claiming that they are about to revolutionize the industry. Proper analysis indicates that they will be a useful tool for mask making purposes, but their costs and throughput are such that feature size improvements they make possible will be offset by increased processing costs.

The industry is probably five to eight years away from the



NOTES:

(1) Theoretical limit, current wafer and feature sizes.

(2) Theoretical limit, assuming continued improvements in wafer size increase and feature size reduction.

(3) Theoretical limit, assuming constant rate of wafer size increase and an *increasing* rate of feature size reduction.

(4) Increase due to design and process innovations.

(5) Increase due to feature size improvement.

(6) Increase due to wafer size.

Figure 2—Past and projected contributions to batch density improvements

time when the cost and throughput of E.B. systems will allow practical use in direct wafer manufacture.

Feature size reduction, alone, does not determine the size of features that will be used, only the lower limit available. The devices from which the circuits are constructed must be scaled within other physical constraints.

Theoretically, MOS transistors, for example, can be scaled to quarter micron feature size, but some device characteristics don't scale well. As devices are scaled, circuit operating voltages and power densities must scale proportionately.

Such scaling requires re-engineering of device structures, process control, and film thicknesses. Parasitic parameters, such as leakage, noise, sub-threshold current, and sheet resistance do not scale as other circuit parameters and will require innovative design and/or materials research to deal with them.

Considering these factors then, it is theoretically possible for the batch density to increase by another 100 times in the next eight years. The task will require very large investments in capital and talent. The number of manufacturers able to make these investments will decrease. Moreover the market for memory products must continue to expand at a rate that will allow amortization of those investments.

It is appropriate at this point to apply this information to predictions of the coming generations of semiconductor memories.

In dynamic RAMs, MOS will dominate. The 16K will be the main production part through mid-1980. By mid-1980 significant quantities of 64K RAMs will be available. The 64K Dynamic RAMs will use scaled MOS devices (4 micron feature size), reduced power supply voltages (probably 5 Volts), $10f^2$ to $12f^2$ cell sizes, and be manufactured on 4 inch wafers. Some of these same techniques may be applied to the 16K RAMs but the cost of packaging four 16K RAMs will be offset by the lower cost of 64K RAMs, both for the manufacturer and for the user.

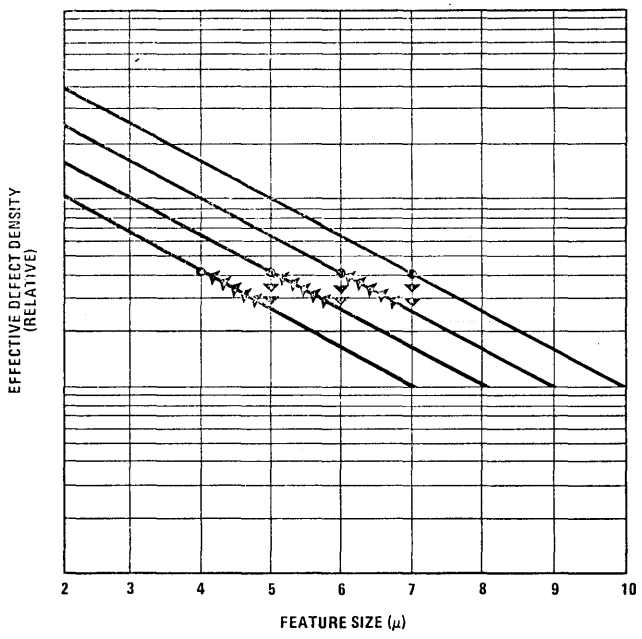

Figure 3—Effective density of catastrophic defects vs. feature size

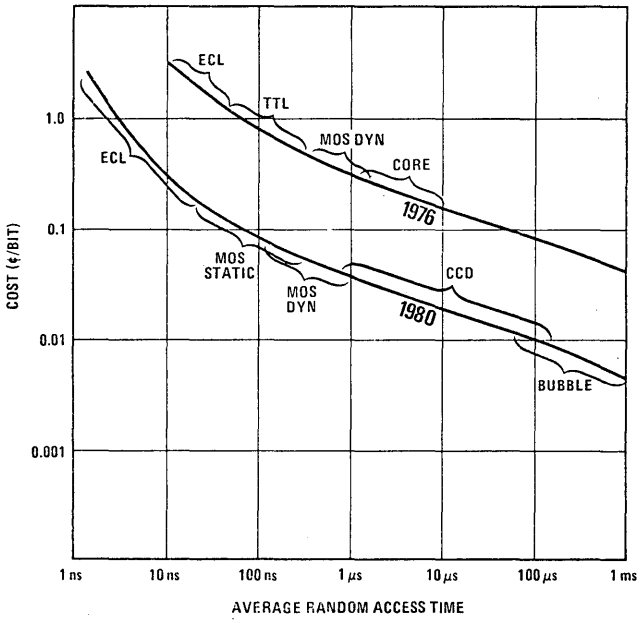

Figure 4—Memory component cost vs. performance

Storage cells for CCD memories are inherently easier to simplify and already 64K CCD's with $5⅓f^2$ cell sizes are close to reality. The disadvantages of serial memory storage will be offset by the lower cost per bit associated with CCD's. Memory system and CPU manufacturers will accept the 5 to 10 percent throughput penalties in exchange for ⅓ to ¼ the cost per bit CCD's will offer.

MOS static RAMs will use scaled MOS to achieve data rates presently served by bipolar technology. They will be used predominantly to serve the IBM Add-on business until the problems of interfacing Dynamic RAMs to the new generations of machines are solved. Currently, 4K static RAMs are becoming readily available. By mid-1980 16K static RAMs will be readily available. Present CPU's are implemented with ECL logic, and the translation from ECL to TTL levels to interface the RAMs adds appreciably to the access time. Future generations of MOS static RAMs will appear with ECL interfaces to eliminate the external level shifting and potentially reduce access times.

Bipolar static RAMs will continue to be the faster and smaller density memory devices. The bulk of the products will be ECL due to interfacing and access time requirements. Products will range from sub-five nanosecond 128-bit memories to sub-twenty-five nanosecond 4K bit memories. Cell sizes will be relatively large ($120f^2$) because of scaling difficulties and complex cell designs. Wafer size will be four inches. Device development will be concentrated towards reduction of parasitics (i.e., passive isolation) and increased gain band-width product of the transistors.

In summary, Bipolar static RAMs will move to higher speeds, MOS static RAMs will fill the speed range presently served by Bipolar RAMs (at lower cost and higher density), MOS Dynamic RAMs will be denser and lower in cost per bit, and CCD's will extend the range of semiconductor memories in the direction of longer access time and lower cost per bit. (Figure 4) The investments in terms of talent and capital will be large for the manufacturers able to stay in the competition.

Grateful acknowledgment goes to Thomas Klein for his analysis of Batch Density relationships.

Bubbles and CCD memories—Solid state mass storage

by J. EGIL JULIUSSEN
Texas Instruments Incorporated
Dallas, Texas

INTRODUCTION

In the last year significant technical advances have taken place in the development of magnetic bubble memories (MBM) and charge coupled devices (CCD). The first bubble memory chip has been introduced with bigger and better chips under development. Although 16K bit CCD chips have been available for two years, it is the recently announced 64K bit chips which will make an impact on computer system designs. The first commercial products based on MBM and CCD chips are now starting to appear.

With this progress it is worthwhile to look at the status of CCD and bubble memories, their applications and future potential.

MBM AND CCD STATUS

Both CCD and bubble memories are integrated circuit analogs to rotating electromechanical memories such as disks and tapes. CCDs store information in rows of capacitors. Bubbles and electromechanical memories store information as rows of magnets. The access methods are different. Electromechanical memories move the media while the magnetized regions remain stationary. In CCD and bubble memories the opposite takes place: the media remains stationary while the information, charge or magnets, move within the media. This avoids all mechanical motion and its associated drawbacks. The result is two solid state mass storage technologies—or electronic disks. For further information on the technical aspects of MBM and CCDs see References 1-10.

The features of MBM and CCDs are shown in Table I. Both technologies are serial access memories and are organized as shift registers. Bubble memories are nonvolatile as the information is retained without power. The electrical analogy of the magnetic bubble, the CCD, does not keep its charge or information as the power is turned off. CCDs are volatile and must be periodically refreshed to retain the information.

Both technologies have the modularity advantages arising from their chip packaging. The resulting low entry price is very important for small systems. As chips they can also be packaged directly with the CPU on PC boards.

The characteristics of today's major CCD and bubble memory components are shown in Table II. The 92K bit MBM chip has an average access time of 4 milliseconds and has a transfer rate of 50K bits per second. The dual-in-line package is larger than most ICs. The MBM package includes two permanent magnets giving non-volatility and two coil windings. The two coils produce a rotating magnetic field which moves the bubbles around the shift registers.

MBM support chips are already available. A minimum bubble memory system which is interfaced to a microprocessor can be made with 7 chips. The coil drivers produce the rotating magnetic fields. The sense amplifier detects the bubble information and is very similar to a core memory sense amplifier. The function timer and driver produce the necessary timing signals to control the operation of bubble memory chips. The controller chip is a LSI device which controls the memory system operations, buffers data and handles interfacing with a microprocessor.

The 64K bit CCD chips have a superior access time over bubble memories. The TI[9] and Fairchild devices have a 410 microsecond average access time and can transfer data at 1 to 5 Mbits per second rate. The Intel device has more shift registers with shorter length that gives better access time, but at a lower transfer rate. During operation the CCD chips use less power than bubble memory chips. The power advantage is reversed to MBMs in a standby mode.

None of the CCD products have any support chips. It should be noted that CCDs do not need an external sense amplifier. This function and the refresh function have been integrated onto the chip (one per shift register).

An assessment of MBM and CCD merits are shown in Table III. The main advantages of bubble memories are the nonvolatility and the large number of bits per chip. In effect MBM is the only solid state technology which is nonvolatile. The major advantages of CCDs are the low access time and the high transfer rate.

Bubble memories have an advantage over CCD from fewer manufacturing steps and fewer masking steps. This is also reflected in a potential higher MBM packaging density. However, the experience from MOS manufacturing is very applicable to CCD production and probably outweighs the

MBM advantage today. As bubble memory producers gain experience, it will be interesting to see if the potential MBM manufacturing advantages can be realized.

In packaging CCDs have an advantage due to the added complexity of the coils and magnets for a MBM chip.

In interfacing complexity MBM currently has an advantage from the availability of support chips. The low transfer rate and these support chips are very advantageous for microprocessor based systems. The high performance requirements of mainframe and supermini computers give CCDs a distinct interfacing advantage for these applications.

The bottom line is price. In the next few years, CCD will probably have an advantage due to MOS manufacturing experience and CCD availability from three or more manufacturers. With increased bubble memory manufacturing experience, MBM should close this gap and have an excellent chance of gaining an advantage over CCDs.

Table IV shows the announced MBM and CCD products the author is aware of. There are undoubtedly more products under development.

The three first MBM products use TI's 92K bit bubble memory chip. The TI 763/765 portable bubble memory terminals are part of TI's Silent 700®* series of terminals. Both terminals have a minimum of 20K bytes of bubble memory with optional expansion to 80K bytes.[11]

Q1 corporation has a microcomputer system with 80K bytes of bubble memory and also has a plasma display. Data Systems MBM system is a floppy disk replacement which is PDP-8 and PDP-11 plug compatible. Storage capacities of 86-519 Kbytes are available.

AT&T's 13A announcement system uses 68K bit bubble memory chips developed by Bell Laboratories and manufactured by Western Electric. The system stores pre-recorded messages which are repeatedly played back as telephone system messages. The system is being field tested by AT&T.[12]

The three CCD systems use Intel's 16K bit CCD chips. Intel's CCD board is an OEM product that can be used to develop end user systems. Technical Analysis Corporation has developed a fixed head disk replacement for their Nova based small business computer.[13] Alpha Data also has a

fixed head disk replacement which is compatible with their other fixed head disk products.

There are many products in the development stage which use the newer 64K bit CCDs, but none are announced yet.

To summarize the status of CCD and bubble memories a list of the companies with known R&D efforts are shown in Table V. As could be expected the major semiconductor manufacturers appear on the CCD list. Until recently only TI of the semiconductors producers had bubble memory effort. In the last year both Intel and National have started bubble memory efforts.

MEMORY SYSTEM TRENDS

It has been the goal for computer systems to have a single memory technology that has both the lowest cost and the highest performance. This goal has not been realized and the memory hierarchy from fast semiconductor RAMs to low cost disks and tapes must be used. The well-known memory hierarchy gap in access time and cost has provided a market pull for new memory technologies. In the early seventies this was the major driving force to develop CCD and bubble memories.

Additional market pull forces are now equally important. The proliferation of microprocessor applications are demanding small, non-volatile mass memory systems. Severe environments and the high maintenance costs need improved reliability. The popularity of virtual memory operating systems need some real and high performance mass memory.

The trend towards using fixed heads in combination with moving head disks is one solution that gives higher performance mass storage. However, there is still a large percentage of computer systems that are disk-bound.

MBM and CCDs are not removable storage technologies and this is a drawback vis-a-vis disks and tapes. There is a trend towards using non-removable disks. This lowers the disk drive cost and also improves reliability. The trend is also advantageous for both MBM and CCDs as both technologies can replace the function of non-removable disks. At the same time, the use of distributed processing systems

TABLE III.—MBM Versus CCD

	MBM	CCD
MAJOR ADVANTAGES	NONVOLATILE BITS/CHIP	ACCESS TIME TRANSFER RATE
MANUFACTURING	FEW STEPS FEW MASK LEVELS	EXPERIENCE FROM MOS MANUFACTURING
PACKING DENSITY	ADVANTAGE DUE TO MASK LEVELS

INTERFACING	ADVANTAGE FOR MICROPROCESSORS	ADVANTAGE FOR MAINFRAMES
PRICE	ADVANTAGE BASED ON PACKING DENSITY	ADVANTAGE FROM MOS MANUFACTURING EXPERIENCE

also lowers the need for removability. The data communication links in many cases are a substitute for removability.

To indicate how MBM and CCDs compare with other storage technologies, the system prices for end users are shown as a function of storage capacities in Figure 1. For small storage capacities MBM and CCDs have cost and physical size advantages. As soon as a few megabits are needed, the disks have a price advantage, but MBM and CCDs retain their performance edge. It is expected that MBM and CCDs, in the future, will be price competitive at higher and higher storage capacities.

MBM AND CCD APPLICATIONS

To gain insight in the use of CCD and bubble memories Table VI shows the various storage peripheral product categories for mainframe, mini and microcomputers. MBM and CCDs are not fast enough to be used as main memory, and are too costly to be used for removable mass storage. As fast auxiliary memory (FAM) both MBM and CCDs have excellent credentials. This is the product category which fills the memory hierarchy gap. In the non-removable mass storage category, MBM and CCDs are very viable, but will see strong competition from disks.

Due to their packaging flexibility, MBM and CCDs add an extra dimension to mass storage applications. They can be packaged directly with the processor and become an integral mass storage device. No extra box is needed as is

TABLE IV.—Announced MBM and CCD Products

MBM

- TEXAS INSTRUMENTS
  - TI 763/765 PORTABLE BUBBLE MEMORY TERMINAL

  - 128K TO 1 MBYTES CCD

usually the case with disks and tapes. Instead the MBM or CCD can be put on the same or different PC board as the processor. The TI 763/765 portable bubble memory terminal is an excellent example of this advantage.

The most likely CCD and bubble memory applications are shown in Table VII. The main bubble memory applications are in small systems. The bubble memory characteristics fit microperipherals and integral mass storage applications very well. In the miniperipheral category, MBM add-in or add-on electronic disks are viable opportunities. Add-in refers to MBM packaged with the CPU, while add-on means a separate box. In essence MBM is a main candidate for distributed mass storage to go along with distributed processing.

The main CCD applications are in closing the memory hierarchy gap. These opportunities are mostly in the large computer market place. In other words, CCD will be the technology which makes virtual memory systems become real.

With MBM and CCDs having similar features, will they compete head-on for the same applications? To answer this question, Table VIII shows the probable MBM and CCD usage.

The high performance characteristics will favor CCDs in mainframe computer applications. CCDs for fixed head disk replacement have already seen usage. Virtual memory and moving head disk cache memory based on CCDs are probably in development.

The nonvolatility and support circuit availability of bubble memories will favor MBMs as integral mass storage for microprocessor based systems. The announced MBM products fall in this category, and more are in the development stage.

The effect is that MBM and CCDs will have little direct application competition.

In summary, the usage of MBM and CCDs will evolve as follows: In 1977 many system designers gained familiarity with the two technologies. In 1978 CCD and bubble memories are designed into many products. In 1979 numerous products with MBM and CCDs will be in production. In the 1980's both MBM and CCDs will have become important storage technologies.

WHAT'S AHEAD IN CCD AND MBMs

CCD and bubble memories will follow the rapid increase in storage capacities and with the resulting decrease in cost per bit which is the characteristic of semiconductor technologies. Every two to three years the storage capacity of semiconductor chips quadruple and similar price per bit reductions take place. Both MBM and CCD chips will improve in this manner. In the beginning new storage technologies improve even faster and CCD and MBMs are likely to do so.

An overview of solid state memory trends is shown in Figure 2.[14] It shows that a 256K bit bubble chip can be expected in a year with a 256K bit CCD chip following a year later. By 1980 a 1 Mbit bubble memory chip is forecasted with the 1 Mbit CCD chip following a year later.

In terms of performance, CCD chips will still have an edge in access time and transfer rate over bubble memories. Both technologies will have higher transfer rates than today. The access time will be a trade-off parameter. To make larger chips will require longer shift registers. This would result in longer access time, unless a faster shift rate is used. It appears that for both MBM and CCD's the increased shift rate will just keep up with the longer shift registers. The result is that the access time of MBM and CCDs will be about the same as they are now.

But how will MBM and CCDs stack up against disks? The moving head disk technology has had impressive advances in the last 15 years, and will probably keep on improving

for another five to ten years. The disk advances have been realized by packing an increasing number of bits in the same area. The result is that large multi-platter disks that stored 2M bytes in the early 1960's now store 300M bytes, and cost about the same. Simultaneously lower priced units have been developed. The cartridge or single platter disk appeared in the late 1960's and now stores about 100M bits. The floppy disk was introduced in the early 1970's and just 2 years ago the minifloppy disk was introduced.

Impressive as these improvements are, the CCD and bubble memories will become increasingly competitive with disks. The disk technology is vulnerable because its bit price is very dependent on the storage capacity. The bit price of a minifloppy is about 50 times higher than the bit price of large disks. By 1980-81 a single MBM or CCD chip will store more than today's minifloppy disk. The single unit OEM price of the minifloppy is about $350 today and may decrease another $100 in the next couple of years. This will be no match for the learning curve pricing of MBM and CCDs. An analogy of what is likely to happen is the microprocessor price which has decreased from several hundred dollars to less than ten in just three years.

In summary, it appears that CCD and bubble memory systems will be price competitive with floppy and cartridge disks by the early 1980's.

SUMMARY

For a new storage technology to succeed it must meet several requirements. The technology must have advantageous features and characteristics including competitive price/performance. Long term technology improvement potentials must exist. Significant R&D investment in the technology by many companies is crucial. There must, of course, be available markets. Equally important is an initial market entry niche.

Both CCD and bubble memories meet these requirements and should therefore succeed in becoming major storage technologies in the 1980's.

Programming and operating systems

Four very different aspects of the areas of programming languages and operating systems are represented in these sessions.

A unique session will be a report on the recent History of Programming Languages Conference. No single topic seems to generate as much varied and heated debate as the merits of a programming language. Since future generations learn of past events through historical documents, special care had to be taken in organizing a History of Programming Languages Conference to insure a balanced and fair treatment of the various topics. An attempt will be made to summarize the technical lessons learned.

The 1970's have seen increasing interest in secure computing systems. Both theoretical results and practical experience with our systems seem to be somewhat discouraging. Nonetheless, our intrepid designers keep trying. A report will be made which focuses on how close we are to achieving such systems.

There has been a flurry of recent work on cryptography which suggests that improved and economical ciphers are available. Different aspects of such work will be discussed. One is the NBS standard while another concerns the use of data dependent keys.

There will be a session of the status of COBOL which will discuss, among other things, the anticipated 1980 standard and also data base interfaces.

Issues in kernel design*

by GERALD J. POPEK and CHARLES S. KLINE
University of California at Los Angeles
Los Angeles, California

INTRODUCTION

As operating systems became larger and more complex, interest increased in segmenting that software in a rational fashion. With respect to operating systems, a number of efforts were made to develop a low level base that would provide basic system functions in a highly reliable way. On top of this skeletal software base, extensive operating system functions and user supports would be built. Early efforts in this direction, although significantly different in scale and goals, include IBM's virtual machine system CP-67,[1] Brinch-Hansen's RC-4000 nucleus,[2] and CAL-TSS.[3]

However, the greatest impetus to this activity grew recently out of the desire for secure operating systems—those that could assure that the access to data stored within was controlled and protected in an uncircumventible way. Efforts have been made by a number of groups to design and develop operating system bases that, in addition to providing necessary primitive functions, were wholly responsible for the security of the operating system, including whatever was built on top of that nucleus. Part of the goal of these efforts typically was to minimize the size and complexity of the resulting nucleus, in the well founded belief that to do so would greatly increase the likelihood that the resulting software would be correctly implemented. Desires to apply program verification methods to this software have heightened the importance of these minimization goals, since current verification methods are applicable only to modest sized, simply structured programs. Such a minimum size, security oriented operating system nucleus is typically called a "security kernel."[4]

It should be noted that these efforts have taken place in an environment where reliable security has become of increasing concern. No general purpose operating system of a more traditional design has successfully provided a satisfactory degree of assurance for those who are seriously concerned about control over their data. Known flaws are so numerous that it is generally recognized a highly systematic approach is required. Since it appears that kernel based architectures will make considerable strides in improving that situation, an understanding of their characteristics is useful.

* This research was supported by the Advanced Research Projects Agency of the Department of Defense under Contract MDA 903-77-C-0211.

There are several considerations that make a kernel based operating system architecture significantly different from a more traditional architecture developed without security as a major design criterion. Reliable security demands that the software upon which security depends be as small and simple as practical. As a result, functions included in operating system bases to enhance performance or increase the convenience of writing software above that base are not needed for security purposes and consequently not included in a kernel. Kernel designs would typically exclude that software despite potentially increased performance overhead or greater non-kernel software complexity. Naturally, the architecture is structured to avoid these costs as much as possible, and it appears that such penalties can generally be minimized.

Conversely, the kernel must contain all security related software if correct enforcement is not to depend on non-kernel software. Therefore, as a countering influence, functions are forced into the kernel that may have been omitted from an operating system base and implemented at an outer level. The body of this paper characterizes the architectural principles that lead to these changes. Examples of the relocation of system functions in an architecture are also given.

EFFECTS OF DESIGN CONSTRAINTS ON KERNEL ARCHITECTURES

While kernel architectures in general exhibit many common characteristics and differ substantially from traditional operating system architectures, they also differ significantly among themselves. The technical constraints concerning security policy, function, hardware and performance must be specified before it will be possible to develop appropriate kernel specifications. Each of these considerations is discussed in turn below.

Security policy

The amount of mechanism that must be included in a security kernel is greatly affected by the particular security policy (control discipline[5] or level of function[6]) that it is desired to enforce. For example, the support required for

isolation is considerably less than what is needed for general support of intimate controlled sharing with domain switches within an individual process.

Kernel architectures have been directed primarily at the goal of reliable "data security": assuring that it is possible for users only to access data to which they are specifically entitled. Issues such as confinement or denial of service have generally not been directly addressed, although care usually has been taken to minimize such problems. Clearly, the more sophisticated the security policy that it is desired to enforce, the more kernel mechanism will likely be needed.

Data security policies themselves may be subdivided on a number of criteria. What are the objects that are protected? An operating system kernel might support any one of the subsets of an extensive list of potential objects: processes, pages, segments, files, file subtrees, messages and/or message channels, records, fields, mini-disks, entire devices (tape drives, disk packs, terminals) or partitions of devices (blocks on a tape, windows on a crt terminal).

Next, what is the *object grain:* the size of the objects protected. Are processes the active objects, or can a procedure call within a process coincide with a domain change, as in Hydra.[7] Perhaps, in a system that supports a family tree of processes for a given user, the entire family is the active object, with no distinction made among processes. That is, all processes in the tree might be required to have the same access rights. This design was used in the TENEX operating system.

What are the rules governing the alteration of system data that records the security policy? That is, what is the *policy grain.* Is control over objects and groups of objects hierarchically distributed as in Multics,[8] or is it strictly centralized, as in the IBM operating systems. What is the precision with which one can specify access control decisions? Can a file be marked with the exact list of users to be given access, or can one only set the access mode as either public or private, to illustrate two extremes.

System functions

Apart from the question of the security policy supported by a kernel, a serious impact on the actual kernel design and implementation results from the functions and services to be supported by that kernel. Is it possible, for instance, to create and destroy objects of all types supported by the kernel, or do certain cases, such as mini-disks, have their allocation fixed at the time the kernel is assembled. To what degree is the number of objects of each type supported and protected by the kernel fully variable. How rich are the set of operators provided to access the kernel protected objects. Are sophisticated message synchronization primitives built, or is a simpler, less efficient facility provided, out of which user software must simulate the desired features.

Type extensibility is another aspect of system function. Is it possible for user programs to create new objects of new types and have these new objects protected in a fashion similar to previously existing objects. This type extensibility first appeared in programming languages, and subsequently in the CAL-TSS system.[3]

Another aspect of system functionality that invariably affects a security kernel concerns device support. For reasons discussed later, most hardware designs require, for security to be reliably enforced, that there be additional kernel software for each device type. Therefore, the more general hardware base to support, the larger and potentially more complex a kernel can result.

Another significant consideration affecting a security kernel is the convenience with which operating system software can be constructed on top of the primitives which are provided. If certain facilities are entirely absent, selected functions may be impossible to provide. The existing Unix kernel does not permit asynchronous I/O within a user process.[9] Other functions may be possible to build, but only in a relatively inconvenient way. The UCLA kernel[17] does not support the process hierarchies required by UNIX, although they can be built outside the kernel using inter-process communication facilities.

In general, one wishes as little functionality in the kernel as is sufficient. In applying this philosophy, one should examine the necessary functions and determine whether a different, smaller and simpler set would suffice. For example, extensive real time functions, synchronization facilities, and interprocess communication mechanisms may be desired. However, the base system might be carefully designed only to include a small set of well chosen I/O primitives, augmented by a signalling call and a mechanism by which a user process could mark itself uninterruptible for a short period. The extensive set of user desired functions might then be constructed in application code using the simple base facilities.

Hardware effects

The hardware base on which a kernel is built can significantly impact the resulting kernel, including its size, complexity, overall architecture, and details of implementation. The richness of the hardware base that must be supported will have considerable effect. A multiple processor system, in which more than one cpu executes kernel functions, may require support for processor coordination within the kernel that single processor systems do not. Certain types of I/O channels may need detailed cpu software support.

Typically, the accesses made by central processors are constrained by memory management units, protection keys, or other hardware support. That support has the characteristic that privileged cpu software can set the controls and then permit untrusted software to run with assurance that it is not possible for software to exceed those access rights recorded in the hardware controls. The hardware implemented control features associated with channel accesses to main memory and to secondary storage are typically much less convenient, or even non-existent. Channels on most machines use absolute addresses to access main memory, instead of having a virtual reference modified and controlled

by relocation hardware. Therefore, unless some other form of hardware enforced protection, such as IBM's storage keys, limit the channel's access, additional kernel software is required to check and perhaps modify the addresses used by the channel in performing I/O. This task can be quite complex and error prone, even on IBM hardware, as reported by Belady and Weissman.[10]

While in some existing machines, channels' main memory access is controlled by programmable hardware assists, it is even rarer also to find hardware support for control of access to the secondary storage connected to the channel. Therefore it is generally necessary for kernel software to check or modify the secondary storage addresses and relevant commands that compose channel programs. Certain machines such as the IBM 360/370 series have some limited hardware supported control over secondary storage access. There, changes in cylinder or track can be blocked for the duration of a channel program's execution. However, such facilities are generally insufficient for direct use by the kernel to protect pages, segments or file systems.

I/O is clearly one area where hardware characteristics considerably affect the security kernel, but it is not the only one. A simple example, the time of day clock, on many machines is located in a way so that only privileged software can read it, despite the fact that the time of day is not relevant to most definitions of data security. On the PDP-11, both the word size and cpu arithmetic are organized on a 16 bit basis. Absolute addresses are larger however. I/O device registers (each 16 bits) have the additional bits located in additional registers, sometimes with little commonality among devices where those bits are to be found. Sometimes carry from the 16-th to 17-th bit is implemented, sometimes not. As a result, special software for each device is typically needed to check address bounds. Additional kernel code is required that could have been eliminated with judicious hardware planning.

There are often a number of such hardware characteristics that considerably complicate the task of building a secure kernel, and that would not require significant changes to greatly diminish those difficulties. The previous examples were largely of this class. More dramatic changes to the hardware base could of course greatly contribute to reliable system security. Capability based architectures have considerable promise in that respect. Kernel designs such as those being pursued at UCLA particularly lend themselves to implementation in firmware. The attractive feature about many of these points is that their adoption should not necessarily imply significantly increased fabrication costs, and both the simplicity and reliability of software would be enhanced.

Performance

The last significant issues which affect the size and complexity of the kernel are performance constraints. Stringent performance requirements as expected make it difficult to develop a straightforward design and implementation. For example, while it may be possible for scheduling decisions to be made through a separate user process which is only interrogated by the kernel, the additional process switch overhead to invoke the scheduler for each expected user process switch may impose unacceptable delays. Expensive domain changing usually exerts pressures that lead to larger, more complex kernels, since one is tempted to integrate such functions as scheduling into kernel code.

The costly effects of this phenomenon are well illustrated by the Multics experience.[11] On its original GE 645 hardware base, ring crossings (domain changes) were quite expensive, since the existence of rings was simulated in software by a complete switch of segment tables and status at each ring crossing. As a result, performance pressures led the highly privileged ring zero to be composed of approximately 80,000 lines of PL/1 code, and a number of security errors. Subsequent research has shown that a majority of that code can be removed.[4]

Even if performance requirements do not alter the functional specifications of a kernel, complexity may be increased by the need to code certain functions in a highly efficient manner. It may be necessary to replace a simple sequential search by a more complex hashing algorithm that uses chaining in a overflow area for collision resolution, as just one example.

These issues of security policy, system function, hardware impact, and performance requirements all affect the size and complexity of a security kernel which can be built. Within any given set of such constraints, however, certain designs are far superior to others. The next section of this paper discusses kernel design principles that generally seem to apply to most of the likely sets of constraints.

PRINCIPLES OF KERNEL DESIGN

A number of design principles have been developed as guides to the design of secure systems, notably "least privilege" and "least common mechanism". See Saltzer[6] or Popek.[8] However, they are little help without explanation of their architectural effect, examples of their application, or discussions of their effect on such operating system problems as resource management or performance.

Here we first make several general observations regarding kernel designs and illustrate specific tradeoffs with examples from existing systems. Most of these observations and illustrations are concerned with the tasks of developing as small and simple a kernel as is practical, under the design constraints discussed earlier.

Overall system architecture

One of the first questions concerns the relationship of the kernel to the rest of the operating system. There are a number of possibilities. In both the Multics system and a Unix prototype under development at the Mitre Corporation, the kernel is essentially part of the user process, even

sharing the process address space in the Multics case. Kernel code and data are protected from user process software by a variety of mechanisms. Kernel tables are shared among all processes. Interrupts may occur at nearly any time, even while running kernel code. Typically, at that point the current process can be suspended and a process switch performed. Therefore kernel data and tables must be designed for parallel access and modification.

An alternate approach, examined at UCLA, more completely separates the kernel from all other software. As in the RC 4000 kernel, the UCLA security kernel is not part of any process. It is run in its own address space, and is better thought of as a hardware extension. That is, each software implemented primitive instruction provides some security relevant function, and runs from invocation to completion without interruption. Functionally it acts as one hardware instruction. Therefore, a process state that indicates running in a powerful mode is never saved or restored, and parallelism complexities are considerably reduced or eliminated. While such an approach may reduce kernel complexity, it requires care in the overall architecture if adequate functionality is to be obtained. The values of each of these approaches are discussed in more detail elsewhere.[12]

Resource pools

One of the most effective ways to reduce the size and complexity of an operating system kernel is to remove, as much as possible, all of the resource management functions for a particular type of resource and relegate those functions to distrusted code. The degree to which this goal can be attained, of course, will vary from system to system, and from one object type to another within a given system.

There are three significant aspects to resource handling in operating systems that are subject to removal from an operating system kernel and supportable by user software. They are type integrity, management policy, and naming. Each is discussed in turn below.

Type integrity

The most extreme action possible is to remove the entire resource as well as all of its supporting software from the base level of the system. As a result, the kernel does not provide protection for these resources as such. Any structure which is needed to insure the type integrity of the resource is the responsibility of the user software. The only protection enforced by the kernel is that provided for the kernel recognized object in which the user implemented resources are placed: segments, pages, disk blocks and the like.

What this strategy generally means is that a single common pool of resources, usually maintained for all processes by the operating system, has now been broken up into a number of smaller subpools, each managed independently. This approach is illustrated by the I/O buffer management in OS/360. Buffer integrity is not assured, since whatever pointer the user supplies in certain SVCs is used by the operating system so long as the indicated transfer involves that user's core.

The tradeoffs involved in pursuing this design are straightforward. By moving all of the resource handling out of a kernel, including the maintenance of the structure or type of the resource, the kernel is further simplified, sometimes considerably. The performance cost is clear from elementary queuing theory. Separate subpools are in general more poorly utilized than the same number of resources in a single common pool, because some subpools may contain idle resources while others are exhausted and unable to fulfill requests directed at them. Alternately, additional resources will be required to maintain the same level of service. A designer must decide what the cost of additional memory or other resources is, or how much delay in response can be tolerated in return for what is likely to be a more secure system.

There are many resources that an operating system typically manages that are not so obvious as I/O buffers. Name spaces are a good example. There are a number of cases where unique names are needed for convenience in communication, like socket numbers in the ARPA net, which are usually assigned and reclaimed by the operating system. However, they could be preallocated to various domains, with each domain expected to do its own management. A kernel, using lower level names, can assure that messages are properly delivered to the appropriate domains in the ARPA net example, but need not be concerned with management of sockets.[13]

Resource management

In those cases where it is not possible to completely exclude support of a resource type from the kernel, it may be possible to remove the management of the resource, but leave that portion of the software responsible for the integrity of the resource objects. That is, the mechanisms which actually operate on the resource are part of the kernel, but the policy software which decides which operations should be performed, and under what circumstances, is distrusted, and part of user processes. This approach, which leaves type integrity as a kernel responsibility but resource management relegated to user code, is essentially the distinction made by Wulf between mechanism and policy.[7]

A good example of the application of this approach occurs in the UCLA kernel architecture.[14] There, process scheduling as well as the management of main memory is the sole responsibility of one particular user level process, containing distrusted code. It issues kernel calls to switch processes, initiate page swaps, and so forth. While this scheduling process therefore can move around the objects that it has the responsibility to manage, it cannot examine any of their contents. This method supports usual functionality requirements and permits sophisticated scheduling, while it considerably simplifies the kernel. However, certain confinement problems are not solved, as discussed later.

Naming

As pointed out by Janson,[15] a considerable amount of code in an operating system is devoted to managing the names of resources, in addition to the management of the resources themselves. A resource may in fact be known by several names, at differing levels of abstraction. In addition to enforcing conventions such as uniqueness of names, the mapping of one name to another must also be done. An example of this mapping can be seen in the handling of segments in Multics. Character string names for segments are used by the file system software (and by users) to specify a segment (analogous to a file). Segment numbers, indexes into a "Known Segment Table," are used by running programs to refer to active segments. The Known Segment Table of that user contains the physical address of the page table for the corresponding segment. Thus there are three different name spaces used to refer to segment resources, and mappings among these spaces must be maintained correctly.

The more of this name management that can be removed from the kernel, the simpler the resulting kernel software. There are several ways to do so. One need not fully support in the kernel each of the name mapping levels. Several of them, including their mapping software, could be built as part of user domains. This approach generally amounts to partitioning the higher level name spaces, with separate partitions managed by separate processes. However, such a design requires care if controlled sharing is supported by the architecture. User software certainly needs to know the names maintained by other user software in order to coordinate references to shared objects. The coordination can be accomplished if each name maintenance package follows the same conventions, and messages are used to exchange relevant information.

Of course, it is true that in any system some conventions must be externally agreed upon, and some information externally exchanged between people, in order to get coordination started, even if it is only where (in what directory perhaps) to look to find relevant information. Here it is being suggested that much of this coordination and convention handling need not be part of the security enforcement of an operating system. The one potential limitation in this viewpoint, concerning so called Trojan horses, is discussed in a later section.

One should note that it is possible to move only a portion of the name support out of the kernel, too. One might partition the name space, allocating each partition to a different user process, and then have the kernel merely enforce that partition. Each user would do his own name management within a given partition. This view is similar to that of type integrity, discussed earlier, with the resource being the names, and the operations implemented in the kernel which operate on names being very limited.

DECOMPOSITION OF SECURE CODE

Up until this point we have maintained the fiction that the appropriate system architecture for highly reliable security placed all security relevant code in the core of the operating system, the kernel, running on the bare hardware. The rest of the system software is encapsulated within user processes, running under the control of the kernel, and making calls to it.

Trusted processes

However, this structure is not the best, as recognized by work at M.I.T.,[11] UCLA,[12] SRI,[16] as well as in specifications for the military network SATIN-IV. Rather, there are a number of security relevant functions that can profitably be moved out of the kernel and placed in so called "trusted processes". These processes architecturally are the same as user processes, except that the information they pass to the kernel is used by the kernel to take security relevant actions.

A good example of such a trusted process appears both in the Multics system at M.I.T. as well as in the UCLA Secure Unix development. One process has responsibility for handling free terminals, logging and authenticating users, and starting up the appropriate software for them. The Multics logger and the UCLA initiator both run as standard processes, except that the Multics ring zero software and the UCLA kernel both accept the authentication decision made by that process, and make security relevant decisions using that information.

Levels of kernels

One sometimes finds that the software composing these trusted processes can be segregated into security relevant and nonsecurity relevant parts. That is, the trusted processes can often themselves be structured so as to be composed of a kernel and other, distrusted software.

The degree to which this segregation is successful can be increased if a few redundant checks are made. For example one might build a sophisticated hashing algorithm with clever collision resolution for password checks, but after the appropriate entry in the hashing table has supposedly been found by distrusted code, the table index can be given to a trusted subroutine to make the actual check and pass information to the operating system kernel. In VM/370, channel program translation is followed by a security check of the resulting code.

The net result of this segregation is a system composed of levels of kernels. Each kernel depends, for its correct operation, only on the correctness of its own implementation, together with that of the lower level kernels that provide security relevant functions. In this way, the necessity that there be security relevant, trusted code at various levels in a large system is met, while at the same time the total amount of code upon which the overall system's security depends has been minimized. Note that this viewpoint differs markedly from that taken at SRI, in which it is argued that the entire operating system design and implementation should be certified or verified.[16]

A more powerful example of the utility of a second level kernel concerns name mapping and file systems. There, conditions occur under which the user needs to refer to

system supported objects by names that are from a different name space than that supported by the kernel. For example, as already mentioned, the kernel may maintain segment numbers, while the user will invariably wish to refer to those segments by character string names, especially when setting access control information, but perhaps also when stating which segment to read or modify. Because of these usage patterns, mapping between name spaces may be highly security relevant. File systems provide an important case of this problem. In the UCLA Unix system, file management is done by a user level process.[17] The kernel of that file manager is responsible for elementary directory management, and other distrusted software in the process can take care of positioning pointers within files, scheduling I/O operations and maintaining resource allocation limits. The directory management consists largely of mapping string names to disk block names supported by the kernel, handling allocation matters, and checking and maintaining protection data.

This multiple level kernel architecture can yield significant advantages in the design and implementation of the base level kernel. If applied in conjunction with other design principles discussed above, the base level kernel can become little more than an implementor of abstract types. It makes segments, processes, messages, and so forth out of hardware memory, status registers, and the like. For some systems, this simplification of the base level kernel may permit further improvement. It may be possible to implement each kernel call (including the interrupt handler, which is just a hardware forced call) as uninterruptible code, without losing any relevant performance characteristics. This design virtually eliminates any concern for parallelism in the security relevant code, and therefore enhances its reliability. If the kernel is simple enough, it is a candidate for implementation in microcode. A packet switch communications processor that hosts no user programming is an example of an application that might only require a kernel simple enough for such an implementation.

A final note on levels of kernels concerns the updating of the protection data used by trusted software to make access control decisions. If a user at a terminal is to have confidence in the security enforced by a system, he must be able to view and change the system's protection data in a highly reliable way. He needs a secure channel between his terminal and kernel code, without any distrusted software intervening, even to manage character handling. One easy method to implement that channel is to provide a simple facility by which the user can switch his terminal to a trusted process and back. In this way he need not be concerned with any software running in his own process(es). While this solution, unless extended, suffers from the inability to permit program generated changes in protection data, such actions do not seem to occur often in practice anyway, except as a way of compensating for some other lack in functionality or flexibility of the protection controls.

INTERNAL KERNEL ARCHITECTURE

Much of the discussion up to this point has concerned the architectural place of a kernel in the larger system architecture, and the effect of kernel goals on that structure. Naturally, the internal structure of a kernel is also important. In general, the task of constructing a reliable kernel is little different from that of developing other highly reliable software. However, there are considerations peculiar to this application which deserve mention, including hardware selection, parallelism, and the effect of finite resource limits on attempts to use abstract type methods for organizing kernel code.

Hardware selection

Since hardware is the zero-th level in a structured, layered software architecture, unnecessary complexity in that interface is as undesirable as complexities in the specification of any other layer in the software, for the usual, good reasons. Therefore, hardware selection requires care, as illustrated earlier. It is worth noting that since the kernel software has already been minimized, the hardware impact on what remains can be substantial. In the UCLA kernel for example, approximately 40 percent of the code is device drivers, much of which could be eliminated if address relocation applied to device transfers.

Parallelism

While there may be some argument over whether algorithms that are expressed as parallel computations or strictly sequential code are inherently easier to understand (to some degree it certainly depends on the algorithm), it seems rather clear that certification or verification of sequential code is presently less difficult. That is the reason for specifying physical or logical uninterruptibility in the software architecture. This goal is, of course, one that has been followed at higher levels in systems since the early days of multiprogramming.

Abstract type structures

The concept of using extended types (such as illustrated by Simula classes,[18] CLU clusters,[19] Alphard forms,[7] or Euclid modules[20]) to organize software is quite valuable. However, Janson[15] points out that most efforts to employ strict type extension methods in programming are done with the underlying assumption of unlimited quantities of resources available. In the internal structure of an operating system or its kernel, this assumption is invalid, of course. One of the most obvious cases where finite resource limits interact with system structure occurs in virtual memory systems, potentially resulting in a structural circularity. Main memory is finite, so system software is constructed to give the illusion of a larger address space by sensing page faults and performing necessary I/Os in a manner invisible to the process involved. However, one may well wish to run this virtual memory software as a process like other processes. Further, the process management software can benefit from being written with the assumption that a large,

virtual address space is available. With the obvious circular dependency in mind, it is not clear whether process types or virtual memory types should be the lower level, with the other built on top. Reed[21] outlines a method of defining multiple levels of types to break the cycle. Lower levels implement a small fixed number or amount of the resource, using small amounts of resources in so doing. Higher levels reimplement the resource in large numbers or amounts, by multiplexing the lower level ones. In medium sized systems such as UCLA Unix, such a multiple tiered structure is not necessary.

CONFINEMENT

The problem of constructing a system so that an arbitrary program can be run in a fashion that assures the program cannot leak any of the information that it contains, is in practice unsolved. While clearly solvable in principle,[22–24] no actual solutions have been designed or implemented for real systems.

Importance

Some have argued instead that confinement is not a serious issue in practical applications. While this viewpoint is clearly reasonable when taken in the context of the current absence of reliable data security, several experiments with the Multics system have illustrated how real the problem may be. It was found possible in principle to drive a user terminal through interprocess communication performed by modulation of paging behavior in one process and the sensing of that modulation by the other. In a separate experiment, a similar bandwidth was discovered through use of the directory system. One process repeatedly made and deleted entries in a directory. This action changed the size of that directory, a value recorded in its parent directory. A second process read the size of that parent directory. In this particular test, the first process was not supposed to be able to communicate to the second.[11]

These two examples are instructive, for they illustrate a timing dependent and timing independent channel, respectively, both involving resource management. The bandwidth is enough to be of concern both to the military (one job might be a "Trojan horse" running with top secret classification, and the other running unclassified) as well as to industry (consider disgruntled programmers).

From a practical point of view, virtually all the channels mentioned by Lampson[23] or illustrated above are related to the allocation or management of resources, and the changes in system data that occur as a result of resource allocation decisions.

Storage and timing channels

Millen et al.[24] partition these channels into storage channels and timing channels. Storage channels are those which permit the passing of information through direct modification and reading of cells in the computer memory. Timing channels are those which permit one user to vary the real time rate at which another receives service, to a degree that the second user can sense. As the examples earlier show, the bandwidth of both types of channels can be significant.

It appears, however, that all resource storage channels can be changed into timing channels, and, on a large system, the bandwidth of the timing channels can be severely limited. Further, it appears that these actions can be taken without losing the values of multiprogramming, which is the primary cause of the problem. Resource storage channels can in general be changed to timing dependent channels in the following way. First, it appears that all direct reads and writes of system storage, such as that illustrated by the Multics file system problem, can be blocked by proper definitions of domains and the association of status data in the appropriate domains. What remains are resource allocation requests and status notifications. The use of resource availability as a channel can then be prevented merely by blocking the process requesting the resource until it is available. To be practical, this replacement of resource status replies by delays should be accompanied by the use of some form of a deadlock detection or prevention algorithm to insure that the system operates efficiently. That code need not necessarily be implemented in a security relevant way, as shown by the discussion of scheduling below.

Some believe that the bandwidth of timing channels can be limited by the scheduling characteristics that can be introduced in a large system. However, the existence of a timing channel is in principle more difficult to identify than a storage channel, since in the latter case there are explicit cells which are being accessed, even if interpretively through system code. While one might argue that if a process has only virtual time available to it, the timing channels are blocked, this viewpoint is probably not practical, given how many real time devices (therefore, clocks) actually exist on real systems. Nevertheless, once the bandwidth is limited to an amount comparable to that expected external to the computer system, the problem has in effect been solved.

Timing independent scheduling channels

While the preceding paragraphs may suggest a general approach to confinement, considerable care in the system architecture and implementation is required, as illustrated below. Earlier it was pointed out that functions such as the scheduling policy for resource allocation could be done outside a kernel. With respect to confinement, however, this approach creates difficulties. A reasonable scheduler must receive considerable information if it is to perform effective optimization. Since it can transmit information by ordering the completion of user requests, there is a clear potential for covert communication whether or not the scheduler had been written to cooperate.

Storage channels can in large degree be blocked however if the scheduler is designed as an information sink. This action can be taken if each user is permitted to submit only one request at a time, and wait for its completion before submitting another. Device completion status can be re-

turned via the kernel. Studies have shown that, for a reasonable number of jobs on a multiprogramming system, these restrictions are generally not ones with significant impacts on performance.[10]

However, such restrictions do not prevent collusion among user processes from providing timing independent channels. That is, a group of cooperating, legally communicating processes may be able to communicate with another such group, with which they are not permitted, even in the face of a scheduler designed to be an information sink. Whether or not this is possible depends on scheduler characteristics. Whenever it is possible for one process, by its own resource utilization actions, to affect the *relative order* in which members of other groups of processes are served, communication is possible.

That is, let processes A and B be one group, X and Y the other. Inter-group communication is not to be permitted. (They may be Ford and G.M. programs). Suppose that A (or B) increases its cpu to I/O ratio so much that the system's adaptive scheduler stops favoring cpu bound processes and begins favoring I/O bound jobs. X is cpu bound, Y is I/O bound. The order in which X and Y are run was changed by A or B. X and Y can easily determine the relative order in which they are run since they can legally communicate. Thus the A,B group has sent one bit to the X,Y group. Clearly this mechanism serves as a basis for extended bi-directional communication.

Many of the interesting scheduling algorithms that are used in practice have the characteristic outlined above, and in fact those that don't seem to ignore precisely that kind of information concerning user behavior upon which meaningful optimization is based. However, not all useful algorithms permit collusion. Round robin does not. The simple, limited algorithm implemented in the new Mitre Unix kernel, in which each process can only set its own priority, and the kernel merely runs that user process with the highest priority, also blocks collusion.

If confinement is felt to be important, considerable auditing of resource management mechanisms and policy will be necessary to block or satisfactorily limit the bandwidth of these kinds of channels.

CONCLUSION

We have attempted to distill the knowledge gained from various security kernel research efforts into a form that will be useful in guiding others who wish to develop highly secure, reliable system bases. It is also hoped that these perspectives are applicable to other environments than operating systems, especially such higher level software projects as message systems and data management, where privacy considerations are especially sensitive.

ACKNOWLEDGMENTS

This paper would not have been written had it not been for Clark Weissman, who often asked one of the authors how one designed a kernel. We also wish to thank Evelyn Walton, who largely built the UCLA kernel, and all the members of the UCLA Security Research Group who participated in discussions that helped form and refine these ideas.

Computer system security evaluation

by PETER G. NEUMANN
SRI International
Menlo Park, California

INTRODUCTION

This paper considers the problem of attaining computer systems and applications programs that are both highly secure and highly reliable. It contrasts two current alternative approaches, one remedial, the other preventive. A remedial approach is outlined based on a classification of software security violations suggested by Bisbey, Carlstedt, and Hollingworth at ISI. This remedial analysis is then related to a preventive approach, illustrated here by the formal SRI Hierarchical Development Methodology. Evaluation of system security is then considered by combining concepts from the preventive and remedial approaches. This combination of techniques seems to have significant potential in the attainment and evaluation of computer system security. Illustrations are given for three types of systems, the first two being systems explicitly designed with security in mind, and the first of those being designed according to a formal methodology. The first system is the SRI design for a Provably Secure Operating System (PSOS), the second is Multics, and the third is UNIX. (The reader familiar with security may wish to skim the next two sections.)

BACKGROUND

Computer systems and applications are increasingly being called on to provide reliable security, although most existing commercial computer systems are incapable of supporting various security-critical applications. Until recently, the task of obtaining highly secure systems has typically been considered to be very difficult, and avoided on the grounds that good solutions would be very expensive. There has been little deep understanding of either how to develop secure systems and applications, or how to assess security; however, there have been efforts to detect insecurity. The interactions between security on the one hand and reliability and survivability on the other have also been largely ignored, as have the interactions with dynamic auditing of security. The term "system defensiveness" is used here to imply security, reliability, survivability, and the auditability of any events that might compromise these aspects of computer behavior.

Recently, the situation has been improving (e.g., see the survey in Shankar[1]). Two approaches to attaining better security are considered here, one basically remedial, the other basically preventive. The first approach involves assessing the security of computer systems (particularly existing ones) and attempting to patch around any security flaws thereby uncovered. A variety of techniques have been used to detect flaws that reduce security. These include searching code for certain patterns of program statements corresponding to classes of would-be security flaws (e.g., Bisbey[2]), as well as more traditional experimental penetration attempts (e.g., McPhee[3]). The second approach involves designing new systems that are intrinsically secure and whose security can in some way be convincingly established. This approach might rely on a suitable design methodology (e.g., Robinson et al.[4]), combining formal specifications (e.g., Parnas,[5] Robinson et al.[4]), suitable design structures, the use of suitable programming languages (e.g., see Löhr[6]), and supporting tools. Examples of such approaches that also support formal verification are found in Robinson et al.[4] and Good.[7]

With respect to the remedial approach, experience in attempting to penetrate allegedly secure systems leads to several observations. First, penetrators do not generally have to work very hard to find major security flaws in traditionally developed systems. Second, patches that attempt to remove such flaws are themselves often flawed. Third, this approach is intrinsically limited because attempts to characterize the still undetected security flaws are speculative, at best. In general, attempting to retrofit security into a basically insecure system is of limited effectiveness, and inevitably leaves much in doubt.

In the long run, use of the preventive approach is likely to be significantly more productive. This approach should proceed with security as a fundamental design goal from the outset. It may include explicit statements of requirements and formal specifications of the design. It should make use of a modern programming language, and might employ formal proofs of significant properties regarding system behavior, such as security (e.g., see Neumann et al.[8]). On the basis of recent research, it is now possible to assess the security of a precisely specified design, prior to implementation, and then subsequently to assess the security provided by the implementation.

The conclusions of Glaseman et al.[9] are extremely pessimistic, at least for the near future, with respect to obtaining quantitative assessments of the cost (risk) associated with various security violations. Similar conclusions are drawn

in the present writing, with regard to attaining meaningful measures of security in conventionally designed systems. However, there are some hopes for attaining secure systems. First, it is helpful to assess insecurity—although it is not very reassuring to know just that another security flaw has been found. Second, it is possible to consider relative measures of insecurity for different classes of would-be violators such as skilled system programmers, data processing supervisors, system operators, skilled users, and casual users. Some security flaws may provide threats only from users in certain of these classes. Knowledge of the would-be violators and the degree to which they are trusted is thus fundamental to any evaluation of risk. Third, there is some short-term hope in a combination of the remedial and preventive approaches in redesigning an existing system so that its security-relevant portions can be isolated into a small and cleanly defined collection of system programs (a "security kernel" plus a few trusted processes, jointly responsible for the security of the system). However, the effectiveness of this combination can be reduced by restrictions imposed on the required redesign, such as the need to maintain compatibility with the original (insecure) system interface. It also may confuse policy (e.g., security strategies) with mechanism (e.g., the protection mechanisms upon which the policy is implemented), potentially embedding high-level policy issues inflexibly into low-level mechanisms. In any case, it is felt that the preventive approach must be involved whenever new systems are to provide substantially more security than existing systems. In particular, the use of a formal development methodology for design and implementation can provide a powerful basis for intrinsic and quantitatively assessable security.

SYSTEM DEFENSES

Defensiveness is considered here as a generalized notion of security, and implies the nonexistence of inappropriate behavior—insofar as possible. For present purposes, defensiveness consists of related and partially overlapping components, namely security, reliability, availability (including recoverability), and auditability.

(1) *Security* as used here involves the protection of the system, its applications, and the shared resources from misuse. The context considered is purposely a broad one. It includes the notions of preventing unauthorized acquisition and unauthorized modification of information, that is, assuring "confidentiality" and "integrity," respectively. It is intended to cover both system security and user data security. [In usage by MITRE, viz., Biba[10] "(data) integrity" is a precise formal dual of multilevel "(data) security" (i.e., confidentiality), the former referring to the writing of data, the latter to the reading of data.] In usage here, security also includes the prevention of denial of service (maintaining the integrity of resources) and the prevention (where possible, or otherwise the limitation) of information leakage through clandestine channels (such as signalling through shared resources or through shared timing channels). (See Lampson,[11] Lipner,[12] Neumann et al.[8]) In certain applications the notion of security may refer to or include multilevel (e.g., military) security with levels such as TOP SECRET, SECRET, etc. (See Bell and LaPadula,[13] Feiertag et al.[14])

(2) *Reliability, Availability,* and *Recovery* involve (respectively) the correctness of system security (including data integrity) and other system functions; the maintenance of a secure running system; and the restoration of a secure running system following any error, accident, willful damage, or disaster that caused a loss of service or security.

(3) *Auditability* involves the monitoring of the continued existence of system security and reliability, including the detection of anomalous or potentially threatening behavior.

Continuous maintenance of security depends on appropriate system hardware and software, including concepts of fault-tolerant architecture and reliable software. It also depends on an appropriate operational environment. It requires global planning and management. The implications of an unreliable system on security are particularly insidious, and thus must be considered along with the more typical considerations of security.

It is a difficult task to assure dynamically the continuous absence of all would-be security violations, e.g., to audit misuse of an intrinsically insecure system. It seems much more fruitful to work on the design of better systems, and then to develop auditing procedures as an integral part of the design. (For example, auditing should obey security policies wherever possible.) However, once a breach of system defenses is discovered, it should be fixed as rapidly as possible. In the sense that the effects of a security violation may already have leaked out, it may not be possible to provide dynamic recovery in the strict sense. Thus auditing is important to help limit the propagation. Good design should anticipate the needs of both auditing and recovery, with auditing that strongly limits the propagation effects of detected violations and that simplifies recovery therefrom.

Given an existing system not designed to be secure, the elimination of potential threats becomes more and more difficult after the first few threats are removed. The process is time-consuming, frustrating, unpredictable, and ultimately limited by the knowledge that although fewer threats are being discovered, many more may still remain undiscovered. It is particularly perverse that the changes necessary to remove discovered threats may themselves lead to new violations, particularly in conventional systems.

Given an arbitrary system, it would be useful to have some assessment of the penetrability of the system. However, even the most innocent-looking flaw may in fact be a hole in the dike that leads to total inundation. In general, the risks from system violations can best be avoided by a combination of good design, good implementation, good operations, and good management, all done with defensiveness in mind. A combination of testing and penetration studies,

and possibly some formal verification is recommended, commensurate with the desired system requirements, the expected difficulty of penetration, and the cost of having violations. Formal verification for the most security-critical portions of the design and its implementation is expected to be cost-effective in the near future. Recent techniques for verifying design properties, independent of any implementations, are particularly promising.

The remainder of this paper is organized as follows. First, a categorization of various typical system violations is given, based on the work of Bisbey, Carlstedt, and Hollingworth at ISI. This provides the framework for a remedial analysis of any particular system. A collection of preventive criteria is then given whose presence in the design, implementation, evolution, and operation of new computer systems may result in systems that are far more defensive than the conventional systems available today.

It is felt that these categories of violations and criteria for defensiveness should be very useful for evaluating the development of new systems and applications, as well as existing ones. They are used here first for a consideration of the design of PSOS (a Provably Secure Operating System), intended to be demonstrably secure. Multics and UNIX are then considered as two (extreme) examples of existing systems. It is seen that a system developed according to the preventive criteria intrinsically avoids many of the flaws indicated by the remedial approach.

VIOLATIONS OF SYSTEM DEFENSES

Nielsen et al.[15] have analyzed over 300 cases of computer misuse (from the files of Donn Parker) and have identified seven types of violations to system defenses, including cases of disaster, accidents, hoaxes, threats and extortions. (Defensiveness is therein called "integrity.") However, system violations are involved in the preponderance of cases (e.g., undesired acquisition, modification, insertion, or destruction of data, along with various other forms of system penetration). Some of the cases involve undesired denial of service. The sophistication of leakage through clandestine channels was apparently unnecessary, given the ease of penetration by simpler means. Nevertheless, in deference to Murphy's Law ("If it can happen, it will"), all plausible violations should be anticipated, and covered by various safeguards whenever the threats are deemed significant.

Classes of system penetrations

Bisbey, Carlstedt, and Hollingworth at the USC Information Sciences Institute (ISI) have studied techniques for identifying potentially vulnerable sections of code, including some techniques that could be carried out automatically. In so doing, they identified 10 categories of system flaws, each capable of producing security violations.[2] These categories have evolved over the last few years, with each violation observed at ISI fitting into at least one of these categories. However, there is no pretense that these categories are either canonical or complete. (Although they were conceived primarily to be applicable to software, most of them are in fact also applicable to hardware.)

Two of the 10 ISI categories are closely related and have been lumped together here. For present purposes, the resulting nine topical categories are grouped into four generic groups of flaws. Each has both design and implementation aspects.

(A) improper protection (initialization and enforcement);
(B) improper validation;
(C) improper synchronization;
(D) improper choice of operation or operand.

The nine topical categories can be associated with these groups as follows.

PROTECTION (initialization and enforcement):
(1) improper choice of initial protection domain;
(2) improper isolation of implementation detail;
(3) improper change (e.g., a value or condition changing between its time of validation and its time of use);
(4) improper naming;
(5) improper (incomplete) deallocation or deletion;
VALIDATION:
(6) improper validation;
SEQUENCING:
(7) improper indivisibility;
(8) improper sequencing;
OPERATION CHOICE:
(9) improper operation or operand selection.

These categories are illustrated in Table I. They cover many different security violations, including undesired reading, writing, and deleting, undesired denial of service, and to some extent undesired leakage through clandestine information channels. For example, visibility of implementation detail (category 2) often leads to potential leakage channels. However, leakage channels also exist in systems that are otherwise secure, because of the natural visibility of elapsed time.

It is not claimed that the four generic categories are orthogonal. Nevertheless, they provide very useful typical cases. Within the first generic category ("improper protection"), the five topical categories exhibit considerable overlap. (Category 1 deals with initialization, while categories 2-5 provide paradigms of improper enforcement.) In fact, there exists a sequence of flaws that exhibits an ordering of (1)⇒(2)⇒(3)⇒(4)⇒(5), as follows. An incorrect choice of protection partition (1) can result in the inability to isolate the implementation of an abstraction from the use of that abstraction (2). Such inability can result in a value presented at the time of call (and expected subsequently to remain constant) being changed during execution (3). Such a flaw can result in a naming problem (4), in which two different paths to the (apparently) same data can give different results. Finally, a naming problem may create a residue problem (5), e.g., if a local symbolic name is not unbound when the object is deleted with reference to its global name—or vice versa. (Since each category may reappear at different levels

TABLE I.—Categories of Protection Flaws (and examples) (Based on Bisbey, Carlstedt, Hollingworth at ISI)

1. Incorrect choice of protection domain or security partition
   (a security-critical function manipulating critical data directly accessible to the user; incorrect initial assignment of security or integrity level at system generation, configuration, or initialization)
2. Exposed representations or implementation detail
   (bypassing an abstraction, e.g., direct manipulation of a hidden data structure such as unmediated user modification of a directory entry; user use of an absolute I-O address; note that the visibility of timing information provides a generic leakage channel, e.g., drawing inferences from page fault activity)
3. Inconsistency of data over time
   (noninvariance of parameters, e.g., change in value of a parameter in a call by reference; change in a file accessible to different processes, e.g., in an improperly protected, shared process directory)
4. Naming problems
   (aliasing, e.g., two distinct names for the same object not being treated identically; ambiguity resulting from use of the same local name for two distinct objects [which may also involve a residue problem, e.g., if name persists in some system table])
5. Residues in allocation and deallocation
   (incomplete deletion, revocation, or deallocation, e.g., such that an apparently deleted value is still accessible—in core, disk, archive store, etc.; incomplete cleanup on abort; ignoring terminal hangup).
6. Nonvalidation of critical conditions and operands
   (invalid or unconstrained parameters such as an out-of-bounds virtual address or absolute I-O address; lack of strong type checking, e.g., a pointer to a structure of the wrong type; absence of quota limit stops such as bounds on queue sizes or number of processes, with overflows resulting in possible system or user crashes)
7. Indivisibility problems (in multiprogramming)
   (interrupted atomic operations, e.g., incomplete interrupt handling [quit during login resulting in partial success, or in perpetual lockup of interlocked data]; faulty read-alter-rewrite in hardware)
8. Serialization problems (in multiprogramming, multiprocessing)
   (incorrect sequencing [e.g., wrong order], improper isolation of atomic operations from one another [e.g., reading during writing, or concurrency among different directory commands on the same directory]; critical race conditions in implementation; deadlocks and deadly embraces)
9. Incorrect choice of operation or operand
   (use of the wrong function, producing incorrect results; use of an unfair scheduling algorithm, producing correct results for each scheduled process, but denying service completely to certain users)

in a hierarchical design, other such orderings may also exist.) Thus the most primitive descriptor of these protection flaws is something like "improper domain selection and enforcement."

There is some overlap between the two topical categories of sequencing flaws. The indivisibility and serialization categories, (7) and (8), respectively, are related when considered at different levels of abstraction, since (logically) atomic operations appearing at one level may in fact be implemented out of (logically) atomic operations at a lower level, with appropriate interlocks. That is, a serialization problem at one level may apparently manifest itself as an indivisibility problem at the next higher level.

Validation problems usually involve the omission of a check on argument validity or on quota limits. The inconsistency of data over time (category 3 above) might conceivably be viewed as a validation problem. (This is the time-of-check-to-time-of-use flaw, or "TOCTTOU," considered by McPhee, Weissman, and others.) However, this view is somewhat like locking the barn door after the horse has escaped: the primitive flaw is not a lack of validation, but rather the lack of either protection or interlocks that permitted the value to change in the first place.

Categories 3, 5, and 6 above have been the subject of experimental study at ISI, including the development of computer tools that search given programs for specific types of violations—notably interprocedure data dependencies, potential inconsistencies of data values over time, and potential residues. (See Bisbey et al.,[16,17] Carlstedt et al.,[18] Carlstedt,[19] and Hollingworth and Bisbey.[20]) However, the analysis of most categories is not generally amenable to systematic investigation.

It is useful here to identify some of the symptoms that may underly flaws of each particular category. Such an identification is attempted in Table II, in which are listed various conditions that can (but not always do) cause flaws in security.

DEFENSIVE SYSTEMS

In general, good design of the hardware and software and good implementation are highly important. In existing sys-

TABLE II.—Symptoms of Potential Protection Flaws, by Category

1. Domain choice. All programs or human actions relating to the initialization or interpretation of protection information are suspect, e.g., any setting or changing of a security level, particularly any action that lessens security (e.g., downgrading).
2. Exposed representations. Any direct visibility or use of implementation detail is suspect. Any use of absolute addresses for memory or input-output. Nonvirtual resources. Direct access to a data structure that is normally used as an abstract data object. Serial dependence within logically combinational functions.
3. Data inconsistency. A called procedure fetches the value of a parameter more than once, or fetches a value it just stored. A parameter is passed by name or by reference. (The value may change between call and return.) An output value is overlaid on top of an input value. Reference is made to a value that is self-modifying upon being accessed. (See Bisbey et al.,[16] Carlstedt et al.[18])
4. Naming. Any object for which two different names can exist is suspect. Use of a local name in one context, a global name in another, e.g., a virtual and a nonvirtual name. Any use of a table index where protection is expected.
5. Residues. Physical deletion of contents is suspect whenever deferred beyond logical deletion, e.g., deferred until reuse of media space. Readable free pools. Accessible backup storage. Reuse of an index or slot number after deletion of entry. (See Hollingworth and Bisbey,[20] which enables isolation of all allocations and deallocations, and searches for potential residues.)
6. Nonvalidation. The absence of any checks on protection information upon access to sharable data is usually indicative of a flaw. The absence of any checks on an input variable or parameter, on its type or value range, or even on the existence of data is suspect. Lack of quotas on real resources or on different virtual partitions of resource usage can provide a leakage channel across partitions. Validation of status at the time of a request for which status may change, without revalidation on completion. (See Carlstedt,[19] Bisbey et al.[17].)
7. Indivisibility. Any allegedly noninterruptible or indivisible operation is suspect, as is the mechanism for achieving indivisibility.
8. Serialization. Any overlapping of operations using the same data is suspect, either with different uses of the same operation, or simultaneous uses of different operations on the same data base.
9. Choice of operation or operand. This category is very hard to formalize. Potentially any operation can be improperly chosen. Operations and data types that do not correspond are suspect, as is the use of mismatched type declarations.

tems, it is usually bad design and bad implementation that lead to violations of system defenses. Thus, good design and good implementation should themselves be considered as (meta-)safeguards relating to software. The *a priori* use of good design practices and good implementation practices is in general enormously more effective than the *a posteriori* retrofitting of patches that attempt to strengthen the defenses.

Factors influencing development of defensive systems

The factors summarized in Table III are relevant to improving the defensiveness of a design and its implementation. Many of these factors have profound effects throughout the development process, involving requirements specifications, design, implementation, system maintenance, long-term evolution, and operation.

TABLE III.—Factors Influencing Defensiveness in Systems and Applications

Well-defined and well-understood requirements, established clearly and agreed upon in advance
Good design (e.g., modularly structured, especially hierarchically, with strict isolation of application programs and system programs, strongly typed operations, unified treatment of storage, input-output [e.g., mapped virtual access])
Suitable implementation languages (e.g., strong typing, avoidance of aliasing, constrained argument passing [such as use of call by value where data inconsistency may be a problem], hiding of implementation detail and device dependence wherever possible, clean control structures, encapsulation of data types)
Well-defined and understandable specifications for the system hardware and software
Structured implementation, reflecting the modularity of the design wherever appropriate, and structured initialization (e.g., hierarchical)
Systematic handling of exception conditions and quota limits
Auditing and recovery integrated into system design, e.g., hierarchical
Careful debugging, testing, verification
Good management of system development (e.g., respecting these factors)
Lessening the need for management as a result of simplifications resulting from use of these factors
Good management of system operation (e.g., rigid adherence to system generation and evolution protocols)
Nonreliance on secrecy of design and implementation
Awareness of the user community (e.g., enforcing the use of random pronounceable passwords rather than guessable ones)

Use of a formal development methodology for secure system development

As an indication of how systems can fare with respect to the presence or absence of potential security flaws, a system is considered here that has been conceived under rather unusual—and hopefully optimal—conditions. This system is PSOS, a Provably Secure Operating System.[8] PSOS has been designed from the outset to be able to support advanced security requirements beyond those of existing systems, and has taken advantage of essentially all of the above factors influencing good design and implementation. In particular, it has been designed according to formally stated requirements, has been formally specified, and has been subjected to formal proofs of its critical design properties. It is designed according to the SRI Hierarchical Design Methodology (HDM), described in Robinson et al.,[4] Neumann et al.,[8] and Robinson and Levitt.[21] The design is represented in a formal language, SPECIAL (A SPECIfication and Assertion Language, Roubine and Robinson.[22]). The system has not yet been implemented, but the nature of would-be implementations has been characterized. The design has been oriented toward provability of the design and of subsequent implementations. (HDM is also being used in the design and implementation of the SIFT computer system for an ultrareliable commercial aircraft application [for which proofs of elementary fault-tolerance properties have been undertaken], the design of a real-time operating system, the design of a family of related message processing systems, and the development of provable security kernels.)

PSOS is a capability-based system in which each capability acts as a protected name or token for an object. A capability for an object is protected, in that its creation and its transfer to other users or processes can be controlled, and once created, it can never be altered. It protects the object to which it refers, in that its presentation is required for that object to be accessed, including access rights appropriate to the operation being performed. (Certain PSOS applications take advantage of store-limited capabilities, which cannot be transferred out of the containing process.)

If formal verification of the design or its implementation is desired, then the following also contribute, both separately and collectively:

Formally stated requirements
Formally specified design, including specifications of modules and their interrelationships (e.g., data representations)
Formal proofs of correspondence between design specifications and requirements
Formal axiomatization of the programming language
Formal proofs of consistency of programs with design specifications
Formal axiomatization of the hardware/microcode
Formal proofs of consistency of hardware/microcode with hardware specifications

An entity analogous to a capability exists in SPECIAL, called a *designator*. A designator serves as a protected name of an object. Its uniqueness in SPECIAL is part of the specification language. In the implementation of PSOS, this uniqueness can be easily guaranteed by the use of capabilities. (Other solutions exist in other systems, such as descriptors.)

Table IV gives an indication of how the use of the methodology together with the use of a suitable programming language can overcome each of the nine categories of flaws summarized in Table II. It is seen that the use of SPECIAL has a very significant impact on the avoidance of these flaws in design. Most of the comments on the design specification in the table are generally applicable to any system specified in SPECIAL. Similarly, the use of the hierarchical design methodology has significant impact on the avoidance of these flaws in implementation.

The use of a suitable modern programming language can also contribute considerably. A language such as Euclid,[23] Modula,[24] Texas' Gypsy,[7] or SRI's HDM-compatible ILPL

TABLE IV.—The Influence of the SRI Methodology and Programming Languages (PL) on Avoiding Characteristic Flaws, both in General and in PSOS (P:)

Category of Flaw	Design (in SPECIAL)	Implementation
1. Domain choice	Design proofs.	Program proofs.
2. Exposed representations	Hidden by hierarchical levels of abstraction. P: Extended types further aid hiding.	PL encapsulation; proofs. P: Extended type mechanism.
3. Data inconsistency	None. No overwrite. Conceptual call by value only.	PL call by value; proofs. P: Argument values on stack unalterable.
4. Naming	Unique designators, nonbypassable, only means of naming. P: Capabilities unique.	PL no aliasing; proofs. P: Uniqueness and nonbypassability of capabilities aided by tagging.
5. Residues	None in specifications. Deallocated values become UNDEFINED, are thereafter unnamable. P: Residues protected.	PL dynamic object deletion and creation; proofs. P: nonreusable identifiers; contents zeroed if desirable on deallocation.
6. Argument and critical condition nonvalidation	Avoidable. Strong type checking, explicit subtypes, explicit exception and error conditions.	PL strong typing; compile or run-time checking. P: Extended types; I-O addresses mapped (via capabilities).
7. Indivisibility	Specifications for each function are logically indivisible.	PL synch primitives; proofs. Completion or no-effect exception provable.
8. Serialization	Sequencing invisible in specifications.	Benignness of overlap provable.
9. Operation choice	Faulty specifications detected by spec proofs. Type checking also helps.	Program proofs.

Many of the characteristic flaws can be avoided in design by the use of a methodology such as the SRI methodology, and in implementation by the use of a suitable programming language.
Note: "PL" refers to language features found in such languages as Euclid, ILPL, and the emerging DoD/1 languages. "P:" refers to PSOS. (See text.)

(due to Larry Robinson, and documented in Neumann et al.[8]) would be particularly helpful, as might the languages emerging from the DoD/1 effort. (ILPL is an extremely basic intermediate-level programming language that gains its simplicity from the power of the supporting methodology, whose formal specifications provide [for example] its data structures as a by-product of the hierarchical levels of abstraction.) Some of the major contributions that such languages can make are indicated generically by the "PL" entries in Table IV. In most cases these contributions result from intrinsic properties of the language. In other cases they may result from simply enforceable language restrictions. Note that not all of the above languages have all of the desired facilities. (At present, Euclid and ILPL [the latter taken together with HDM] are probably the most complete in this respect. Modula and Gypsy are currently being extended, and support for Gypsy and ILPL is currently being developed.)

Finally, for many of these flaws, relatively simple proofs are possible to demonstrate that the particular flaw is absent in various explicit forms. The design aspects result from properties of the specifications, e.g., they follow from proofs of consistency between the specifications and formal requirements, or are intrinsic to the methodology and the specification language. The implementation aspects result from proofs of program correctness, or are intrinsic to the use of the programming language. With this methodology, it is sufficient to show consistency between the programs and their specifications.[21] However, many proofs are possible without having to prove program correctness in general. Nevertheless, program proofs are becoming feasible as tools to support them continue to be developed.

The comments in Table IV are generically applicable to systems designed and implemented according to the methodology. In addition, those prefixed with a "P:" are particularized to the design and the would-be implementation of PSOS (e.g., in one of the above-mentioned languages). It is seen that a system designed according to a formal methodology like HDM is likely to avoid the characteristic flaws without much additional effort. In particular, PSOS has none of these flaws intrinsic to its design, and it is believed that an implementation essentially free of these flaws can be developed—and if desired, proved.

Above and beyond merely avoiding the nine characteristic problems, the use of HDM has a significant impact on the integrity of PSOS in other ways. These include the explicit statement of formal requirements for security, formal specifications for the design and its hierarchical structure, a unified design, a systematic approach to the handling of exception conditions and quota limits, and a structured implementation capable of taking advantage of the hierarchical design without losing much in efficiency. These factors contribute to the suitability of the design and implementation, and to the possibility of carrying out formal proofs, if desired. This additional impact is summarized in Table V.

Application of this evaluative approach to other systems

The evaluation of PSOS with respect to security flaws is clearly favorable. This is not surprising, in that PSOS was designed with security in mind from the outset, using the formal SRI methodology (which itself evolved simultaneously as a result of its application to PSOS). However, it is instructive to consider two other types of systems: the first which designed with security in mind, but without a formal methodology; the second designed with security only superficially in mind for its implementation. The examples taken are Multics and UNIX. (Conventional commercial operating systems are ignored here, as they are for the most

TABLE V.—Additional Influences of the SRI Methodology on the Integrity of PSOS

Formal requirements of security: basic principles concerning acquisition and modification of information, and a formal model for multilevel (military) security. These provide simple intuitively understandable design objectives.

Formal specifications of the design. These provide precise specifications for the system. Their consistency with the formal requirements can be formally proved. They provide the basis for implementation, as well as the basis for proofs of consistency of the implementation and the design. Proven specifications also provide a strong basis for compatible alternate implementations on the same or different hardware.

Hierarchical structure of the design. This encourages separation of policy and mechanism, and simplifies the initial implementation significantly. Recovery is done hierarchically, as is initialization. Recovery is therefore predictable and controllable. This increases the persistence of security during failure (partial or total).

Unified design. Auditing functions conform to the security requirements. Recovery functions are also integrated into the design and use standard functions. Hardware design is also integrated with software design. This increases the ability of the hardware to provide an appropriate basis for the software. [Use of a pronounceable password generator might be enforced to avoid guessable passwords.]

Systematic handling of exception conditions and quota limits. This increases the predictability of system behavior, and permits proofs of completion. Most information channels resulting from missing exception conditions in specifications can be detected and eliminated.

Implementation. To simplify the maintenance of security during system evolution, a highly compartmentalized implementation is very helpful. The hierarchical structure of the design can be retained in implementation wherever it is efficient to do so, and can otherwise be simplified without compromising the security of the system. The choice of implementation language would be constrained to support data abstraction, strong typing, exception conditions, etc. See Table IV.

Verifiability. Having followed the design methodology of using formal specifications for the user-visible functions, it is relatively simple to prove properties of the PSOS design or of an application environment, e.g., supporting multilevel security. Similarly, with the hierarchical design and formal specs for internal functions, program proving seems feasible, assuming an appropriate choice of programming language. The language features noted above all tend to improve verifiability.

part intrinsically insecure.) In essence, Multics is a large-scale general-purpose system with security superior to other commercial systems, with some emphasis on its being able to recover from outage, and some emphasis on audit. UNIX, on the other hand, makes little pretense of being secure, except for its attempts to provide access control and its encryption of the password file. It is fundamentally insecure.

Multics,[25] like PSOS, is a system that was innovatively designed (albeit in 1965) to take advantage of what was then known about advanced design and implementation techniques. UNIX[26] is a system that was developed at Bell Labs to take advantage of then recent operating system experience (e.g., Multics), on a much smaller scale—with judicious choice of simplifications intended to give high efficiency. However, UNIX was designed to be a system operating in a cooperative user environment, and was not conceived as a system providing any rugged sense of security. Nevertheless, it is a widely used and highly useful system. The discussion here is not intended in any way as a condemnation of UNIX as an insecure system, but rather as a simple illustration of how insecure a system can be in the absence of a pervasive concern for security from the outset.

Table VI presents a summary of how Multics and UNIX fare with respect to the nine characteristic problems. It is clear from the table that Multics is relatively secure. It is equally clear that UNIX is not. Table VII presents a comparison in terms of the methodological concepts of Table V.

After considerable improvement upon the implementation of a basically sound design, Multics has reached a level of significant security, and has become difficult to penetrate. Although it was subjected to various penetration efforts on its earlier hardware, and was indeed penetrated, the current hardware and software have long since removed the flaws permitting those penetrations.

UNIX has thus far apparently been used only in benign

TABLE VI.—Evaluation of Multics and UNIX with Respect to Characteristic Flaws

Category of Flaw	Multics	UNIX
1. Domain choice	Good. System, users in multiple rings. Ring 0 capture omnipotent, but unlikely. Outward migration of less critical functions. Provable layered security kernel designed by Honeywell, but not implemented.	Poor. Nonstratified. Capture of the entire system easy through superuser infiltration. Security kernel implementations exist (UCLA, MITRE), improving on original decomposition.
2. Exposed representation	Access within a ring all or nothing. Considerable hiding via ring mechanism.	Superuser easy to capture, defaults open. Trojan horses galore. Process temporaries readable and writable, main memory readable.
3. Data inconsistency	Argument pointer is copied onto stack by call. Arguments are copied within the system code to avoid this flaw internally.	Argument itself is copied, but only by convention. Process-temporary files are alterable in midcomputation by user or other users.
4. Naming	Collisions of local names: Trojan horse!	Default on directory entries: unprotected. Memory aliases (''/dev/mem''). Trojan horses abound.
5. Residues	Core zeroed only before reallocation, but is not virtually addressable after deallocation. Disk never zeroed, just overwritten. Residues after crash.	Core zeroed only before reallocation, and is until then still readable. Disk never zeroed, just overwritten. Residues after crash.
6. Nonvalidation	Hardware checking at ring and segment levels. All kernel args validated. Compile-time data-type checking.	Very few checks on resource or I-O bounds, interuser ops. Easy to crash.
7. Indivisibility	Locking makes kernel ops atomic. Exception handlers force no-effect noncompletion.	Exception handling bad.
8. Serialization	Locks prevent overlap. Lock hierarchy used to avoid deadlocks.	OK? System functions logically synchronous (until IPC installed).
9. Op choice	Possible problems?	Possible problems?

TABLE VII.—Evaluation of Multics and UNIX with Respect to Methodological Considerations

Influence	Multics	UNIX
Requirements	Informal	Informal
Specifications	Implementation laden	Implementation laden
Design structure	Implicit hierarchy	Procedural structure
Design	Fairly unified	Fairly clean
Exceptions,quotas	Fairly systematic	Poor
Implementation	Segmentation useful	Device independence OK
Programming language	PL/1 somewhat more helpful than C	C poor on abstraction, strong typing
Verifiability	Difficult because of size, PL/I, no specs	Pointless because of insecurity, C, no specs

environments, and is at present simple to penetrate. It appears that major renovation would be required to substantially improve its security (although a planned new release of UNIX is expected to eliminate a few of the problems).

From the methodological considerations of Table VII, Multics again appears to be better off than UNIX. However, from this vantage point, UNIX does not seem to be irreparably insecure. For example, a reimplementation with the imposition of constraints on C (or modifications to the language) and better handling of exceptions would be beneficial.

It is interesting to note that each of these three systems has been considered as a basis for supporting multilevel security. The PSOS design is augmented with a multilevel security policy manager that can be efficiently implemented on top of PSOS (or within it, if that is to be the only policy).[14] Multics and UNIX both have experimental redesigns retrofitting a kernel responsible for system security into the existing design. MIT, Honeywell, and the Air Force have undertaken the restructuring of the existing Multics system to improve (among other things) its security. As a component of that work, Honeywell has designed a Multics security kernel, for which formal requirements and formal specifications exist (using the SRI methodology). However, the funding for that project (Guardian) has expired before the kernel could be implemented. UCLA[27] and MITRE have independently designed and implemented prototype security kernels to be retrofitted into UNIX. These prototypes have provided the impetus for a competitive design effort between two groups (FORD-Aerospace and SRI as one group, TRW as the other), expected to result in a demonstrably secure kernel upon which is built a secure version of UNIX.

CONCLUSIONS

This document attempts to take a broad view of the development of secure systems, combining a remedial approach with a preventive approach. In particular, it characterizes various common flaws that can lead to security violations. It then uses this characterization to evaluate a constructive methodological approach to computer system development, and shows how such a methodology can intrinsically tend to avoid the characteristic flaws. This combination is thought to be useful for analyzing existing systems and for developing new systems.

Given a computer system whose design did not originally have security as a major goal, and which consequently may be flawed, it is in general extremely difficult to converge on a secure system by successively patching flaws as they are recognized. Nevertheless, the search for such flaws is desirable. In general, given a system that has evolved after extensive penetrate-and-patch efforts, or given a computer system that has been expressly designed to be secure, it is still a difficult matter to assess how secure the system really is. The evaluative approach presented here is felt to be useful. However, compatibly with this approach, recent advances in formal proof seem increasingly applicable. Such advances indicate the feasibility of proofs of the security of a design, given a suitable formal representation of the design and formal statements of security requirements. These proofs may be carried out prior to and independent of any particular implementation of that design. In addition, proofs of selected critical properties are feasible. Furthermore, the technology for handling proofs of consistency between design specifications and programs implementing those specifications is progressing well. Various semiautomatic computer tools for carrying out such proofs now exist and are being integrated. However, the approach outlined here is aimed at improving the resulting system dramatically, even if no program proofs are ever carried through.

A goal that emerges here is to be able to gain increasing confidence in the design and implementation throughout a system development, and to minimize reimplementation late in the development process by avoiding fundamental design flaws early in the process. The combination of approaches discussed here is seen to be relevant. A highly secure system can be attained, with a well-conceived design, careful implementation, selected formal proofs (particularly proofs of design properties), and the use of penetration efforts. However, it should be emphasized that a completely secure system is unlikely in any case, partly because of the intrinsic problems presented by leakage through timing channels.

PSOS is an example of a new system design whose stated goals from the beginning included support for advanced security requirements and provability. The experience gained in that and related efforts is used here to establish criteria that appear to be useful in helping to evaluate other efforts. For example, the ISI criteria and the methodological considerations clearly show some of the strengths of PSOS and Multics. It is hoped that this paper will lead to further refinements in security evaluation, and that it will be useful in evaluating other systems. It is also hoped that it will influence the subsequent development of secure computer systems.

ACKNOWLEDGMENTS

The writing of this paper has been supported by National Science Foundation Grant No. DCR 74-23774. The author is grateful to Richard Bisbey, Jim Carlstedt, and Dennis Hollingworth for sharing some of their experience, and to

Norman R. Nielsen and Brian Ruder for their helpful comments. The central person responsible for the SRI methodology (HDM) discussed here is Larry Robinson. He, as well as Rich Feiertag, Karl Levitt and Bob Boyer have made major contributions to the design of PSOS and to proofs of security. The author is indebted to the reader who has worked his way through the varied levels of discourse of this paper, from introductory verbosity to tabular terseness, recognizing that this paper may not have succeeded in trying to be meaningful to a wide range of readers.

History of programming languages

by JEAN E. SAMMET
IBM, Federal Systems Division
Cambridge, Massachusetts

This panel session will provide information on the planning, problems and results of a conference sponsored by ACM SIGPLAN held June 1-3, 1978, and entitled "History of Programming Languages". This conference is intended (1) to *initiate* the preservation of a historical record for some major current languages and to give impetus to others to continue adding to this record, and (2) to provide information from one or two key contributors to the early technical development of the selected languages.

Thirteen languages were selected for presentation and discussion at this conference, based on the characteristics that the languages (1) were created and in use by 1967, (2) are in use in 1977, and (3) have had considerable influence on the field of computing. The actual criteria for choosing the languages were: usage, influence on language design, overall impact on the environment, novelty, and uniqueness. This is not a conference on the entire history of programming languages, nor even a conference on the entire history of the selected languages; it covers primarily their early developments, with emphasis on the technical aspects of the language design. The languages selected are: ALGOL 60, APL, APT, BASIC, COBOL, FORTRAN, GPSS, JOSS, JOVIAL, LISP, PL/I, SIMULA, SNOBOL.

The organization of this conference was unusual in several ways. The invited speakers were assisted in preparing high quality papers by giving them about 13 pages of questions which applied to all languages, and which it was hoped would be answered in many of the papers. In addition to that, specific questions pertaining to individual languages were sent to each speaker. Examples of the general questions are "What languages were known to you when you started work on your language and what influence did they have?" and "What class of users was your language designed to help?" and "To what extent did concerns about compilation efficiency affect the design?" Examples of specific questions are "In COBOL why is there a COMPUTE verb allowing formulas, as well as ADD, SUBTRACT, MULTIPLY and DIVIDE verbs to do arithmetic" and "Why wasn't there any input/output included in ALGOL 60?"

The problems of having contemporary technical history written by people who were personally involved but are not trained historians are formidable. They include the difficulty of resisting the temptation to use *only* memory rather than written documents for some material, of avoiding insults to people still living and actively working, of making sure that proper credit is given to co-workers and in general the problem of handling delicate issues involving interpersonal conflicts.

The preprints of the papers are being produced as the August 1978 issue of ACM *SIGPLAN Notices*. Following the conference, a book is planned which will include these papers (which may be revised in the light of experience and comments on the presentation) and the commentary from the audience since the entire conference will be audiotaped for future listening by anyone.

COBOL—The 1980 standard, a preview

by GEORGE N. BAIRD, MARGARET M. COOK and ROGER J. GORG
Department of the Navy
Washington, DC

INTRODUCTION

It is quite reasonable to state that COBOL is the most widely used programming language in the world. Originally defined by the Conference on Data Systems Languages (CODASYL) in 1959, COBOL has received wide acceptance. One of the reasons for this is the standardization of the language which gives the user the anticipated ability of being able to transport COBOL programs from one computing system to another without a massive conversion effort. Other reasons for its acceptance are its easy to understand and English-like structure, its ease in being maintained, and its precise data definition which includes editing capabilities.

The standardization of COBOL was first accomplished in 1968[1] after a six year effort. The subsequent conversion from nonstandard COBOL to COBOL 68 resulted in language conversion programs being produced which aided users in converting to standard COBOL compilers that were not necessarily compatible with their predecessors. The advantage to the user in performing this conversion was to obtain COBOL application programs based upon a stable language specification which offered some guarantee that compilers (vendor's version of the COBOL language), would also have stability between releases.

COBOL 68 was revised in 1974.[2,3] This resulted in areas of incompatibility between the two standards. Some of the incompatibilities could not be avoided. They were the result of ill-defined language specifications having been included in COBOL 68 which were subsequently explicitly defined in COBOL 74 (e.g., the COBOL 68 Random Access module was replaced in COBOL 74 with the Relative I-O and Indexed I-O modules). The reason for other incompatible differences could not be as easily explained. The EXAMINE statement being replaced by the INSPECT statement is an example. The EXAMINE statement could have been enhanced to include all of the capabilities of the new INSPECT statement resulting in compatible programs between the two standards.

The technical committee responsible for the standardization of COBOL, American National Standards Committee (ANSC) X3J4, is in the process of preparing for the revision to COBOL 74. This paper presents a preview of what the revised COBOL standard might be. The earliest date that a new COBOL Standard could be developed and approved is the year 1980, so this paper will refer to the revision of X3.23-1974 as COBOL 80.

THE COBOL STANDARDIZATION PROCESS

COBOL is unique in that one organization, CODASYL, develops the COBOL language and another organization, the American National Standards Institute (ANSI), standardizes the language. This arrangement is beneficial in that two separate groups are involved with COBOL resulting in more immediate exposure than is afforded when a single committee is responsible for both the development and the standardization of a programming language. The negative aspect of the COBOL standardization process is that the language specifications for the revision to the COBOL standard must be already included in the existing standard or must be contained in the CODASYL COBOL Journal of Development (JOD)[4] as of a given date. Thus any new feature must first be approved by CODASYL before ANSI can include it as part of a COBOL standard.

The ANSI technical committee responsible for the standardization of COBOL, X3J4, is currently making preparations to produce the revision to COBOL 74. There are two opinions concerning this revision. One opinion is that the new COBOL standard should reflect the latest CODASYL specifications and that compatibility with the previous standard is not a primary consideration. The other viewpoint is that compatibility between versions of the COBOL standard is extremely important because of the investment in existing programs. There will be cases where compatibility may be sacrificed in order to attempt to keep up with all of the changes made in the CODASYL COBOL Journal of Development since COBOL 74, the previous standard, was produced.

When ANSC X3J4 is considering making changes to the COBOL standard during a revision process there is a specific set of selection criteria which is used in determining the acceptability of each change. The set of criteria is as follows:

(1) The general usefulness of an element or function in terms of:
   a. The degree of implementation;

b. Acceptance by users;
c. The degree to which a function was required.

(2) The overall functional capability of the language, considering such things as redundancy.
(3) The state-of-the-art technology with regard to implementing the language feature.
(4) The usefulness, in terms of application requirements, of language capabilities within each level of a module.
(5) Compatibility with other standards.
(6) The cost of implementing versus advantages of use.
(7) Overall language consistency within a defined level or module.
(8) Upward compatibility of levels within a module.

One must carefully examine each of these eight criteria and ask how the impact of any proposed change to the language is measurable in terms of quantity (dollars and cents), or whether it is measurable only in a qualitative sense (relatively good or bad). Vendors have a large investment in existing software products which include certain language elements and features that are extensions to the current standard. Users, however, have a larger investment in the programs they have produced using those compilers. The emphasis of the revision of a language standard should be for compatibility with the previous standard where possible.

AN ANALYSIS OF CODASYL COBOL SINCE 1972

The cutoff date of the CODASYL COBOL JOD for COBOL 74 was January 1, 1972. That was the latest dated document from which language elements were candidates for inclusion in COBOL 74. The cutoff date for COBOL 80 will be January 1, 1978. Roughly six years of development of COBOL as defined by CODASYL will have taken place between COBOL 74 and COBOL 80.

Since the input to the revised ANSI COBOL standard is limited to what is in the CODASYL COBOL JOD, the majority of the potential changes are already known and can be analyzed in terms of their impact if they are included in the revised COBOL standard. From a negative standpoint, language elements deleted from the COBOL JOD since the COBOL 74 cutoff date could influence the deletion of those elements from COBOL 80 as well. Therefore, within the scope of this paper, we can discuss language elements and capabilities which are either new, changed or deleted. The latter two categories will require program modification in order to produce programs conforming to COBOL 80 from programs which currently conform to COBOL 74.

New language elements which give additional capability

Many of the changes made to the CODASYL COBOL JOD have resulted in additional language capabilities. Some of these changes have relaxed punctuation rules while others have changed the category of some required reserved words to optional reserved words. Other changes are merely cosmetic in nature which could make program writing easier. These general changes will be discussed first.

General language changes

Source program punctuation has been clarified and simplified. The use of the semicolon, comma, and space can be used interchangeably in a source program. In COBOL 68 the semicolon and comma could be used interchangeably but only in certain places. This relaxation of the punctuation rules will permit the semicolon and comma to appear after any word or character-string contained in the source program. This should reduce syntax errors due to the misuse of the punctuation characters semicolon and comma.

The Environment Division which was a required division in a COBOL 74 program is now optional. The Configuration Section within the Environment Division is also optional when the Environment Division is present. This change was made primarily because of the new interprogram communication facility which is described later. However it will simplify the production of source programs by reducing the number of required lines of code which must be produced. The presence of an Environment Division in a called program which has no files in it is a waste of time and effort. If the Configuration Section is specified and the Source Computer and Object Computer paragraph headers are present, but the computer name has not been specified, then the compiler will insert the computer name in the appropriate place(s).

Another change which will reduce unintentional syntax errors in source programs permits user-defined words to be the same as system names supplied by the compiler writer. COBOL 74 prohibited these names from being identical. For reasons of portability and conversion this will reduce problems by requiring the compiler to accept user-defined names which are the same as system names. The compiler in this case uses the context in which the word is found to distinguish between a system name and a user-defined word.

The order of clauses within entries in the Environment and Data Divisions is very rigid in some places while other cases permit the clauses to appear in any order. The adopted changes to the SELECT statement and File Description entries will allow their subordinate clauses to be specified in any order. This will make programming easier and it is the clause ordering procedure which has been adopted for other areas in COBOL. The I-O Control paragraph in the Environment Division and the Communication Description entry in the Data Division now permit their subordinate clauses to appear in any order. Another case of inconsistency that has also been resolved regards words which are sometimes optional and other times required. The COBOL word "IS" is optional throughout COBOL 74 except for the Environment Division. This difference has been resolved by making the presence of the word "IS" optional in the Environment Division as well.

The COBOL character set, after having consisted of 51

characters for 18 years, has been expanded to 59 characters. The new characters are the commercial "@," question mark "?," colon ":," apostrophe "'," ampersand "&," percent "%," number sign "#," and exclamation point "!." The characters which can be used in alphanumeric literals include all of the characters in a given computer's character set. There is no guarantee that the characters outside the COBOL character set would be available on different systems. The addition of these eight characters in the COBOL character set means they will be available on all systems supporting COBOL and may preclude some reprogramming when moving programs and data around.

The sequence area (positions 1-6 of the COBOL source statement) is restricted to containing numeric characters in COBOL 74. The adopted changes will allow it to contain a combination of any characters in the computer's character set. There is no requirement that the source statements be in any sequence based on the sequence area and there is no requirement that the sequence area in any particular statement be unique within the source program. COBOL 74 specifies that nonnumeric literals cannot be longer than 120 characters. This restriction has been lifted in CODASYL COBOL with no upper limit. Presumably if the standard reflects this change it will contain a minimum length that must be supported.

An enhancement in the Data Division which will ease the coding of programs is the change which makes the word FILLER optional. COBOL 74 requires that data items which are not to be referenced directly in a COBOL program be present in such a way that they represent the data being ignored. The data area they represent uses the word FILLER in the place of a data name in the data description entry. The presence of the word FILLER in effect does nothing. Under the adopted changes FILLER will be an optional word so that data areas which must be defined, but will not be referenced directly, need not have either a data-name or the word FILLER specified in their data description entry.

A new technique by which data can be referenced in COBOL has been defined. Reference modification permits the programmer to reference a portion of a data item by naming the data item, by specifying a starting position within the data item, and by associating a length with that particular reference. The starting position and length can be specified through variables. By this method a character string of one or more characters can be easily located within a string of data.

COBOL 74 had a restriction that tables could only be three dimensions (i.e., arrays nested three deep). This restriction has been removed and the number of dimensions a table may have has no upper limit. The standard, if this change is adopted, will probably place an upper limit on the number of dimensions that a table may have.

One last inconsistency has been cleared up. This is in the area of character string continuation. All character strings can be continued in COBOL 74 except for the PICTURE character string. This inconsistency must have been brought about by an oversight during the maintenance of the language. Now at long last, a PICTURE character string can be continued.

The majority of the general changes merely makes the rules for the language consistent throughout COBOL. Other changes are for the programmer's convenience. The only changes which will really give additional capability are reference modification and tables with dimensions greater than three.

Nucleus module additions/enhancements

The Nucleus module is the functional processing module of the COBOL standard. A new capability in the JOD is the Boolean or Bit data item. The Bit data item allows the programmer to define a data item in terms of bits. It can represent one or more bits and is used to represent data which can have only two distinct values, 1 and 0.

The ACCEPT statement has been expanded to include the DAY-OF-WEEK as a conceptual data item from which information can be obtained. DAY-OF-WEEK is composed of a single data element that represents the day of the week. The values obtained from DAY-OF-WEEK are one through seven. One represents Monday, two represents Tuesday . . . seven represents Sunday.

The DISPLAY statement has been modified to provide a new capability for interacting with hardware devices for which positioning has meaning. When the new WITH NO ADVANCING phrase is specified, the hardware device will not be reset to the next line or changed in any way following the transmission of the last operand specified in that DISPLAY statement. If the WITH NO ADVANCING phrase is not specified, then after the last operand has been transmitted to the hardware device, the positioning of the device (e.g., cursor) will be reset to the leftmost position of the next line of the device.

The INSPECT statement has been enhanced in two major areas. A new format of the INSPECT statement contains the CONVERTING phrase. The CONVERTING phrase causes the INSPECT statement to work semantically like the TRANSFORM statement which is supported by many COBOL implementations but is not contained in either COBOL 74 or the COBOL JOD. The data item containing the data to be inspected is named. Two additional operands indicate the characters to be converted and what each character should be converted to.

```
INSPECT DATA-ITEM CONVERTING "AX2" TO
                             "M5B"
        DATA-ITEM (before) "1A2BWHYX"
        DATA-ITEM (after)  "1MBBWHY5"
```

This is a simple way to convert a number of characters in a string of data. COBOL 74 requires a series of "old character" BY "new-character" phases to accomplish the same thing.

A second enhancement to the INSPECT statement allows the inspection to be initiated and terminated within the string

of data being inspected. This is accomplished through the use of BEFORE and AFTER phrases.

```
INSPECT DATA-ITEM REPLACING 'X' BY 'Y'
  AFTER INITIAL 'A' BEFORE INITIAL 'Z'
  DATA-ITEM (before) X1A2X3Z4X5
  DATA-ITEM (after)  X1A2Y3Z4X5
```

Replacement begins after the first 'A' is located and terminates when the first 'Z' is encountered.

Note that the operation of the above example is data dependent. If the 'A' and 'Z' are not encountered in the proper sequence, different results would occur.

The MOVE statement has been modified so that numeric edited data can be moved to a numeric data item and the editing characters/symbols will be removed. This will help with data interchange among other systems and other languages. When the CORRESPONDING phrase is present in a MOVE statement, there can be more than one receiving group specified. COBOL 74 only permits one receiving group.

The PERFORM statement has been overhauled in an attempt to satisfy the syntactic and semantic needs of structured programming. These will be discussed under the general type of changes for structured programming. Other changes in the PERFORM statement parallel the changes to the definition of tables. COBOL 74 allows tables to be up to three dimensions. With the newly adopted changes no upper limit will be specified. The PERFORM statement in COBOL 74 can vary up to three indexes/identifiers, corresponding to the number of dimensions permitted with a table. The upper limit of three varying phrases has been removed, permitting an unspecified number of VARYING phrases. Presumably, there will be an upper limit in COBOL 80.

The SET statement, used strictly to modify indexes associated with tables in COBOL 74, has been expanded to include the ability to change the collating sequence used by the Program, the Sort/Merge process, or the Code-set for files during the execution of the program. It also permits the status of external switches to be changed and the value of conditional variables (88 levels) to be altered.

There are some interesting changes which have been made to the Nucleus module which will make programming easier in some respects. However, no change of any real impact has been accomplished.

Input-output module—Additions/enhancements

A technique for establishing a padding character for sequential files is available for inclusion in COBOL 80. COBOL 74 does not address padding characters, the problems of a short block, or a block that is not completely filled with valid data records. By including the PADDING CHARACTER IS clause in the Select statement for a file, the character specified will be used to fill out that portion of the block that exists beyond the last physical record. Another change is the RECORD DELIMITER IS phrase which can be used to specify an implementor defined technique for producing/identifying variable length records. In COBOL 74 determination of how to produce variable length records and subsequently recognizing them is left to an undefined implementor technique.

The ability to specify an optional file (one which may or may not be present at execution time) is permitted only for sequentially organized files in COBOL 74. This facility has been expanded to include files whose organization is either Relative or Indexed. OPEN. . .EXTEND will also be permitted for Relative and Indexed files. COBOL 74 permits the EXTEND option (which allows records to be added beyond the end of a file) to be specified only for sequentially organized files. Another enhancement to the OPEN statement affects the use of the I-O phrase. COBOL 74 permits the use of the I-O phrase only if a file already exists. This causes some confusion to programmers and it makes little or no sense as a restriction. The file could have been opened for output, one record written, the file closed, and then opened for I-O. Now the use of the I-O phrase can be used for a file that has not been previously created.

The RERUN statement has been modified. This statement is used to trigger a checkpoint dump to be taken during the execution of a program. The file to be used can be either an implementor named file or a file described in the COBOL program. COBOL 74 requires that if the file being used is described by the program that it be a sequentially organized file. The rules also have been changed so that a relative or indexed file can be used as well. The wisdom of using a relative or indexed file for storing checkpoints may be questionable but the capability now exists.

The MULTIPLE FILE TAPE clause found in the Input-Output Control paragraph has been clarified. In COBOL 74 there is a question regarding whether a File Description entry must be present in the program for files which are on the tape but are not going to be referenced. Under the adopted changes the introduction of a pseudo-file-name will be used to identify these files. The new facility also allows a multiple file tape to be contained on more than one reel or physical volume.

Variable length records will be requested using the new form of the RECORD clause in the File Description Entry for those files.

```
RECORD IS VARYING IN SIZE FROM SHORT-
  LENGTH TO LONG-LENGTH CHARACTERS
  DEPENDING ON LENGTH-INDICATOR
```

The minimum and maximum record lengths are specified in the RECORD VARYING clause. The DEPENDING ON phrase names the data item which will be used to define the length of the current record. This data item will be defined in the Working Storage or Linkage Section. Prior to the record being written, the length of the current record is placed in the Depending On data item by the programmer. This establishes the logical length of the record to be written. Later when the record is read, the input/output control system places the length of the record in the Depending On data item. Using this value the programmer then will know the size of the record just read.

The LABEL RECORDS clause has been made optional, whereas COBOL 74 requires the clause be present for each file described in the source program. When the LABEL RECORDS clause is not specified, the file will be treated as though the STANDARD option had been specified. Another change makes the words RECORD/RECORDS optional words in both the LABEL RECORDS and DATA RECORDS clauses.

The REEL/UNIT phrase can be used in a CLOSE statement for a sequentially organized file which is a report file (i.e., produced by the COBOL Report Writer). This is explicitly prohibited in COBOL 74. The usefulness of this function may be questioned since a report file is subsequently passed to the operating system for printing.

The DELETE statement has been modified so that a file can be referenced as well as a record within a file. When the FILE format of the DELETE statement is used, the referenced file is deleted and any associated storage medium is released and made available to the operating system. The file being deleted must not be a sequentially organized file. After the DELETE statement has been executed, the file is no longer available to the Input-Output Control System.

Somewhat related to the Input-Output modules is the Sort-Merge module. Only a few additions have been made. Both the SORT and MERGE statements can have multiple files named in the GIVING phrase. This permits two or more copies to be created of the file produced as a result of a SORT or MERGE operation. In addition, the GIVING phrase of a SORT or MERGE statement now may reference relative or indexed files. COBOL 74 requires that the giving file be a sequentially organized file.

The SORT statement has a new phrase, the WITH DUPLICATES IN SEQUENCE phrase, which will cause records whose keys are identical to remain in the sequence in which they are input to the sort process. The absence of this phrase, as in COBOL 74, leaves the task of sorting records with duplicate key-values to the implementor.

Inter-program communication module additions/ enhancements

One of the two major enhancements to CODASYL COBOL since the COBOL 74 cut-off date is the modification made to the interprogram communication facility (CALL statement). The impetus to make this modification was the recent emphasis on software engineering and structured programming. The other major enhancement to COBOL is the inclusion of the syntax and semantic forms necessary to be able to do structured programming in COBOL directly without having to simulate the major structured programming constructs. The structured programming aspect of COBOL will be addressed later.

COBOL 74 suffers in software engineering circles due to the structure of the language. Data within a given program is available throughout the program. There is no method by which data for a given set of procedures can be earmarked as being available only to those procedures. The JOD COBOL has been modified to provide a solution to these problems.

Source programs can be contained within other source programs. The contained source programs are referenced by the CALL statement. A program will always be in its initial state when called if the program is identified as being an INITIAL program. If a contained program is to be accessible to programs other than the program which contains it, its PROGRAM-ID statement must indicate that the program is COMMON. The END PROGRAM statement terminates a contained program.

```
IDENTIFICATION DIVISION
PROGRAM-ID.  PROG1.
  .
  .
  .
IDENTIFICATION DIVISION
PROGRAM-ID. PROG2 IS COMMON INITIAL
  PROGRAM
  .
  .
  .
END PROGRAM PROG2.
  .
  .
END PROGRAM PROG1.
```

PROG2 is a source program contained in PROG1. When PROG1 calls PROG2 parameters can be passed via the USING phrase of the CALL statement, as was the case in COBOL 74. Further, data in the contained program (PROG2) described as EXTERNAL can be referenced by the containing program and by any other program in the run unit. The data items in the referencing programs must be described in the same manner and using the same datanames and equivalent attributes as were used to define the data items in the called program. Names in the containing and contained programs that are identical, but not identified as being EXTERNAL in the contained program, reference unique items within each program. Data items in the containing program (PROG1) identified as GLOBAL can be referenced by the contained program (PROG2). The names of GLOBAL data items must not be duplicated in other programs referencing them.

There is also an additional option in the passing of parameters when using the CALL statement. If the BY CONTENT phrase is used in naming a parameter to be passed, then the called program can modify its version of the parameter but it has no effect on the value of the parameter in the calling program. If the BY REFERENCE phrase is used in naming parameters, the result is the same as it is in COBOL 74. Any changes to the data in the called program will affect the data in the calling program.

Structured programming enhancement/additions

COBOL 74 has, at best, co-existed with structured programming. The basic control structures are not available in COBOL 74 and have to be simulated using variations of the

PERFORM statement. Additionally, the number of places that asynchronous interrupts can occur in COBOL is well beyond what is suggested in structured programming.

IF-THEN-ELSE and Asynchronous interrupts

The problems associated with the COBOL 74 IF statement have been solved in the JOD COBOL. Pure nesting of the COBOL 74 IF statement was precluded because of the syntax of the language. The END-IF phrase has been introduced to make the IF statement more functional.

```
IF
  Condition
THEN
  statement-1
ELSE
  statement-2
END-IF
```

In COBOL 74 an IF statement is terminated by an ELSE phrase associated with an IF statement at a higher level or by the separator period. Using the JOD COBOL the END-IF phrase can be used to specifically terminate a nested IF statement.

The statements containing asynchronous interrupts have been handled in a similar fashion.

```
ADD identifier TO identifier
  ON SIZE ERROR imperative-1
  NOT ON SIZE ERROR imperative-2
END-ADD
```

Using the ADD statement as an example the ON SIZE ERROR phrase illustrates the true line path of the condition, whereas, the NOT ON SIZE ERROR phrase is the ELSE (or false) side of the condition. The END-ADD phrase terminates the ADD statement and its inter-related conditional statement. The END-verb phrase has also been included in all statements which can cause an asynchronous interrupt (i.e., statements containing the ON SIZE ERROR, AT END, ON EXCEPTION, INVALID KEY, ON OVERFLOW, WHEN, and NO DATA phrases.).

DO-WHILE and DO-UNTIL

The PERFORM statement in JOD COBOL has been expanded to include an inline looping capability.

```
PERFORM WITH TEST [BEFORE]
                  [AFTER ] ...
  .
  .
  .
Procedural Code
  .
  .
  .
END-PERFORM
```

By specifying the TEST BEFORE phrase, the procedural code will be executed as a DO-WHILE construct. If the TEST AFTER phrase is specified, then the procedural code will be executed as a DO-UNTIL construct.

The EVALUATE statment, which is much too complex for the scope of this paper, represents CODASYL's answer to the CASE construct in structured programming. The EVALUATE statement can also be used to express a decision table in a COBOL format.

Incompatible changes to/deletion of language elements

As the CODASYL COBOL specifications evolve changes are made to the existing syntax and semantic actions of language elements; and language elements are deleted. These changes, if reflected in COBOL 80, will require source programs to be modified in some cases quite extensively. The most drastic of the incompatible changes are itemized in the following paragraphs. Language elements which have been deleted from CODASYL COBOL are:

- The 77 level data item. The rationale for this deletion is that an elementary 01 level data item accomplishes the same thing.
- The ALTER statement. The value of using the ALTER statement has been questioned for some time due to the way in which it can obscure the logic of a program.
- Numeric Paragraph and Section names in the Procedure Division.
- The REVERSED phrase of the OPEN statement.
- Initial segments (Segmentation Module) 50-99.

The following language elements have been modified such that their inclusion in COBOL 80 will require source programs to be changed in order to continue to use the function.

- The BLOCK CONTAINS clause, and the CODE-SET clause have been removed from the File Description entry in the Data Division and placed in the SELECT statement of the Environment Division.
- The ACCESS MODE, RECORD KEY, ALTERNATE RECORD KEY and FILE STATUS clauses have been deleted from the SELECT statements in the Environment Division and placed in the File Description entry of the Data Division.
- The rules for the RECORD CONTAINS clause state that the absence of the clause will cause fixed length records to be written regardless of the record descriptions. COBOL 74 treated the RECORD CONTAINS clause as a comment and used the actual record descriptions to determine the length of records.
- SORT or MERGE files cannot be named in a RERUN statement to trigger a check point to be taken during the execution of a Sort or Merge operation. Also, a SORT or MERGE statement cannot be referenced in a USE FOR EXCEPTION statement in the DECLARATIVE portion of the program.
- For the INSPECT statement (remember the EXAMINE

statement), both TALLYING and REPLACING cannot be included in the same statement as was permitted in COBOL 74.

- The description of the DEBUG-ITEM associated with Debugging procedures has been changed.
- All files included on a multiple file tape must have the same labeling scheme, i.e., STANDARD or OMITTED. COBOL 74 has no such restrictions.
- The REDEFINES clause cannot be specified in the Data Description entry for an index data item.

The changes described in this section, with the exception of the deletion of the ALTER statement, are questionable. If all of these changes are reflected in COBOL 80, every COBOL program ever written would have to be modified to be acceptable to a COBOL 80 compiler. There is a possibility that X3J4 will allow a transition period for some of the incompatible changes; for example, the clauses that have been moved from the File Description entry to the SELECT statement in CODASYL COBOL will appear in both places in COBOL 80. Language elements in COBOL 80 will be annotated to indicate that they will be deleted when COBOL 80 is revised. This will give the COBOL user advanced warning about potential changes to COBOL which impact existing programs.

CONCLUSION

The revision cycle for developing COBOL 80 from COBOL 74 and the 1978 JOD is under way. It seems appropriate at this point to ask two basic questions. Based on the enhancements which can be included in COBOL 80, is the industry ready for a new COBOL standard? What would COBOL users gain by adoption of a new standard?

COBOL compilers based on COBOL 74 have only been available since late 1975 and early 1976, and some vendors had not released COBOL 74 compilers by the end of 1977. Most of the COBOL community has not yet undergone the conversion effort required for changing COBOL 68 programs to COBOL 74. After they have gone through this process, most will not be ready to accept another conversion effort five years later.

Once a revision cycle is started, it develops its own momentum, and the question of whether the user community is ready for a new standard may be lost. With the exception of reference modification, variable length records, and structured programming changes, there does not appear to be any enhancements justifying the program modifications which would be required, and the increase in size and cost of COBOL compilers. The COBOL community has the responsibility to communicate their views on these questions to the American National Standards Institute.

Data Base Facility for COBOL 80

by MARGARET M. COOK
Department of the Navy
Washington, DC

INTRODUCTION

The American National Standards Committee (ANSC) X3J4 is responsible for developing the standard for the programming language COBOL. ANSC X3J4 is currently in the process of revising American National Standard Programming Language COBOL, X3.23-1974.[1] As part of this revision process, X3J4 is developing a candidate Database module for inclusion in the next COBOL Standard. The earliest date that a new COBOL Standard could be developed and approved is the year 1980, so this paper will refer to the revision of X3.23-1974 as COBOL 80.

Direction for developing the COBOL Standard is given to X3J4 by its parent committee, ANSC X3, the ANSI technical committee responsible for Computers and Information Processing. According to X3 direction, the source of the language specifications for COBOL 80 must be either the current COBOL Standard or the CODASYL COBOL Journal of Development.[2] Thus the only possible candidate for standardization of a Data Manipulation Language (DML) for COBOL is the CODASYL database facility. X3J4 cannot consider any other database model, such as relational, for standardization.

In order to develop a candidate Database module for COBOL 80, X3J4 has established a Database Task Group, X3J42, which has the responsibility of reviewing the database facility specifications in the CODASYL COBOL Journal of Development (JOD) and identifying those elements which are to be included in the candidate Database module. The JOD cutoff date for COBOL 80 has been established as January 1, 1978. Database elements in the JOD as of the cutoff date are the source of the database specifications which can be included in COBOL 80.

This paper discusses the structures which can be defined according to the CODASYL database specifications and the language elements which are available for standardization. The standardization effort by X3J4, and hence its subcommittee X3J42, is limited to that portion of a Database Management System (DBMS) which pertains to the defining of a Sub-schema and the Data Manipulation Language statements proposed for the host language COBOL. The portions of a DBMS which are outside the purview of COBOL, such as the Data Definition Language and the Device Media Control Language, are not candidates for standardization by X3J4. However, the functions and structures of the Data Definition Language, because of their close relationship to the Sub-schema definition, are discussed in this paper.

OVERVIEW OF THE DATA BASE FACILITY

The portions of the CODASYL database facility which are of concern to X3J4 are the database functions which permit an application program written in COBOL to communicate with the Database Management System. The functions required are a definition of that portion of a data base of interest to an application program and the procedural statements required to access the database.

The entire database is defined in the Schema. The Schema contains a description of inter-record relationships and the data items comprising each record in the database. Because the Sub-schema definition is a subset of the Schema definition, understanding the Schema and its capabilities is a prerequisite for understanding the Sub-schema definition.

The COBOL Sub-schema defines the portion of the database available to an application program. The part of the database that is not required by a given application area is not defined in the Sub-schema. The Sub-schema definition is a subset of the Schema definition but can define data items in a different manner than the Schema, as long as the definition is consistent with the Schema.

The COBOL Data Manipulation Language statements for the database facility contain update functions for data items and record relationships, and record and item retrieval functions. The DML statements are contained in the Procedure Division of a COBOL program and can only reference records and record structures which have been defined in the Sub-schema referenced by the COBOL program.

The Schema, COBOL Sub-schema and Procedure Division DML statements combined provide a database facility through the host language COBOL. The succeeding sections of this paper discuss each of these components in detail.

THE SCHEMA DEFINITION

The logical definition of the database is provided by the Schema. The Schema defines the record types in the database, the inter-record relationships, and the access control

mechanisms. The specifications for the Schema definition are contained in the CODASYL Data Definition Language Journal of Development.[3]

Record definition

The basic unit of access in the CODASYL database facility is the record. Each record type in the database is defined in the Schema. The record definition specifies the data items and data aggregates which comprise records of a particular record type. The smallest unit of data is the data item. In data subentries within a record definition, complete descriptions are given for each data item in the record. Among the data characteristics specified are the data type, that is, arithmetic, character or bit string, system generated identifier (database key), or implementor-defined extension; validation values for checking accuracy of data item contents when storing items in the database, and access control locks for retrieving, storing, or modifying data items. A named collection of data items in a record type is called a data aggregate and permits the definition of vectors and repeating groups.

In addition to data items whose contents are supplied by the user, the definition of derived data items is also permitted in the CODASYL Schema. Derived data items are data items whose contents are generated by the DBMS according to specifications in the data subentry. There are two types of derived data items, actual and virtual. The DBMS generates the contents of an actual derived data item during a store or modify and the contents are stored as part of the record. A virtual derived data item is generated by the DBMS when a record is retrieved from the database. The item does not exist in the database but is available to a user program as if it were stored in the database.

Within the Schema definition an arbitrary number of record types may be defined, and there is a record description for each type of record in the database. For any given record type defined in the Schema, there may be none, one, or an arbitrary number of occurrences of records in the database.

Set definition

A Set is the basic structure by which inter-record relationships are defined in a CODASYL Schema. Unfortunately, the use of the word set is confusing to those familiar with set as a mathematical entity. The misuse of the letters "SET" according to Steele is "That linguistic atrocity perpetrated by the DBTG Report wherein the nineteenth, fifth, and twentieth letters of the Roman alphabet are used in that order as the name of a peculiar object. This may seem harsh, but the point at issue represents a prize example of the manner in which the information processing sciences generate confusion for themselves and others by casual misuse of words."[4]

A set type in the Schema is defined by a single owner record type and one or more member record types. A record type may be defined to be the member of more than one set type, and a member of one set type may be the owner of a different set type. The set type relationship permits the definition of network structures in the CODASYL database facility.

There are restrictions on the record relationships permitted in the Schema set definition. A record type cannot be defined as both owner and member of the same set type, and a set type may not have more than one owner record type. Thus the many-to-many owner-member relationship is not directly supported by the CODASYL structure.

Set membership

There are two classes of set membership defined for each record type. The first class concerns the insertion of records into a set, and the second class concerns the removal of records from a set. For the insertion of records the member record types can be either automatic or manual. If automatic membership is specified, membership in a set is established by the DBMS when a record is created in the database. If manual membership is specified, a Data Manipulation Language statement is required to connect an already existing record in the database to its owner record.

For the removal of records from a set, the member record types can be either mandatory or optional. If mandatory membership is specified, once a record is a member of a set it cannot be removed from membership in that set type. If optional membership is specified, a member record can be disconnected from a set of the given set type by the execution of a DML statement.

Set selection

The method for the selection of a specific set from the totality of sets in the database is specified in the set selection criteria. The identifiers are specified which are to be used in navigating from owner record to member record in a series of sets on a continuous path, where the member of a given set is the owner of the next set in the path. The values of the named data items are used to select a specific set in the database.

Set order

Each set type defined in the Schema must have an order specified for the member records of a set of the given set type. The member records may be ordered by ascending or descending keys. The keys can be data items, member record names, or system generated identifiers. The member records may also be ordered based upon the insertion order of new member records into the set, for example, first, last, or before another member record selected by an application program.

REALMS

In the Schema the database can be defined to be logically divided into realms (areas). A realm is similar to a COBOL file in that a Data Manipulation Language statement is required before a program can access records within a given realm. The record type definition specifies the realms in which the records of a particular type may appear. An individual record can be associated with only one realm, and a record may not change realms.

There may be an arbitrary number of realms defined in the Schema, and records can be assigned to realms independently of their inter-record relationships (set structure). An owner record and member records of a set may be contained in the same realm or in many different realms. Similarly, a given record type or set type may have occurrences which appear in the same realm or in many different realms.

COBOL SUB-SCHEMA DESCRIPTION

A COBOL Sub-schema definition specifies the data items, record types, set types and realms which can be accessed by a COBOL program. A COBOL Sub-schema contains an individual program's view of the database. Only those data items, records, sets, and realms described in a COBOL Sub-schema may be accessed in a COBOL program referencing that Sub-schema. The portions of a database beyond the scope of an individual program are not defined in the Sub-schema referenced by the COBOL program and are not accessible to the program.

There may be an arbitrary number of COBOL Sub-schemas described for the Schema, and definitions for different Sub-schemas may reference the same Schema entries. A COBOL program references only one Sub-schema, but an arbitrary number of programs may reference the same Sub-schema.

COBOL Sub-schema relationship to schema

A COBOL Sub-schema definition is a subset of the database description given by the Schema. A Sub-schema specifies the data items, records, sets and realms which can be referenced by a COBOL program. A Sub-schema cannot define new record types or set types, and all data defined in the Sub-schema must have been previously described in the Schema.

Important differences in the definitions for the Schema and COBOL Sub-schema are permitted in the CODASYL database facility. The Database Management System uses the Schema and COBOL Sub-schema definitions to perform the data conversion required for access by a COBOL program.

The Sub-schema references data items and records in the Schema by their names given in the Schema. The names for identical data items in the Sub-schema and Schema can differ if they are the subject of an Alias Description entry, in which case use of the Sub-schema names is equivalent to use of the Schema names. The COBOL program always references the data-names defined in the Sub-schema.

Only a portion of a Schema record need be defined in the Sub-schema record and the data items in the Sub-schema may be specified in a different order. The data mapping is performed by matching data-names and record-names to the data-names and record-names in the Schema. The mapping is performed at the elementary item level, and the data description in the Sub-schema is the description used by the COBOL program.

The characteristics of data items defined in the Sub-schema can differ from the Schema specifications as long as the results are consistent with the Schema definition. Data transformation of equivalent data items is performed according to the MOVE statement rules for elementary sending and receiving items. Alternately, a database procedure could be defined in the Schema which performs the required transformation, in which case the MOVE statement rules do not apply.

Data item validation is performed by the DBMS as it stores data into the database or retrieves data from the database. The data item validation values specified in the Sub-schema may be different from the validation values specified in the Schema, but the Sub-schema specification must be within the range of the Schema specification. The DBMS checks the contents of data items when retrieving them from the database and does not retrieve items outside of the Sub-schema specified range.

Access control locks for a given realm, set type, record type, or data item can be declared in either the Schema or Sub-schema, or in both. If an access control lock for a given entity has been declared in both the Schema and Sub-schema, the Sub-schema access control lock overrides the Schema lock and the Sub-schema access control lock must be satisfied by the COBOL program.

The set description in the Sub-schema permits the specification of the arguments to be used by the DBMS in defining the set selection criteria. If set selection criteria are defined for a record type in the Sub-schema, they replace the set selection criteria defined in the Schema. If set selection criteria for a record type are not defined in the Sub-schema, then the Schema set selection criteria remain in effect.

Data independence

Although the data items defined in the Sub-schema must be defined in the Schema, important differences are permitted which give COBOL programs data independence. The definition of data in the database is contained in the Schema which is a step removed from the COBOL program's view of the database as given in the Sub-schema. Because of the differences between the Schema and Sub-schema which are permitted in the CODASYL database facility, changes can be made to the Schema without making any modifications to the programs accessing the database.

Modification of the Schema may require modification of the Sub-schemas based on the Schema. If the changes redefine the set structures or remove data items from a record type, then changes to the Sub-schemas referencing these structures and items must be made. If the changes are the addition of new data items, record types, and set structures which are not referenced by the Sub-schema, or if the data descriptions are changed, Sub-schema modifications are not required.

COBOL Sub-schema divisions

A COBOL Sub-schema source program consists of three divisions: Title, Mapping, and Structure. The Title Division specifies the name of the Sub-schema and the name of the Schema to which the Sub-schema is related, the Sub-schema access control key which must satisfy the Schema access control lock in order for the Sub-schema to be placed in the Sub-schema library, and the access control locks associated with the use of the Sub-schema. The Mapping Division contains the Alias Section where Sub-schema names not defined in the Schema are equated to names defined in the Schema. Identifiers, realm-names, record-names, and set-names may be named in the Alias Section.

The Structure Division contains the Realm Section, the Set Section, and the Record Section. This division specifies the portion of the database that is to be made available to a COBOL program and the structure of that portion of the database. The Realm Section specifies the Sub-schema realms and the access control locks associated with the use of the realms. The Set Section specifies the Schema set types to be made available to the Sub-schema, the set selection criteria, and access control locks associated with the use of the Sub-schema sets. The Record Section specifies the Schema record types and the data items within the record types that are to be made available to a Sub-schema. Access control locks associated with the use of records and data items, and the data item characteristics are also specified in the Record Section.

Compilation and binding time of COBOL Sub-schema

The Schema, COBOL Sub-schema and COBOL program are required to operate as a unit in order to perform database functions. The time of compilation of the Sub-schema and the binding time of the Schema, Sub-schema, and COBOL program as a run unit are extremely important. Some of the possible times for binding are COBOL compile time, COBOL Sub-schema compile time, execution time, or any other implementor-defined time.

The results for a program using the database facility could vary depending upon the binding time. For example, if a Sub-schema and COBOL program are compiled and bound together with a Schema as a run unit, and the Schema definition is then changed, the results of the execution could be quite different from compiling and binding the Sub-schema and COBOL program with the Schema after the changes are made to the Schema.

COBOL 80 Sub-schema subsetting

If a COBOL database facility is included in COBOL 80, it is quite probable that the COBOL 80 Sub-schema will be a subset of the COBOL Sub-schema specifications in the CODASYL COBOL Journal of Development. The X3/SPARC Database Systems Study Group has expressed concern over declarations in the Schema being overridden by declarations in the Sub-schema. Votes taken by ANSC X3J4 indicate that this concern is shared by X3J4.[5] It is probable that the specifications for access control locks for realms, set types, record types and data items will not be contained in the COBOL 80 Sub-schema. If access control locks were permitted for these resources, they would take precedence over access control locks specified in the Schema for the same resources.

The set selection criteria specified in the Sub-schema replaces the set selection criteria in the Schema and may not be included in the COBOL 80 Sub-schema for that reason. In the case of the set selection criteria, there is sentiment in X3J42 that the Sub-schema override of the Schema is not a problem and set selection criteria should be included in the COBOL 80 Sub-schema.

DATA DIVISION SUB-SCHEMA SECTION

If the database facility is included in COBOL 80, the Sub-schema Section will be added to the Data Division. The Sub-schema Section consists of a Sub-schema entry which specifies the COBOL Sub-schema that is to be accessed by the COBOL program, and the access control key which must satisfy the access control lock associated with the Sub-schema.

Only one Sub-schema entry is permitted per COBOL program. Multiple Sub-schemas per program are not presently permitted by the CODASYL Journal of Development and hence cannot be permitted by COBOL 80.

PROCEDURE DIVISION DML STATEMENTS

The Procedure Division Data Manipulation Language statements provide an interface to the database for a COBOL program. The Procedure Division DML statements provide the capability to update the database, to retrieve records and data items from the database, and to control the availability of realms to the COBOL program.

Update function statements

There are DML statements which provide update functions for both set structures, records, and data items within a record. Records are stored in the database by executing a STORE statement. The record stored becomes a member

of each set type in which it has been declared in the Schema to be an automatic member, and the record becomes the owner of an empty set (set with no members) for each set type for which it has been defined to be an owner. Records are removed from the database by executing an ERASE statement. The ERASE statement can remove one record, or with the use of additional options, all records within a set structure for which the current record is the owner record.

A record becomes a member in one or more sets for which the record type has been defined to be a manual member by executing a CONNECT statement. A record is removed from one or more sets for which its record type has been defined to be optional by executing a DISCONNECT statement.

The MODIFY statement is used to change the contents of one or more data items in a record, the set membership of a record, or to change both data items within a record and the set membership of a record. Execution of a MODIFY statement without the ONLY option causes the DBMS to replace in the database the contents of data items within the current record with the contents of the record area associated with the record. Derived data items may be indirectly changed by execution of a MODIFY statement. If the INCLUDING option or the ONLY option is specified in a MODIFY statement, the set membership of the current record is changed in accordance with the set ordering criteria of each set type.

The ORDER statement permits the logical reordering of members of the set of which the current record is either an owner or a member record. The logical reordering may apply to only the current run unit, or the reordering of the set member records may occur in the database. The object records of an ORDER statement may be all the records referenced by a given record-name, all records in which a given data-name is defined, or all records that are members of the set containing the current record.

Retrieval function statements

The two DML statements which are used to locate records and retrieve all or part of a located record are the FIND and GET statements. The FIND statement is used to locate a specific record in the database which then becomes the current record of the run unit. Execution of the FIND statement does not retrieve the selected record but identifies it as the current record for use in subsequent DML statements. The record selection expression in the FIND statement specifies the criteria to be used in determining the object record of a FIND statement. The record selection criteria may be based on record contents, system generated identifiers, or a record's relationship with other records.

The GET statement is used to move all or part of a record from the database into its associated record area where it can be accessed by other Procedure Division statements in a COBOL program. The GET statement without any identifier specified or with identifier consisting of a record-name, moves the portion of a database record defined in the Subschema into its associated record area. If identifiers referencing data items are specified, the contents of those data items are moved into the associated record area. Data items not referenced are unchanged in the record area. In all cases the current record of the run unit is the database record accessed.

Control function statements

There are two DML statements which control a COBOL program's access to database realms. The READY statement prepares one or more realms for processing and specifies whether the records in a realm can be accessed and modified, or only accessed. The READY statement also indicates whether the records in a realm are for the exclusive use of the run unit, or if other run units are allowed to access the realm but prevented from updating the specified realm.

The FINISH statement terminates the availability of one or more realms to the run unit. The individual realms to be terminated can be specified by name, or a set name can be referenced in which case all realms which contain the owner or members of the named set are terminated.

The DML includes the COBOL IF statement with database conditions as the conditional expression to be tested. There are three database conditions which may be tested: Tenancy, Member, and Nullity. The Tenancy condition determines if the correct record of the run unit is the owner, member, or either an owner or a member of a set of a given set type. The Member condition determines if a given set has any member records. The Nullity condition is used to determine if a specified data item has the null attribute.

USE declarative statement

The USE declarative statement for the COBOL data base facility specifies the procedures to be used in producing access control keys for satisfying Schema and Sub-schema access control locks pertaining to functions performed on realms, records, sets or identifiers. The USE statement also specifies the procedures to be executed on database exception conditions.

Concurrent run units

There are three DML statements which are included in the COBOL database facility to monitor concurrent usage of records by different run units. The three COBOL statements are KEEP, FREE, AND REMONITOR. The entire area of monitored mode and the functions of these verbs are expected to change from those specified in the Journal of Development in the Fall of 1977, so these statements will not be further explained. ANSC X3J4 has agreed that the KEEP, FREE, and REMONITOR statements, and the extended monitored mode as they are specified in the Fall 1977 COBOL JOD are not suitable for standardization and hence will be excluded from COBOL 80.

COBOL 80 DML statements subsetting

As mentioned earlier in the Sub-schema explanation, ANSC X3J4 is concerned about Sub-schema declarations replacing Schema declarations, and Sub-schema declarations being overridden by programmer action. Votes taken by X3J4 give an indication of the possible subsetting which will occur in determining the DML functions suitable for standardization.[5,6] The ORDER, KEEP, FREE, and REMONITOR statements have been identified as statements which will not be included in COBOL 80. Also, it is probable that the USE statement for data base functions will be subset for COBOL 80.

There are many problem areas which CODASYL is trying to resolve before the cutoff date. Among the data base features which have been identified as problem areas are the NULL concept (Is NULL a value or an attribute?), the results of MODIFY on derived data items not available to the Sub-schema, and the cascading effect of the ERASE ALL statement. Some of these problems may be eliminated by subsetting the database facility.

CONCLUSION

There are many obstacles in the path of the standardization of a database facility for the language COBOL. The Database Task Group X3J42 must develop a candidate Database module based on the CODASYL COBOL Journal of Development 1978. The proposed module must then be approved for publication for public comment as a draft proposed standard, either as a separate document or as a module of COBOL 80. The public comments are reviewed by X3J4, and changes made to the draft Database module based upon the public comments. The final Database module specifications must then be approved by letter ballot by X3J4 and their parent committee X3. After approval by X3, the Database Module is forwarded to the ANSI Board of Standards Review for approval of the publication of the Database module as an American National Standard.

Even if a Database module is approved for inclusion in COBOL 80, much work is still required before there will be a database standard. The inclusion of a database facility in COBOL 80 would only standardize the COBOL Sub-schema and COBOL Data Manipulation Language statements. There would then exist the anomaly of a standard for the COBOL database facility without a standard for the Data Definition Language. Standardization of a COBOL database facility is meaningless without a Data Definition Language standard.

COBOL—Its relationship with other American national standards

by L. ARNOLD JOHNSON, PATRICK M. HOYT and GEORGE N. BAIRD
Department of the Navy
Washington, DC

INTRODUCTION

The standards which interface with COBOL can effect the degree of machine independence a COBOL program has. COBOL 74[1] provides the capability to process the standard coded character set defined by the American National Standard Code for Information Interchange (ASCII).[2] In that regard, COBOL 74 relies on the ASCII Standard for defining the character codes and the collating sequence that are to be reflected by the program when processing that particular character code. Additionally, COBOL can specify that ASCII be recorded on external media such as punch cards[3] or magnetic tape[4] with magnetic tape labels.[5] If that data is to be used for information interchange, then the recording of the data should be in accordance with the respective media standards. The American National Standards which interface with COBOL must be properly defined and implemented on a computer system for a COBOL program to be independent of the computer system. In the process of validating COBOL compilers, we use these other American National Standards related to COBOL and have found that data cannot be easily transported between computer systems.

ANSC X3 ROLE IN COBOL AND RELATED STANDARDS

American National Standard Committee X3 through its three standing committees is responsible for the standardization of COBOL and other subjects related to systems, computer equipments, devices and media for information processing.[6] Three committees assist X3 in discharging its responsibilities concerning the administration, evaluation, allocation and scheduling of standards projects. The Standards Planning and Requirements Committee (SPARC) and the International Advisory Committee (IAC) of X3 have staff responsibilities while the Standards Steering Committee (SSC) has line responsibilities. The IAC is responsible for coordinating the work of ANSC X3 with respect to international organizations. The purpose of SPARC is to review the need for standards, make recommendations to X3 on the desirability of standards and determine that work of the technical committees is responsive to the original objective of the standardization project. The administrative arm of X3 is the Standards Steering Committee which monitors and coordinates the standards projects that are being developed by the project groups. Individual projects are classified as being in one of three project groups, hardware, software or systems. The technical committees (established for each individual project) designated for the development and maintenance of American National Standards for COBOL, character codes, magnetic tape labels, and data representation are part of the software group. Technical committees for the standardization of physical media associated with magnetic tape and punched cards are included in the hardware group.

The basic objectives of the American National Standards Institute (ANSI) as well as its subordinate committees are the (1) promulgating of standards, (2) coordination of standards development, (3) establishment of standards, and (4) exchange of information. The underlying purpose of the COBOL standard is to "promote a high degree of machine independence in such programs in order to permit their use on a variety of automatic data processing systems."* Further, one of the criteria used by ANSC X3J4 (technical committee for COBOL standardization) for considering a COBOL element as a candidate in the 1974 COBOL standard was its compatibility with other standards. A philosophy similar to COBOL is reflected in the standards associated with magnetic tape, punched cards, magnetic tapes labels and standard coded character set in that these standards are concerned with a common format for information interchange between computer systems. Based on experiences noted later in this paper, there is a question as to whether COBOL and related standards, as yet are fully effective in providing information interchange.

STANDARDS INTERFACING WITH COBOL

There are five different American National Standards which may either directly or indirectly interface with American National Standard Programming Language COBOL,

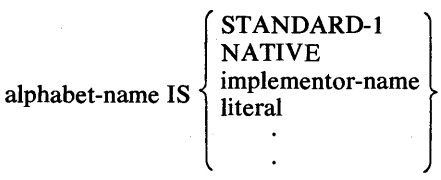
* See Paragraph 1.1, page I-1 in Reference 1.

X3.23-1974. The COBOL 74 Standard conveniently includes the language syntax which make these interfaces possible and thereby provides a common definition for the purpose of data interchange. American National Standard Code for Information Interchange (ASCII) is the common character code used for the interchange of data. Ideally, a standard data interchange on punched cards or magnetic tape is possible between computer systems when ASCII together with the appropriate American National Standards for punched cards or for recorded magnetic tape and magnetic tape labels are used. For data interchange as well as program interchange to be possible, a fundamental assumption is that each of the computer systems between which the data interchange is to occur must implement and support the applicable ADP standards.

Until COBOL 74, there was no definition within the COBOL language which allowed for the designation of a program collating sequence or how data would be represented on external media. Without such a definition each implementor was permitted to use his own techniques regarding the character collating sequence used, recording of signed data on external media, and the character code used for external media. The facilities in COBOL 74 for defining the collating sequence, the character code and representation of signed data are the COBOL features associated with the PROGRAM COLLATING SEQUENCE clause, CODE-SET clause, alphabet-name clause and SIGN SEPARATE clause. For the first time, it is possible for COBOL programs to read, process and produce data that is interchangeable in accordance with related ADP standards.

COBOL 74

The COBOL language feature by which ASCII is written to or read from an external media is the CODE-SET clause plus an associated alphabet-name clause. The CODE-SET clause in an optional clause of the File Description Entry in a COBOL program. When it is present, this clause specifies the character code convention used on the external media. Any conversion that may be required of the code, as represented internally in the computer system, and the code as represented on the external media occurs during execution of either an input or output operation (a READ or WRITE statement). The construct of the CODE-SET clause is "CODE-SET IS alphabet-name." Alphabet-name is defined in the SPECIAL-NAMES paragraph and has the form:



When the STANDARD-1 phrase is specified, the character code or collating sequence identified is that defined by the American National Standard Code for Information Interchange, X3.4-1976. Each character of the standard character set is associated with a corresponding character of the native character code. Note the COBOL Standard does not require that the computer system's architecture use ASCII, only that the computer system and associated COBOL compiler process the character code as if it were ASCII.

The ASCII character code standard defines the bit configuration for representing characters in the standard data format. The value of numeric fields may be represented in either binary or decimal form depending on the equipment. If more than one type of numeric representation is available for a computer system, this selection may be specified through COBOL by use of the USAGE clause. The two options of the USAGE clause are COMPUTATIONAL (binary) and DISPLAY (decimal). Therefore, in order to produce ASCII on an external media via COBOL, data descriptions for the file must be explicitly or implicitly defined as DISPLAY.

Another factor which effects the ability to interchange data between systems is the representation of signed data. The positive or negative characteristic of a numeric value may have, as many possible representations. Signs may be represented as part of the bit configuration associated with the high order or low order position of the numeric value. Signs also may be represented as a separate character which may be either leading or trailing. Since the ASCII character code does not provide for signed data values, the sign characteristic of a numeric value must be carried as a separate character. This is defined through COBOL using the SIGN SEPARATE clause.

Data is only interchangeable if the sequence of data is characteristic of the character code selected and the COBOL program processes it accordingly. This sequence is controlled within the COBOL program by use of the PROGRAM COLLATING SEQUENCE IS alphabet-name clause located in the OBJECT-COMPUTER paragraph. The PROGRAM COLLATING SEQUENCE clause is optional, but if specified, the program uses the collating sequence defined by a corresponding alphabet-name clause. If the alphabet-name clause specifies the ASCII character code (alphabet-name option STANDARD-1) then all nonnumeric comparisons for any relation conditions during program execution should reflect the ASCII code collating sequence.

AMERICAN NATIONAL STANDARD CODE FOR INFORMATION INTERCHANGE (ASCII)

ASCII is the standard coded character set to be used for information interchange among information processing systems. The ASCII Standard describes the code insofar as the bit arrangement or configuration relates to an associated graphic character. A minimum of 7 bits is used to represent an ASCII code character. The Standard does not define the means by which the code set is to be recorded in any physical medium but there is a bit relationship with the ASCII code to other standards such as the American National Standard Recorded Magnetic Tape for Information Interchange, X3.39-1973 (1600 CPI, PE) and also X3.22-1973 (800 CPI, NRZI). For COBOL to produce or recognize ASCII data, the language feature CODE-SET in combina-

tion with the STANDARD-1 option of the alphabet-name clause is required.

The binary bit pattern of the character code gives a collating sequence position for each character in the code. For an implementation to support the ASCII standard, the computer system must be capable of not only accepting and producing ASCII, but also must be able to process ASCII coded data in the proper collating sequence.

AMERICAN NATIONAL STANDARD HOLLERITH PUNCHED CARD CODE X3.26-1970

The Hollerith Punched Card Code Standard specified 256 Hole-pattern in twelve-row punched cards. These Hole-patterns are assigned to the 128 characters of 7-bit ASCII and to 128 additional characters for use in 8-bit coded systems. This standard relates these punched Hole-patterns to a particular bit pattern in an 8-bit data system. An example of such a system noted in this standard is the American National Standard Recorded Magnetic Tape for Information Interchange (800 CPI, NRZI), X3.22-1973. In addition to relating Hole-patterns to a particular bit construct, the code table presented in this standard also associates a graphic character to that particular position within the table. Columns 0-7 of the table correspond to the bit pattern and associated graphic character of that defined in the ASCII standard. The standard does not specify a card sorting sequence; however, when we consider the bit patterns of any two ASCII characters there is a well-defined sequence relationship.

Since the CODE-SET clause gives COBOL the capability to specify the character code convention used to represent data on the external media (such as punched cards) a relationship does exist through the ASCII character code standard for a COBOL program to accept, process, and create data on punched cards in accordance with X3.26-1970.

AMERICAN NATIONAL STANDARD MAGNETIC TAPE LABELS FOR INFORMATION INTERCHANGE, X3.27-1976

The magnetic tape label standard gives specifications for the recording of magnetically recorded labels on magnetic tapes used for information interchange. Rather than specify how the labels of the tape are to be processed or the data bit structure on the tape, this Standard identifies the information and the structure of tape labels that are recorded on tape. As such, the tape label standard is applicable to either 7 track or 9 track magnetic tape.

The standard makes note of the fact that the physical recording size of labels may be larger than the required 80 characters subject to hardware constraints. These 80-character records are grouped together based on their respective locations on tape related to beginning of tape volume, beginning of file, end of the file and end of tape volume. A tape mark, both before and after the file data, separates a label record group from the file data. Each label record is uniquely recognized by the first four characters in that record. A record group may have one or more records depending on the implementation and an agreement between the data interchange parties. For a single volume tape all label records are optional except for label records identified as VOL1, HDR1 and EOF1 which respectively define the beginning of the volume or tape, header label for beginning of each data file, and label record immediately following the data file. An illustration follows:

VOL1----HDR1---*File Data*[†]
EOF1----**

The tape label standard identifies the information and the data category (numeric or alphanumeric) that is to be stored in each field of the label record. ASCII is mentioned by the standard as a character code which can be used; however, the standard is applicable to any code structure. Certain fields of the label records are designated as optional by the standard. These optional fields may be recognized and processed or may be ignored at the option of the implementor.

COBOL includes provisions for specifying labels for data files through the LABEL RECORD STANDARD clause of the File Description Entry. However, COBOL 74 does not describe the format, structure, or content of file labels. It states only that file labels will be present when the clause is specified. If an implementation claims support of the tape label standard for use with COBOL, then the implementor should be expected to accept and process ANS tape labels on input, process those tape labels and create ANS tape labels on output, both in accordance with the magnetic tape label standard, X3.27-1976.

AMERICAN NATIONAL STANDARD RECORDED MAGNETIC TAPE FOR INFORMATION INTERCHANGE (800 CPI, NRZI), X3.22-1973 AND (1600 CPI, PE), X3.39-1973

The standards X3.22-1973 and X3.39-1973 for recorded magnetic tape provide specifications for the format and recording of half inch, 9-track magnetic tape to be used for information interchange with systems and associated equipment utilizing the ASCII code, X3.4-1976. These standards define the physical requirements for magnetic tape and the bit pattern for the recording of information on 9-track tape. Seven of the nine tracks are used for data; one track is used for character parity; and one track is treated as a bit of higher order than ASCII bits (shall be a zero bit). Each of the tracks used for the recording of data are assigned a particular bit identification which corresponds to the bit assignment used by the ASCII character code standard.

COBOL 74 does not reference the recorded magnetic tape standards; however, it includes COBOL syntax and general rules governing the semantics for the COBOL statements which apply specifically to the treatment of files on magnetic

[†] Each "*" represents a tape mark.

tape. Within COBOL 74, Sequential I-O module statements such as the CLOSE REEL, CLOSE WITH NO REWIND, OPEN WITH NO REWIND and OPEN REVERSED are used to specify the actions for files stored on tape or analogous sequential media. Also the general rules associated with the READ and WRITE verbs define the actions to be taken when an end of reel is recognized during a read or write.

USING COBOL WITH RELATED STANDARDS

Programs written in compliance with the 1974 COBOL Standard language specification do not necessarily accept or produce data files that comply with the other data processing standards on many systems. Part of our work, here at the Federal COBOL Compiler Testing Service, involves the validation of COBOL compilers with respect to Federal Standard COBOL[8] (ANS, X3.23-1974 COBOL). Because we are continuously implementing the COBOL Compiler Validation System (CCVS)[9] on different computer systems, the underlying purposes for which standards are developed are of vital importance to our operations. More importantly, we test COBOL compilers and as part of those tests we validate the compiler's capability to read, process and write ASCII in accordance with the 1974 COBOL Standard.

Briefly stated, the 1974 CCVS consists of some 250 COBOL programs which collectively test a COBOL compiler's conformance to COBOL 74 language syntax and semantics. That part of the CCVS used to validate the compiler's ASCII capability consist of three COBOL programs, an ASCII-encoded punched card deck, and an ASCII-encoded magnetic tape. The ASCII validation requires three steps. In the first step, the first of the three-program set produces an ASCII-encoded magnetic tape and punched card file. The two remaining COBOL programs read and check the files produced by the first COBOL program. For the second step, the two programs which read and check the ASCII-encoded files are again executed. However, for this run they use as inputs an ASCII-encoded tape file and punched card file produced on another computer system. The purpose of this run is to validate that the compiler/computer system being tested is capable of processing ASCII (represented both on magnetic tape and punched cards) that was produced by another computer system in accordance with the appropriate American National Standards. The final step is to take the magnetic tape and punched card file produced during the validation to a different computer system for further checking. The purpose of this latter step is to determine whether the compiler/computer system being tested can also produce ASCII (represented both on magnetic tape and punched cards) which is capable of being processed on another computer system.

Since COBOL 74 is not definitive regarding labels that are used for magnetic tape, the labels used for the ASCII portion of the compiler validation are dependent on the system under test. If the system under test supports the ANSI tape label standard, then tape labels conforming to ANS X3.27-1976 are placed on the magnetic tapes. If the system under test does not support ANSI tape labels then the magnetic tapes for the validation were supplied without tape labels.

To recognize a system under test as being in full support of COBOL and associated data related standards, the system is expected to do the following:

(1) Compile and execute the audit routines (CCVS programs) that conform to the 1974 COBOL Standard (ANS X3.23-1974) without requiring any modifications to the source code,
(2) Pass all the semantic tests made by the audit routines as reflected in the execution report of each audit routine,
(3) Accept ASCII-encoded (ANS X3.4-1976) data files from tape and punched cards that conform to the Magnetic Tape Standard (ANS X3.22-1973 and ANSI X3.39-1973) and Hollerith Punched Card Code Standard (ANS X3.26-1970) respectively,
(4) Produce ASCII-encoded data files on tape and punched cards that conform to the same standards noted in 3 above, and
(5) Accept and produce magnetic tapes containing magnetic tape labels that conform to Magnetic Tape Label Standard (ANS X3.27-1976).

Very few of the compiler/computer systems validated to date were successful in meeting all of the above criteria. The type of problems that were found follow:

(1) *Date recording formats unacceptable.* One system tested resulted in an end of file condition occurring after processing the first record of a 50 record tape file. Another system could not read either a labeled or an unlabeled magnetic tape. However, this same system, for some unexplained reason, was able to create a tape that, when read on another computer system, proved to be correct according to applicable standards.
(2) *Data code not read or recorded correctly.* One system tested produced records on tape which included an additional character located in the first character position of each record thus causing the contents of the record to be offset by one character. Another system did not provide proper character translation of all ASCII characters when reading punched cards.
(3) *Incompatible Tape labels.* Some systems tested simply did not support ANSI tape labels while others required the presence of optional labels HDR2 and EOF2.
(4) *Non-standard COBOL syntax.* One system tested required that the nonstandard clause "RECORDING MODE IS STANDARD-ASCII" be added to the SELECT Entry for all tape files. (The CODE-SET clause in the File Description Entry should have accomplished this function). One system, oddly enough,

could properly read and write ASCII on punched cards only when the CODE-SET clause was removed from the program.

A number of special considerations were necessary in order to process ASCII. Some implementations required that specific hardware models of magnetic tape and card readers/punches be used. Others required that specific options be invoked through the job control language, and still others required particular system generation parameters be used when the operating system is generated.

IMPACT OF COBOL 74 REVISION WITH REGARD TO OTHER STANDARDS

In looking to the future to see how the revision to COBOL 74 might affect the interfaces of COBOL with related standards, it appears that there will be little or no impact. In a sense this is unfortunate because the COBOL standard could give more guidance as to the type of file labels that are to be used. The only feature for defining file labels within COBOL is via the LABEL RECORD STANDARD clause, which in COBOL 74 merely requires that labels will be present and conform to the implementor's label specifications.

The difficulty most often found in transporting magnetic tape files between computer systems, next to improper implementation of standards related to COBOL, was the tape label. Many COBOL compiler/computer systems tested did not support ANSI magnetic tape labels. If the COBOL interface mechanisms for ANSI magnetic tape labels were similar in detail to the interfaces now present for ASCII, COBOL would have a direct link to another American National Standard.

CONCLUSION

One thing became quite apparent while testing the interfaces to ASCII and other standards related to COBOL. Even when strict adherence to American National Standards is maintained, COBOL programs and associated data files are not easily interchangeable among computer systems. This, in part, is due to improper implementation of ADP Standards by the parties involved in the interchange. Another factor is that the goals and objectives of X3 do not emphasize the compatibility of related standards or encourage interaction of related standards.

Ciphertext/plaintext and ciphertext/key dependence vs number of rounds for the data encryption standard

by CARL H. MEYER
International Business Machines Corporation
Kingston, New York

INTRODUCTION

One property of the Data Encryption Standard (DES) is that each bit of ciphertext is a complicated function of all plaintext bits and all key bits. A method is developed which evaluates how fast this dependence (defined as intersymbol dependence) builds up as a function of repeated mathematical operations called "rounds." It is shown that the minimum number of rounds to achieve intersymbol dependence for plaintext as well as key is five.

Cryptography deals with the methods involved in preparing cryptograms—messages or writings intended to be incomprehensible to all except those who legitimately possess the means to recover the original information. The designer of a cryptographic system, or cryptosystem, is a cryptographer.

The opponent or antagonist of a cryptosystem is a cryptanalyst. Cryptanalysis is concerned with techniques used to penetrate communications and recover the original information by means other than those available to the legitimate recipient.

Cryptology is the science of disguised or secret communications. It embraces both cryptography and cryptanalysis.

The basic challenge in cryptography is to devise a method that transforms messages (known as plaintext) into cryptograms (known as ciphertext) in a cryptographically secure way—that is, the method must withstand intense efforts of cryptanalysis. Plaintext can be protected by either of two techniques: it can be encoded using a code system, or it can be enciphered (encrypted) using a cipher system.

Code systems require a code book or dictionary that relates the words, phrases, and sentences of the vocabulary (the plaintext) to its equivalent code group (the ciphertext), and vice versa. The number of plaintext messages that can be encoded depends on the number of combinations of phrases that can be obtained from the code book. Although that number may be large, not every combination or pattern of bits can be encoded. Hence the versatility and usefulness of code systems is limited, especially in computer applications, which would have to be programmed to handle all such exceptions.

Cipher systems require two basic elements: a set of rules or steps—that is, an algorithm—constituting the basic cryptographic procedure, which is constant in character and agreed upon in advance, and a specific cryptographic key, selected from a large set of possible keys, which is known only by the communicators.

A cryptographic algorithm can be represented as an extremely large number of possible mathematical procedures called transformations. Each transformation defines how sequences of intelligible data (representing a message) are changed into sequences of apparently random noise (gibberish) that are unintelligible to humans or machines. The cryptographic key is a secretly held sequence of numbers of characters, usually very short, which identifies the transformation to be used.

To be useful, the algorithm should have, for each of its transformations, a unique inverse operation that changes the gibberish back into intelligible data. (This process is called decipherment or decryptment.) However, this can be done only if one has exact knowledge of the key that was used in the initial encipherment (transformation). A cryptographic algorithm will, therefore, provide data security between two nodes of a data processing system if those two nodes have the algorithm installed (in hardware or software), and if both nodes have exact knowledge of the key.

It is important to note that for good data security, only the key need be kept secret. The details of the algorithm are assumed to be known to everyone. The cryptographic key, therefore, is often considered analogous to the secretly held combination number of a safe.

It is always possible to construct an unbreakable system if the number of characters in the key is equal to or greater than the number of characters of plaintext to be enciphered.[1] It is required, however, that the key be randomly selected and used only once. This approach is impractical in data processing systems because of the large amount of message traffic. In a practical system, the key must be of fixed length, relatively short, and capable of repeated use.

Basically there are three general classes of ciphers: transposition ciphers, substitution ciphers, and combinations of these called product ciphers. A transposition cipher involves

the rearrangement or permutation of the plaintext symbols without change in their identity. A substitution cipher involves the replacement of plaintext symbols by one or more symbols without changing their sequence. Cryptographic research conducted during World War II showed that strong encryption systems could be obtained using alternate steps of substitution and transposition, resulting in a product cipher.[1]

Further research into the development of strong product ciphers was not undertaken in the private sector until the late 1960's. During the period from 1968 to 1975, a cryptographic procedure consisting of 16 alternate steps (or rounds) of key-controlled substitution and fixed permutation, based on work done by Horst Feistel, was developed at IBM.[2] This algorithm was accepted as a standard by the National Bureau of Standards on July 15, 1977, and is known as the Data Encryption Standard (DES).[3]

Next in importance to having a strong algorithm is the incorporation of the cryptographic device into the system. In a weak implementation, by manipulating certain cryptographic functions, it may be possible for an opponent to obtain the desired information. For an example of a strong system implementation of the DES, see Reference 4 from which this introductory material was taken.

Furthermore, if the key required for decrypting data is lost or unknown, the data cannot be recovered from the ciphertext. It is just as difficult for the authorized user to decrypt these data when the key is unknown as it is for the opponent.

The Data Encryption Standard's principle of operation (without initial and final permutation on input and output, respectively) is shown in Figure 1. For strength, the DES relies on (1) the complexity of the function g, which incorporates substitution as well as transposition[2] (or permutation), and (2) exercising the function g a sufficient number of times (defined as rounds).

After 16 rounds are employed by the DES, the 64 bits of plaintext are transformed into 64 bits of ciphertext under the control of a 56 bit key. During each round a subset of the key [defined as $K(i)$ for round i; $i=1,2,\ldots,16$] is used.[3] The input to round i, $X(i-1)$, is expressed as the concatenation of two 32 bit quantities:

$L(i-1)$ represents the 32 input bits to the left half of the one round cipher operation (see Figure 1) and $R(i-1)$ the 32 input bits to the right half, i.e.,

$$L(i-1)=l_1(i-1), l_2(i-1), \ldots, l_{32}(i-1)$$

$$R(i-1)=r_1(i-1), r_2(i-1), \ldots, r_{32}(i-1)$$

Hence the input to round (i) is defined as

$$X(i)=L(i), R(i).$$

whereas the output from round (i) is defined as

$$X(i-1)=L(i-1), R(i-1),$$

One property of the DES is that each bit of the produced ciphertext is a complicated function of all 64 plaintext bits and all 56 key bits.

To give a representative demonstration of this property let X represent a 64-bit block of input data (plaintext), Y a 64-bit block of output data (ciphertext), and K a 64-bit cryptographic key (eight bits may be used for parity checking, hence are not used by the algorithm itself). The notation $f_K(X)=Y$ means that the encipherment (f) of X under key K is equal to Y, and the notation $f^{-1}{}_K(Y)=X$ means that the decipherment (f^{-1}) of Y under key K is equal to X.

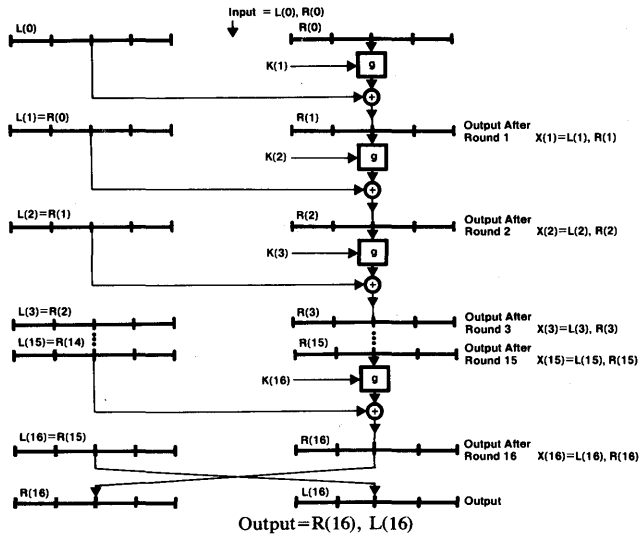

Figure 1—Basic block cipher design used by the data encryption standard

Enciphering the plaintext

$$X=1000000000000001$$

with a key

$$K=3001010101010101$$

results in

$$Y=f_K(X)=958E6E627A05557B$$

where hexadecimal notation is used.

If the same key is used to decipher this quantity, X is recovered.

However, by letting

$$Y^*=858E6E627A05557B$$

instead of Y be deciphered with K, where Y^* differs only in 1 bit from Y, the result is

$$f^{-1}{}_K(Y^*)=8D4893C2966CC21$$

which shows the drastic effect of only a single bit ciphertext change on the decipherment process and, hence, indicates how strong a ciphertext bit depends on all plaintext bits.

If, on the other hand, a key

$$K^*=1001010101010101$$

is used to decipher Y, where the 56 independent key bits of K^* differ from K in only 1 bit, the result is

$$f^{-1}{}_K{}^*(y)=6D4B945376725395$$

which shows the effect of only a one bit key change on the decipherment procedure and, in this case, indicates how strong a ciphertext bit depends on all key bits.

The dependence of each ciphertext bit on all plaintext and key bits is defined here as "intersymbol dependence."

There are many applications which can take advantage of this.[5] Two applications, which are demonstrated below, effectively expand the block size of the DES by using chaining methods. When block encryption is used, each 64-bit block of data is enciphered separately. In chained block encryption on the other hand, the encipherment of each block is also made dependent on prior information (plaintext, ciphertext, or the like) that is available when the block is enciphered. Two important chained block encryption techniques are ciphertext feedback and plaintext-ciphertext feedback, as defined below.

Let $X_1, X_2, \ldots, X_n$ denote blocks of plaintext to be chained using key K, let Y_0 be a nonsecret quantity defined initializing vector, and Let $Y_1, Y_2, \ldots, Y_n$ denote the blocks of ciphertext produced. When ciphertext feedback is used, the following relationship holds:

$$Y_i = f_K(X_i \oplus Y_{i-1}) \text{ for } i \geq 1$$

where $\oplus$ represents module 2 addition. When plaintext-ciphertext feedback is used, the following relationships hold:

$$Y_1 = f_K(X_1 \oplus Y_0)$$

and

$$Y_i = f_K(X_i \oplus Y_{i-1} \oplus X_{i-1}) \text{ for } i \geq 1.$$

With blockchaining a ciphertext bit in block i therefore depends not only on all plaintext bits in block i but also on the plaintext bits of block 1 through $(i-1)$. Thus chained block encryption (or block chaining) can be used to extend the intersymbol dependence between ciphertext and plaintext.

Plaintext-ciphertext feedback has the additional property of error propagation. Corruption of a single bit of ciphertext will cause each subsequent bit of recovered plaintext to be in error with probability 0.5. By appending a known pattern of bits to the end of the plaintext prior to encryption, and comparing that value to the value recovered, the error propagation feature can be used for checking the true context of a message. Chaining techniques are useful for encrypting data, and the block cipher (with no chaining) is useful for key transformation operations.[5]

In the analysis to follow, a method is developed which shows how fast the intersymbol dependence builds up as a function of the number of rounds. The approach evaluates whether or not an output bit depends upon an input bit. Although the degree of complexity is not measured, a distinction is made between three kinds of functional relationships. To discuss these relations, details of g (the kernel of the DES cryptographic approach) are illustrated in Figure 2.

The right half of the input to round (i) is expanded from 32 bits to 48 bits and is denoted by $E[R(i-1]$, using the E Bit-Selection Table.[3] The result is:

$$\begin{aligned} E[R(i-1] = {} & r_{32}, r_1, r_2, r_3, r_4, r_5, r_4, r_5, r_6, r_7, r_8, r_9, r_8, r_9, r_{10}, r_{11}, \\ & r_{12}, r_{13}, r_{12}, r_{13}, r_{14}, r_{15}, r_{16}, r_{17}, r_{16}, r_{17}, r_{18}, r_{19}, \\ & r_{20}, r_{21}, r_{20}, r_{21}, r_{22}, r_{23}, r_{24}, r_{25}, r_{24}, r_{25}, r_{26}, r_{27}, \\ & r_{28}, r_{29}, r_{28}, r_{29}, r_{30}, r_{31}, r_{32}, r_1 \end{aligned} \quad (1)$$

where the parentheses have been dropped for convenience of representation. The purpose of using the E expansion is to achieve a dependence of each ciphertext bit on all plaintext bits in as few rounds as possible.

Next $E[R(i-1)]$ is added modulo-2 to $K(i)$, resulting in a 48 element vector, (A).

$$A = E[R(i-1)] \oplus K(i)$$

$$= a_1, a_2, \ldots, a_{48}.$$

[Although (A) is different for each round and should therefore be indexed by (i), to avoid unnecessary details, it is not done here.]

In Figure 2 the elements of vector (A) are used as arguments in the substitution operations (S-boxes) S_1 through S_8.[3] Each S-box is described as a matrix of four rows (labeled 00, 01, 10, 11) and 16 columns (labeled 0000, 0001, . . . , 1111).

Each S-box can now be represented by four substitution functions, i.e., S_i^{00}, S_i^{01}, S_i^{10}, S_i^{11} for S-box S_i where the superscript identifies the row of the matrix, each mapping four input bits (which determine the column of the matrix) to four output bits given by the element of the matrix.

The first and last input of the six entries to the DES substitution box S_i in Figure 2 determine which of the four substitution functions in S_i are selected. Because these bits are derived from input bits (i.e., message bits if the input is interpreted as a message) as well as key bits, the selection of substitution functions not only depends on the key but also on the input data. Thus the E expansion, in effect, introduces an autoclave or self keying feature. Since (i) ranges from one through eight, there are 32 functions that are obtained with the eight S-boxes.

With a_1 through a_6 being the inputs to the first S-box,

$$S_1^{a_1, a_6}(a_2, a_3, a_4, a_5)$$

represent the first four bits of (B), i.e., bits b_1 through b_4.

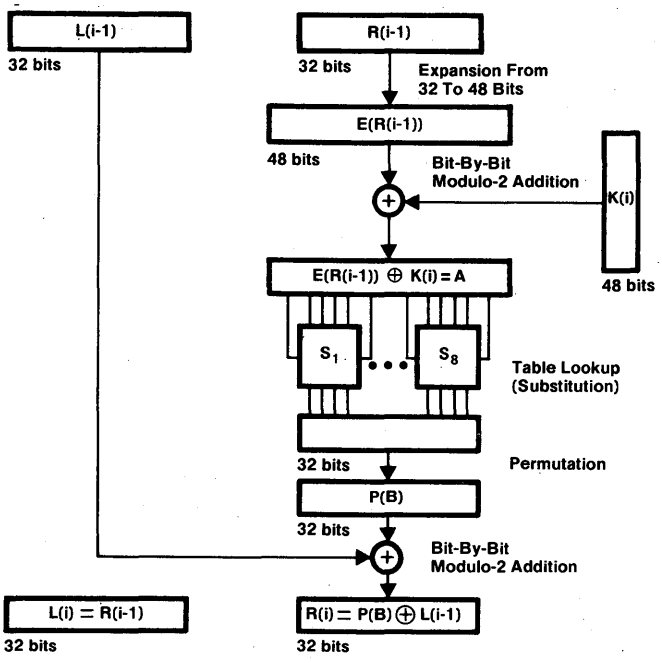

Figure 2—Details of (g) enciphering function

The last four bits, from S_8, i.e., b_{29} through b_{32} are given by

$$S_8{}^{a_{43},a_{48}}(a_{44}, a_{45}, a_{46}, a_{47}).$$

Knowledge of the 48 bits represented by vector (A) therefore allows the 32 bits represented by vector (B) to be determined. By permuting the elements of B, $P(B)$ is obtained as follows.[3]

$$P(B)=b_{16}, b_7, b_{20}, b_{21}, b_{29}, b_{12}, b_{28}, b_{17}, b_1, b_{15}, b_{23}, b_{26}, b_5, b_{18}, b_{31}, b_{10}, b_2, b_8, b_{24}, b_{14}, b_{32}, b_{27}, b_3, b_9, b_{19}, b_{13}, b_{30}, b_6, b_{22}, b_{11}, b_4, b_{25} \quad (2)$$

The output of round (i) thus becomes

$$L(i), R(i)=R(i-1), P(B)\oplus L(i-1)$$

Furthermore,

$$L(i)=R(i-1) \quad (3)$$

and

$$R(i)=L(i-1)\oplus g(K(i), R(i-1)) \quad (4)$$

where the 48 bits of $K(i)$ are a subset of the inputted key as previously discussed.

In the following two analyses, the dependencies of output $X(i)$ on plaintext $X(0)$ and on the key are treated separately.

INTERDEPENDENCE BETWEEN CIPHERTEXT AND PLAINTEXT

To investigate the functional relationship between the input to the $(i+1)$-th round (which is equal to the output of the (i)-th round, $i=1, 2, 3, \ldots, 16$), and the input to the first round, a matrix is defined. Consisting of 64 rows and 64 columns and referred to as $G_{i,j}$, its element $a_{l,m}$ for row l and column m shows the type of relationship which exists between the l-th bit of $X(i)$ and the m-th bit of $X(j)$. In particular, $a_{l,m}$ is "blank" if a dependence does not exist between $x_l(i)$ and $x_m(j)$. If there is a dependence via message bits only, $a_{l,m}$ is set to "x". If the dependence is via autoclave, $a_{l,m}$ is set to "$-$". If message bits as well as autoclave bits influence the output, $a_{l,m}$ is set to "*".

In a well-designed system, an output bit depends on more and more input bits as the number of rounds increases. These input bits come into play via message (x) dependence, autoclave $(-)$ dependence, or both (*). The design goal is to have each output bit depend on each input bit after only a few rounds, with autoclave as well as message dependence being achieved.

It is advantageous to partition matrix $G_{i,j}$ into four submatrices of 32 rows and 32 columns each, i.e.,

$$G_{i,j}=\begin{bmatrix} G_{i,j}^{(L,L)} & G_{i,j}^{(L,R)} \\ G_{i,j}^{(R,L)} & G_{i,j}^{(R,R)} \end{bmatrix}$$

Using the definition of $G_{i,j}$, the submatrices' elements express the relationships as shown in Table I.

Let the relationships between the output and the input of one round, i.e., $G_{i,i-1}$ be evaluated first. The dependence of the output bits from the substitution operation (vector (B) in Figure 2) on the input bits $R(i-1)$, explained below, is shown in Figure 3. [The numbers identifying the row and column of the matrix also refer to the index of the element of the appropriate vector, i.e., (B) vs $R(i-1)$, respectively, in Figure 3. Furthermore, note that (B) vs $R(i-1)$ is identical to $R(i)$ vs $R(i-1)$ if the permutation is not present].

TABLE I.—Functional Relationships

Submatrix	Relationship expressed in submatrix
$G_{i,j}^{(L,L)}$	$L(i)$ vs $L(j)$
$G_{i,j}^{(L,R)}$	$L(i)$ vs $R(j)$
$G_{i,j}^{(R,L)}$	$R(i)$ vs $L(j)$
$G_{i,j}^{(R,R)}$	$R(i)$ vs $R(j)$

The selection of the substitution function (S-function) in the first S-box, S_1, depends on the 32nd and fifth bit of $R(i-1)$. This follows from the fact that (1) the first and sixth input bits to S_1 select the S-function, and (2) the first and sixth bits of the expanded version of $R(i-1)$, which is determined by $E[R(i-1)]$, is equal to $r_{32}(i-1)$ and $r_5(i-1)$, respectively, according to Eq. 1. Therefore, all output bits from S_1, i.e., b_1 through b_4, depend on $r_{32}(i-1)$ and $r_5(i-1)$ via autoclave. However, they depend on $r_1(i-1)$ through $r_4(i-1)$ via message. $R(i-1)$ is considered to be the input message in this case. Hence, the entries in rows 1 through 4, columns 32 and 5 in Figure 3 are equal to "$-$". The corresponding entries in columns 1 through 4 are equal to "x". All other entries of rows 1 through 4 are blank since b_1 through b_4 only depend on six input bits. Repeating this analysis for S_2 through S_8 results in the matrix of Figure 3.

Taking permutation into account, the matrix rows have to be rearranged according to the permutation schedule given by $P(B)$ in Eq. 2. The result is shown in Figure 4 and rep-

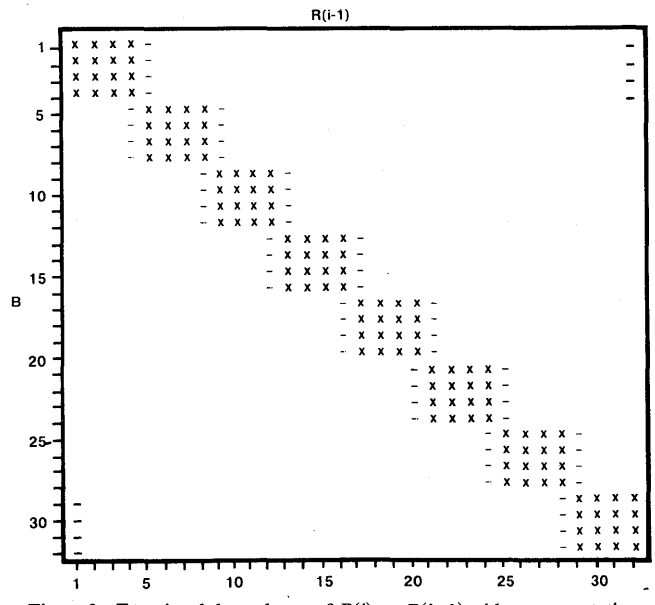

Figure 3—Functional dependence of $R(i)$ on $R(i-1)$ without permutation

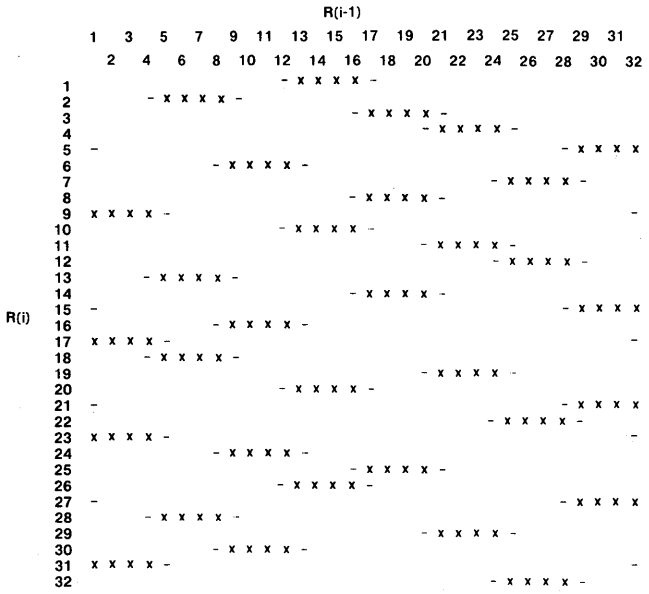

Figure 4—Functional dependence of $R(i)$ on $R(i-1)$, matrix $G_{i,i-1}^{(R,R)}$

resents the type of relationship that exists between $R(i)$ and $R(i-1)$; thus, $G_{i,i-1}^{(R,R)}$ is obtained (see Table I).

From $L(i)=R(i-1)$, see Eq. 3, $L(i)$ does not depend on $L(i-1)$ but has a linear dependence on $R(i-1)$. Hence the elements of $G_{i,i-1}^{(L,L)}$ are blank since they express the relationship between $L(i)$ and $L(i-1)$.

The relationship between $L(i)$ and $R(i-1)$ is expressed by the elements of $G_{i,i-1}^{(L,R)}$. Due to the linear relationship between $L(i)$ and $R(i-1)$, as discussed before, the elements located on the diagonal are set to "x" as shown in Figure 5. Eq. 4 shows the relationship of $R(i)$, $L(i-1)$, $K(i)$, and $R(i-1)$. Since the dependence on $K(i)$ is not of interest here, the expression

$$R(i)=L(i-1)+h[R(i-1)] \tag{5}$$

shall be used hereafter. The relationship, therefore, between $R(i)$ and $L(i-1)$ is also linear and, hence, the diagonal elements of $G_{i,i-1}^{(R,L)}$, which relate $R(i)$ and $L(i-1)$, are set to "x", whereas the remaining elements are blank, as shown in Figure 5.

Having evaluated $G_{i,i-1}^{(L,L)}$ through $G_{i,i-1}^{(R,R)}$, the matrix $G_{i,i-1}$ is completely defined and is shown in Figure 5.

Let $G_{i+1,i-1}$ be expressed next in terms of $G_{i,i-1}$. From Eq. 3 the relation $L(i+1)=R(i)$ can be established. Thus the functional dependence of $L(i+1)$ on $X(i-1)$ is identical to the functional dependence of $R(i)$ on $X(i-1)$. Since the dependence of $L(i+1)$ on $X(i-1)=[L(i-1), R(i-1)]$ is given by $G_{i+1,i-1}^{(L,L)}$, $G_{i+1,i-1}^{(L,R)}$, and the dependence of $R(i)$ on $X(i-1)$ is given by $G_{i,i-1}^{(R,L)}$, $G_{i,i-1}^{(R,R)}$, according to Table I, it follows that

$$G_{i+1,i-1}^{(L,L)}=G_{i,i-1}^{(R,L)} \tag{6}$$

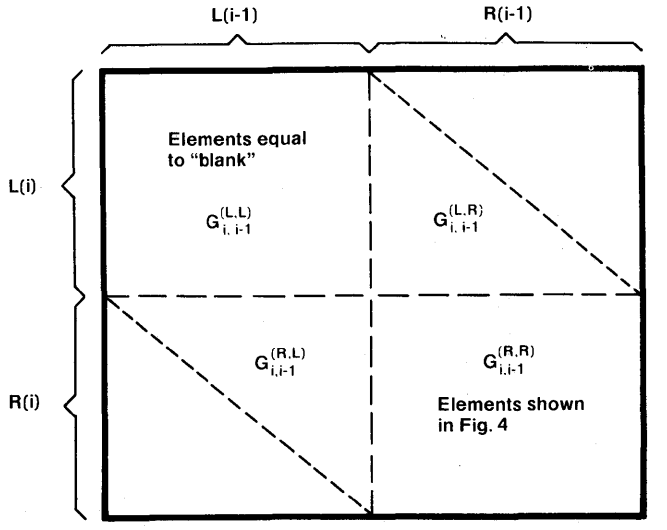
and

$$G_{i+1,i-1}^{(L,R)}=G_{i,i-1}^{(R,R)} \tag{7}$$

Before showing how $G_{i+1,i-1}^{(L,L)}$ and $G_{i+1,i-1}^{(R,R)}$ may be obtained, a more general case is considered, i.e., the evaluation of $G_{j+1,i-1}^{(R,L)}$ and $G_{j+1,i-1}^{(R,R)}$ ($j\geq i$) from $G_{j,i-1}$. (Note that for $j=i$ the above stated special case is obtained).

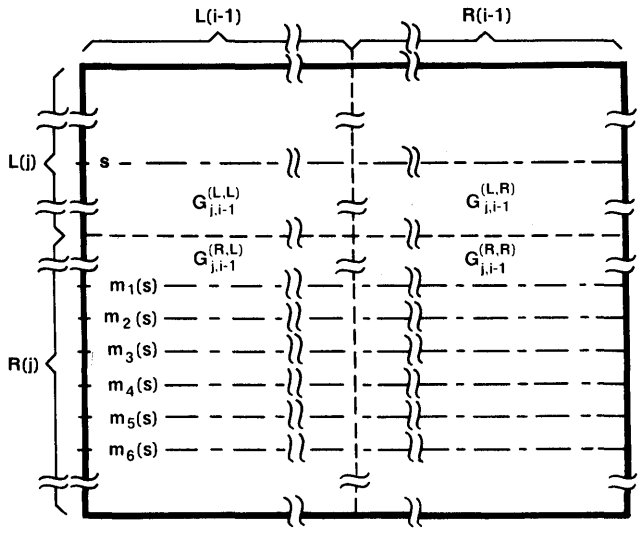
The elements of row s of $G_{j+1,i-1}^{(R,L)}$ give the relationship between bit s of $R(j+1)$, i.e., $r_s(j+1)$ and $L(i-1)$, whereas the elements of row s of $G_{j+1,i-1}^{(R,R)}$ give the relationship between bit s of $r(j+1)$ and $R(i-1)$. To evaluate these elements the relationship between $r_s(j+1)$ and $X(j)=[L(j), R(j)]$ is obtained first by using Figures 4 and 5. Bit s of $R(j+1)$ linearly depends on $L(j)$ as shown in Figure 5, i.e., on bit s of $L(j)$ via message dependence (x). From Figure 4 it follows that bit s of $R(j+1)$ depends on $R(j)$ via -$xxxx$-, i.e., bit s depends on two bits of $R(j)$ via autoclave and on four bits of $R(j)$ via a message relationship. Let the column locations of these entries in $G_{i,i-1}^{(R,R)}$ (equal to $G_{j+1,j}^{(R,R)}$ if $i=j+1$) be designated as $m_1(s)$ through $m_6(s)$. For example, using Figure 4, the following is obtained for $s=4$: $m_1(s)=20$, $m_2(s)=21$, $m_3(s)=22$, $m_4(s)=23$, $m_5(s)=24$, and $m_6(s)=25$. Since the dependence of $X(j)$ on $X(i-1)$ is given by $G_{j,i-1}$ and the dependence of bit s of $R(j+1)$ on $X(j)$ is known, the relationship between $R(j+1)$ and $X(i-1)$, given by rows 32 to 64 of matrix $G_{j+1,i-1}$ can be determined by properly combining elements of row s, $m_1(s)+32$, . . . , $m_6(s)+32$ of $G_{j,i-1}$. This method is indicated graphically in Figure 6.

The question still to be answered is, "What rule should be used to combine rows of matrix $G_{j,i-1}$ so that the dependence of $x_{s+32}(j+1)$ on $X(i-1)$ can be evaluated?" Since the main objective of this analysis is to determine how fast the functional dependence between output and input builds up it would be sufficient to simply indicate if a functional relationship between an output bit and an input bit exists or not. However, to gain more insight on the influence of au-



Elements of $G_{i,i-1}^{(L,R)}$ and $G_{i,i-1}^{(R,L)}$ located on the indicated diagonal are equal to "x" whereas the remaining elements are equal to blank.

Figure 5—Functional relationship between $X(i)=L(i)$, $R(i)$ and $X(i-1)=L(i-1)$, $R(i-1)$, matrix $G_{i,i-1}$



Note: X(j + 1) = [L(j + 1), R(j + 1)]vs X(i-1) is obtained by combining the elements of row s, $m_1(s)$ through $m_6(s)$, where $m_1(s)$ through $m_6(s)$ are the columns in which the elements in row s of $G^{(R,R)}_{i,i-1}$ occur. ($1 \leqslant s \leqslant 32$.)
$G^{(R,R)}_{i,i-1}$ is defined in Figure 4

Figure 6—Evaluation of functional dependence of $X(j+1)$ vs $X(i-1)$ from $X(j)$ vs. $X(i-1)$

toclave, a rule was devised which highlights the autoclave influence. Thus all elements of $G_{j,i-1}$ for rows $m_1(s)+32$ and $m_6(s)+32$ are set to "−", indicating an autoclave relationship. Note that the elements of row $s+32$ of $G_{j+1,i-1}$ describe the dependence of $x_{s+32}(j+1)$ on $X(i-1)$. Since $x_{s+32}(j+1)$ depends on $x_{m_1(s)+32}(j)$ and $x_{m_6(s)+32}(j)$ via an autoclave relationship, the dependence of $x_{m_1(s)+32}(j)$ and $x_{m_6(s)+32}(j)$ on $X(i-1)$ is changed from "−", "x" or "*" to an autoclave dependence "−". By adopting this rule, previous history, as far as the autoclave entry to an S-box is concerned; is eliminated, thereby increasing the emphasis on the last autoclave dependence.

In order to take into account previous history for the entries to an S-box not associated with autoclave, the elements of $G_{j,i-1}$ are left unchanged for rows s, $m_2(s)+32$, $m_3(s)+32$, $m_4(s)+32$ and $m_5(s)+32$.

In combining the proper rows of $G_{j,i-1}$ one or more entries can occur in the same column. Only if entries are either all "x" or "−" will the final dependence be correspondingly set. If mixed entries ("x" and "−") occur, the final dependence is set to "*". If entry "*" occurs at least once, then the final dependence is set to "*", regardless of what the other entries are.

Procedure summary

To generate the elements of row $(s+32)$ of matrix $G_{j+1,i-1}$, for $1 \leq s \leq 32$ determine $m_1(s)$ through $m_6(s)$ from the given matrix $G_{i,i-1}{}^{(R,R)}$. They are the columns in which the nonzero (i.e., non-blank) elements in row s of $G_{i,i-1}{}^{(R,R)}$ are located (Figure 4 gives these entries). Take matrix $G_{j,i-1}$ and select row s, $m_1(s)+32$ through $m_6(s)+32$. The entries in row $(s+32)$ of matrix $G_{j+1,i-1}$ are now obtained by combining the elements in the indicated rows using the established rules.

As a corollary, the following can be stated:

Elements in row s of $G_{j+1,i-1}{}^{(R,L)}$ are obtained by combining row s of $G_{j,i-1}{}^{(L,L)}$ with rows $m_1(s)$ through $m_6(s)$ of $G_{j,i-1}{}^{(R,L)}$. Elements in row s of $G_{j+1,i-1}{}^{(R,R)}$ are obtained by combining row s of $G_{j,i-1}{}^{(L,R)}$ with rows $m_1(s)$ through $m_6(s)$ *of* $G_{j,i-1}{}^{(R,R)}$.

Let the special case $j=i$ be considered now, i.e., let $G_{i+1,i-1}$ be evaluated from $G_{i,i-1}$. Using the stated rules, the submatrix $G_{i+1,i-1}{}^{(R,R)}$ can be derived. The result is shown in Figure 7.

Furthermore, it can be shown that

$$G_{i+1,i-1}{}^{(R,L)} = G_{i,i-1}{}^{(R,R)}$$

using an approach similar to the one applied in the proof by induction shown below and hence (from Eq. 7)

$$G_{i+1,i-1}{}^{(R,L)} = G_{i+1,i-1}{}^{(L,R)} = G_{i,i-1}{}^{(R,R)} \tag{8}$$

Using also Eq. 6 the evaluation of $G_{i+1,i-1}$ in terms of $G_{i,i-1}$ can be completed.

The proof by induction is used next to show that the following general rule (for $j \geq i$) holds:

$$G_{j+1,i-1}{}^{(L,L)} = G_{j,i-1}{}^{(R,L)} \tag{9}$$

$$G_{j+1,i-1}{}^{(L,R)} = G_{j,i-1}{}^{(R,R)} \tag{10}$$

$$G_{j+1,i-1}{}^{(R,L)} = G_{j+1,i-1}{}^{(L,R)} = G_{j,i-1}{}^{(R,R)} \tag{11}$$

The first stage of the proof was already completed by showing that these statements are correct for the smallest value of j, $j=i$. (See Eqs. 6, 7 and 8.)

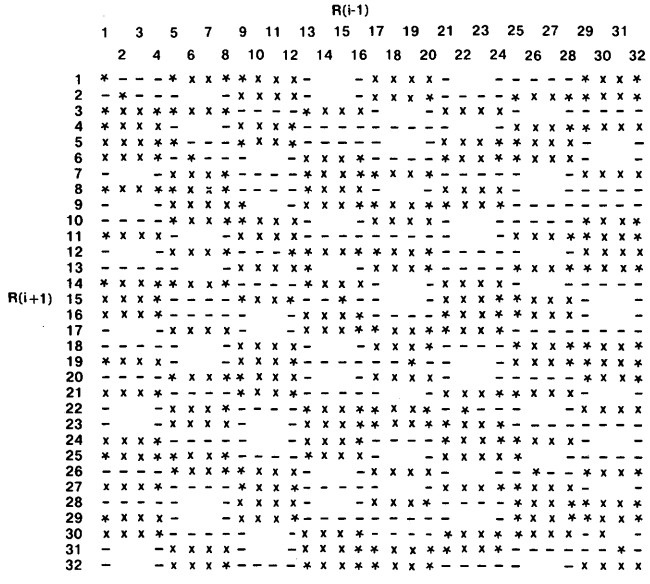


Figure 7—Functional dependence of $R(i+1)$ on $R(i-1)$, matrix $G_{i+1,i-1}{}^{(R,R)}$

From the relationship (Eq. 3)

$$L(j+1)=R(j),$$

it can be determined that $L(j+1)$ depends on $X(i-1)$ in the same way $R(j)$ depends on $X(i-1)$. Thus,

$$G_{j+1,i-1}{}^{(L,L)}=G_{j,i-1}{}^{(R,L)}$$

$$G_{j+1,i-1}{}^{(L,R)}=G_{j,i-1}{}^{(R,R)}$$

which proves Eq. 9 and 10.

To prove Eq. 11 the results stated in the corollary are used as follows:

$G_{j+1,i-1}{}^{(R,L)}$ is obtained by properly combining the elements of $G_{j,i-1}{}^{(L,L)}$ (row s) and $G_{j,i-1}{}^{(R,L)}$ (rows $m_1(s)$ through $m_6(s)$). But $G_{j,i-1}{}^{(L,L)}=G_{j-1,i-1}{}^{(R,L)}$, $G_{j,i-1}{}^{(R,L)}=G_{j-1,i-1}{}^{(R,R)}$, if the stated rule holds.

$G_{j+1,i-1}{}^{(L,R)}=G_{j,i-1}{}^{(R,R)}$ is obtained by properly combining the elements of $G_{j-1,i-1}{}^{(L,R)}$ (row s) and $G_{j-1,i-1}{}^{(R,R)}$ (rows $m_1(s)$ through $m_6(s)$). But $G_{j-1,i-1}{}^{(L,R)}=G_{j-1,i-1}{}^{(R,L)}$ if the stated rule holds.

Hence, $G_{j+1,i-1}{}^{(R,L)}$ is obtained in an identical way as $G_{j,i-1}{}^{(R,R)}$ and, likewise, $G_{j+1,i-1}{}^{(L,R)}$ is obtained. Therefore, $G_{j+1,i-1}{}^{(R,L)}=G_{j+1,i-1}{}^{(L,R)}$ which completes the proof (see Figure 8 for a graphical representation).

Minimum required number of rounds to achieve ciphertext/plaintext intersymbol dependence

For each output bit to depend on all plaintext bits after round (j), no element of $G_{j,o}$ can be blank. When this condition is satisfied, it follows from the developed relationships between $G_{j,o}$ and $G_{j-1,o}$, $G_{j-2,o}$ that (1) no elements of $G_{j-1,o}{}^{(L,R)}=G_{j-1,o}{}^{(R,L)}$ can be blank and (2) no elements of $G_{j-2,o}{}^{(R,R)}$ can be blank.

By assuming that all row entries of the matrices are independent, an approximate result for the minimum number of rounds can be obtained, as shown below. (In actuality the elements of eight sets of four rows each of $G_{i,i-1}{}^{(R,R)}$ are highly correlated. Therefore, the buildup of intersymbol dependence will be slower than predicted by the approximation.)

Since $G_{1,0}{}^{(R,R)}$ has six entries (Figure 4) in each row and $G_{1,0}{}^{(L,R)}$ has one entry in each row (Figure 5), then $G_{2,0}{}^{(R,R)}$ can have at most 1+6·6 or 37 entries. (Note that $G_{2,0}{}^{(R,R)}$ is obtained from $G_{1,0}{}^{(L,R)}$ and $G_{1,0}{}^{(R,R)}$.) There are, however, only 32 columns in $G_{2,0}{}^{(R,R)}$. Therefore, it is possible that none of the elements of $G_{2,0}{}^{(R,R)}$ are blank. Thus, it is possible to fill all 32^2 entries of $G_{2,0}{}^{(R,R)}$, $G_{3,0}{}^{(L,R)}=G_{3,0}{}^{(R,L)}$, $G_{4,0}{}^{(R,R)}$ after rounds 2, 3 and 4 respectively. Hence, all 64^2 entries of $G_{4,0}$ could be filled after four rounds.

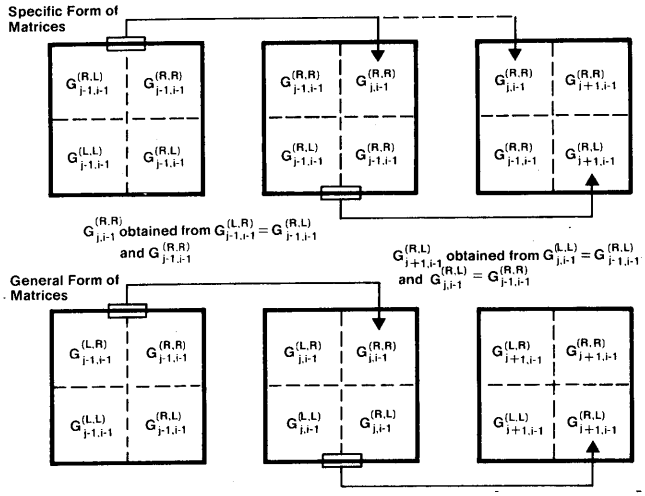

Figure 8—Graphical presentation of proof that $G_{j+1,i-1}{}^{(R,L)}=G_{j+1,i-1}{}^{(L,R)}$

From the evaluation of $G_{i+1,i-1}{}^{(R,R)}$ (Figure 7) there are 28 non-blank elements in each row, except for row 30 which contains 31 elements. It can also be shown that all entries of $G_{i+2,i-1}{}^{(R,R)}$ are equal to "*". Thus, after Round 4 each output bit of $L(4)$, except bit 30, depends on 28 bits of $L(0)$ and all 32 bits of $R(0)$. Bit 30 of $L(4)$ depends on 29 bits of $L(0)$ and all 32 bits of $R(0)$. Each bit of $R(4)$, on the other hand, respectively depends on all 32 plaintext bits of $L(0)$ and $R(0)$.

Let the degree of intersymbol dependence be measured

TABLE II.—Ciphertext/Plaintext Intersymbol Dependence

Round j	Output/Input Relation				
	$L(j)$ vs $L(O)$	$L(j)$ vs $R(0)$	$R(j)$ vs $L(0)$	$R(j)$ vs $R(0)$	$X(j)$ vs $X(0)$
1	0.00	3.13	3.13	18.75	6.26
2	3.13	18.75	18.75	88.18	32.20
3	18.75	88.18	88.18	100.00	73.78
4	88.18	100.00	100.00	100.00	97.05
5	100.00	100.00	100.00	100.00	100.00

NOTE: Table entries express the degree of intersymbol dependence, i.e., the percentage of non-blank elements in the appropriate relation.

by a factor, ξ, which is obtained by evaluating the percentage of non-blank elements. Respectively, for $G_{1,0}^{(L,L)}$ through $G_{1,0}^{(R,R)}$ (Figures 4 and 5), ξ is 0; $100 \cdot 32/32^2 = 3.125$; 3.125; and $100 \cdot 32 \cdot 6/32^2 = 18.75$ percent. With the total $G_{1,0}$, ξ is equal to 1/4 (0+3.125+3.125+18.75) or 6.25 percent. To obtain ξ for $G_{2,0}^{(R,R)}$, either Figure 7 or the previously quoted results can be used to arrive at $100 \cdot (32^2(31 \cdot 4 - 3))/32^2$ or 88.18 percent. Hence, using the rules obtaining $G_{3,0}$ from $G_{1,0}$, ξ associated with $G_{2,0}^{(L,L)}$ through $G_{2,0}^{(R,R)}$ is 3.13 percent, 18.75 percent, 18.75 percent, 88.18 percent, respectively, whereas ξ for $G_{2,0}$ is equal to 1/4 (3.125+18.75+88.18) or 32.20 percent. Because none of the elements of $G_{3,0}^{(R,R)}$ are blank (they are actually all "*") ξ, as associated with $G_{3,0}^{(R,R)}$, is equal to 100 percent. The results are summarized in Table II.

INTERDEPENDENCE BETWEEN CIPHERTEXT AND KEY

The basic ideas developed in the previous analysis can be used to investigate the intersymbol dependence between the output of the (i-th) round and the 56 bit cryptographic key. However, since the keys used in the different rounds vary, the analysis is slightly more complicated. Since the condition $L(j+1) = R(j)$ introduces a certain symmetry, it is advantageous to evaluate the dependence of $L(j)$ and $R(j)$ on the key in addition to the dependence of $X(j)$ on the key. The details of the analysis are shown in Reference 5 and the results are quoted in Table III.

It is concluded that the minimum number of rounds is equal to five to achieve intersymbol dependence between ciphertext and key.

SUMMARY AND CONCLUSIONS

On July 15, 1977 an encryption algorithm, called the Data Encryption Standard (DES), became effective as a U.S. Federal Standard. The algorithm utilizes a secret cipher key (a sequence of bits) to transform 64 bits of plaintext into 64 bits of ciphertext.

One property of the DES is that each bit of ciphertext is a complicated function of all plaintext bits and all cipher key bits. This property, defined as "intersymbol dependence" was analyzed by evaluating how fast intersymbol dependence was achieved as a function of repeated mathematical operations which were defined as rounds. Each of these operations consists basically of substitution and transposition.

TABLE III.—Ciphertext/Key Intersymbol Dependence

Round j	Output/Input Relation		
	$L(j)$ vs Key	$R(j)$ vs Key	$X(j)$ vs Key
1	0.00	10.71	5.36
2	10.71	79.02	44.86
3	79.02	96.43	87.72
4	96.43	100.00	98.22
5	100.00	100.00	100.00

NOTE: Table entries express the degree of intersymbol dependence, i.e., the percentage of non-blank elements in the appropriate relations.

Three different forms of dependencies were considered. If an input bit affects the selection of a substitution function in one round, the corresponding output was said to have an autoclave dependence on the input.

If an input bit affects the argument of a substitution function in one round, the corresponding output was said to have a message dependence on the input.

Since the basic operation involving substitution and transposition is repeated several times, the functional relation between a ciphertext bit and plaintext bit can, in addition to the already defined relation, be a combination of both.

It was shown that after five rounds each ciphertext bit depends on all plaintext bits via message as well as autoclave dependence. In addition, a similar analysis revealed that each ciphertext bit depends on all key bits after five rounds.

The method applied to the DES is, in general, applicable to ciphers which (1) split up the input into two parts, (2) operate on one part first, and (3) combine the results of that operation with the other part using modulo 2 addition.

INTRODUCTION

The concept of a data dependent key for use in conjunction with a selective encryption device is presented. The use of an encryption key extracted from the data or a function of extracted data eliminates the problems associated with a statistical assault on encrypted data which was all encrypted using the same key. If this key extraction is done in hardware then the security of the key is reduced to the physical security of the device which encrypts/deencrypts and not on the personnel doing the data entry. This work is premised on and builds from work done by Carson, Flury, Summers and Welsh,[1,2] establishing the concept of selective encryption terminals as a feasible technology.

With the passage of the Privacy Act of 1974,[3] a new area of concern has been presented to the data processing industry, i.e., the required protection of data on individuals.

The recently published report on the Privacy Protection Study Commission[5] goes further. ". . . the ability to search through . . . records to identify individuals with particular characteristics of interest is at once the most important gain, and the most important source of potential harm, stemming from the automation of large scale personal-data-record-keeping systems, and its importance is likely to grow in importance as 'textual search' techniques are refined."[6]

In light of this, various methods of protecting data have been suggested. Among these is the adoption by the National Bureau of Standards of an "Encryption Algorithm for Computer Data Protection." The algorithm is designed to encipher and decipher blocks of data consisting of sixty-four bits under control of a sixty-four bit key.[4] This algorithm was implemented in an experiment performed by the METREK Division of the MITRE Corporation in 1975 and 1976. They developed the Selective Encryption Terminal which consists of a Tektronix 4023 terminal and an LSI-11 microcomputer in communication with a host computer where the database was stored. For this experiment the host was an IBM 370/145 running the VM/CMS operating system.[1,2]

SELECTIVE ENCRYPTION

The concept of selective encryption allows the terminal operator to encrypt only those portions of an individual's record for which protection is required or to encrypt the identification portion of a record so that the individual is not associated with the data. The latter is useful in databases where statistical studies are made with respect to certain aspects of the individual's files. Selective encryption also allows the terminal operator to change the key so that different sections of an individual's record can be encrypted with different keys. In the METREK experiment, a hospital database was used. Here, medical information was encrypted under one key for use by physicians while accounting information was encrypted under another key for use by the hospital's administration.

The most important feature of the Selective Encryption Terminal is best expressed in this excerpt from the METREK report.

> *The protected material remains in encrypted form throughout its residence in the host system and is decrypted only upon return to the terminal. In this manner, neither the protection (encryption/decryption) software, the protection key, nor the plaintext of the protected information is ever present in the host computer.*[1]

The plaintext referred to is the data before encryption.

VULNERABILITY OF THE KEY

It is important to note that the security of the METREK system and any other system utilizing the NBS algorithm is entirely dependent on the security of the key or keys. Given the information that the NBS algorithm was being used, an outside intruder could get access to the protected data by one of three ways. First, the key could be obtained by trial

and error: iterating through all possible values of the key until found. Second, the encrypted text could be analyzed statistically so that any patterns in the data might reveal the key. And finally and most simply, the key could be obtained from those personnel who are exposed to the key, such as terminal operators.

What is to be considered then, are variations in the implementation of the algorithm which would combat these problems. One such variation is the concept of using data dependent keys in performing the encryption. Discovering the key by trial and error even when the data dependent keys are not used is a difficult task. With an eight byte key, each byte an ASCII character in which only seven of the eight bits vary, there are fifty-six bits which numerate all possible keys, and if it were possible to process each attempt in one microsecond, it would take on the average over one thousand years to find the key.[7] The problem occurs if the intruder trying to break the system gets lucky or utilizes some fast and advanced multiprocessing system. With the key found, the entire database is at his disposal.

DATA DEPENDENT KEYS

Consider, rather, a data dependent key. For each record of data in the database, the key entered by the operator could be used to select certain bytes of the plaintext data which will not be protected by encryption in the record, which could then be used to derive the key for the encryption of the data to be protected. In this way, if the key used to encrypt one record was discovered, that specific key would be useless in decrypting any other records.

It is assumed, of course, that the data dependency of the key is kept as confidential as the key itself. However, if such is not the case, the data is still fairly well protected. Given that the eight bytes of the key are selected directly from the plaintext data with replacement, it would take on the average $(N^8)/2$ attempts to break the key where N is the total number of plaintext unprotected bytes available. If N were one hundred bytes and each attempt took one microsecond, the data would be protected for an average of over one hundred and fifty years. It should also be noted that the one microsecond figure is unreasonable for the technology available. The best figures to be found are those reflecting the implementation of the algorithm using T^2L devices. Here the time to encrypt sixty-four bits is five microseconds.[7]

Protection using the above scheme could be further improved by not using the plaintext data itself as the key but rather as input to a function which creates some function of a key from the data chosen. A simple arithmetic maneuver, such as a hashing code, could increase protection manyfold while not significantly affecting processing overhead. Different functions could be used for different fields and the types of functions used could be varied. Thus one function might have the property of creating widely scattered keys from varying plaintext. Such a key function would have a high velocity. Another function might be a highly noninvertible function (not one-to-one) such as adding the low order bits of the plaintext bytes.

Data dependent keys improve security against the second method mentioned, discovering the key by statistical methods. With each data record encrypted with a different key, the amount of encrypted data in each record would be too minimal to draw any conclusions about the key.

MASSIVE DATA ENTRY SYSTEMS—ENCRYPTING THE SOURCE

For a large database where data is entered by many different people but only retrieved by a few, another scheme might be in order. The premise here is that some data is available to all for statistical purposes but only a few could examine or identify a specific individual. Most massive data entry systems employ the key to disc concept. Many operators enter records at many terminals which tie into one processor storing the data on a disc. If this processor is physically local to the terminals, i.e., there is no security problem due to lines which can be tapped, then the encryption can be done at the processor and not at the terminal.

Given this configuration, the data can be encrypted at the key to disc processor using some subset of the identifying fields of the record, such as the name and/or the social security number, as the encryption key. With this key the protected records including the identifying fields can be encrypted. To retrieve the data, a special decryption terminal can be designed which, when given the identifying information used to encrypt the record, can determine the key in the same manner and retrieve the record. Here one would extract the plain text seed for various key functions. Encrypt the fields that are to be protected and then encrypt the plaintext header information (name, social security) using as a key a function of extracted subfields of the plaintext header data.

In this manner, only an individual authorized to use a decryption terminal could enter the specific name and social security number and from this extract the records on that individual. No one else could ever identify uniquely those individuals who had characteristics of interest. The data base is essentially not invertible and yet certain fields which are not encrypted could be made available to everyone for analysis.

This scheme is superior to those previously discussed in that there is no plaintext stored in the database. Furthermore, each encrypted record is encrypted with its own key, making attempts to intrude on the database via statistical methods futile. And perhaps most important, the data entry personnel do not see the encryption and may not be aware that it exists and do not have any retrieval capability at their terminal at all.

HARDWARE IMPLEMENTED KEYS

Protecting the key from the third source of disclosure, disloyal personnel, is probably the more difficult problem to solve. Personnel, such as terminal operators who are readily exposed to keys in use as well as some information concerning the implementation of the encryption are the weak-

est link in the security system. Depending on the terminal used, information concerning whether the key entered at the terminal is used to derive a data dependent key or applied directly as the encryption key might easily be obtainable through the keyboard. What is needed here then is a scheme by which the operator may utilize the encryption/decryption facilities of the terminal but without ever allowing disclosure of the key or the details of the implementation.

One such scheme would involve entering the key at the terminal using hardware. It is possible to fashion an intelligent terminal with insertible ROM's (Read Only Memories) similar to those used on Hewlett Packard's 9820 calculators. HP 9820 users can purchase various pre-programmed ROM's which when inserted in the calculator give the user access to a library of subroutines.[8] A terminal with a microprocessor could be so equipped and utilize subroutines on the ROM for encrypting, decrypting, deriving keys from data and supplying the main key itself to these routines on the ROM. What is important to note about the architecture of the HP 9820 is that the information on the ROM can only be used as instructions for the processor. The code in the ROM is not available to the user as data. Data and user supplied programs can only be entered and retrieved from the calculator's RAM (Random Access Memory). It is in the RAM where the program which calls the ROM subroutines resides.

Given a terminal with the mentioned specifications, the key and the method of implementing the encryption can now be physically protected. The ROM could easily be designed so that it can be locked into the terminal for safety only to be removed by some authorized personnel. All that the operator will see is the data being processed at the terminal.

It might be useful to consider designing the terminal with two ROM ports for use when converting an entire database from encrypted under one key to encrypted under a new key. A ROM in one port would be used to re-encrypt the data.

Security, of course, would be required when the ROM program is burned in. Once the implementation of the algorithm is established, a number of ROMs could be prepared at one time leaving the key field blank to be entered when needed and at a proper time and place. There should also be some method of sealing the ROM.

Another variation of this scheme would make use of recently developed semiconductor devices, such as the Motorola "Info-guard,"[9] to perform the NBS encryption/decryption of the data. If this device were already present in the terminal and its capability available to the data processing program in the RAM, the ROM need only contain the routines for deriving and/or supplying the key to the devices. Using a dedicated device rather than a general purpose processor to perform encryption/decryption generally implies that one could expect much faster processing time.

CONCLUSION

The Selective Encryption Terminal is by far one of the most promising developments for Privacy Protection. The data is secure from the moment it leaves the terminal. By simply supplying extra protection to prevent disclosure of the encryption key using either data dependent keys and/or a hardware implemented key, a data base is well protected from any accidental disclosure or unfriendly intrusion. The protection of data is now reduced to the physical protection of a device.

Using data dependent keys for encryption and supplying a key to the terminal via ROM instead of through the keyboard may seem awkward in terms of processing overhead and generating the ROMs themselves. However, each contributes significantly in spoiling a possible intruder's plans to a point where any attempt would be completely discouraged. These ideas, then, appear to be well worth developing. They may provide an attractive solution to the simultaneous needs of privacy and statistical reporting in government applications.

Security in communication networks

by MARTIN E. HELLMAN
Stanford University
Stanford, California

INTRODUCTION

It may seem anomolous that electronic mail and other computer communication systems require cryptographic protection when almost no physical mail is given this protection. The difference is that computer readable traffic is extremely vulnerable to automatic sorting at very low cost. Physical mail would also need to be encrypted if it were all written on postcards and could be sorted at a cost of only $1 for several million pages. Even seemingly innocuous facts can be damaging when such vast amounts of data can be screened for all messages mentioning one of a list of key words (e.g., computer communications, electronic mail, EFT, etc.). Analog voice circuits are as vulnerable to wiretapping, but are expensive to sort.

Fortunately, the digital nature of the data makes high grade encryption possible at low cost. Analog circuits are almost impossible to adequately secure without going through a digital interface and encryption. The National Bureau of Standards has promulgated a national data encryption standard which can be implemented on a single LSI chip.[1] In large quantities it should therefore cost on the order of $10, an insignificant addition to the cost of a computer terminal. While some have criticized the standard as being inadequately secure,[2-4] this is not due to technical constraints, but rather appears to be a political problem.

While the cost of the encryption hardware is not a barrier to the widespread use of cryptography in computer oriented systems, there are other costs and problems which must be considered. Key distribution is one such problem.[5] In a network with n users there are approximately $n^2/2$ possible pairs of users who may wish to converse securely from all other users. The distribution of this many keys by courier, registered mail, etc. is clearly uneconomic even for n equal to one million. This problem can be solved by having the system itself distribute keys, encrypted in user specific system keys or passwords, but this requires the system to be secure.[6,7] A more useful approach was suggested by Diffie and Hellman[5] and Merkle.[8] They proposed that it is possible to converse securely over an insecure channel with no prearrangement through use of "public key systems." The second section describes the public key systems of References 5 and 8 as well as systems devised by Rivest, Shamir and Adleman,[9] McEliece,[10] and Merkle and Hellman.[11]

While none of these public key systems has been broken thus far, it is necessary that they withstand the test of time and concerted mock attacks by dedicated "opponents" before they can be trusted because no methods are currently known for proving even conventional cryptosystems secure. In this regard we applaud the work of Simmons and Norris[12] which looked for potential weaknesses in one of the public key systems. More such work is needed, and it would not be surprising if weaknesses were found in one or more of the currently known systems, much as conventional cryptography also went through a learning period.

Digital signatures are discussed in the third section. Conventional cryptographic systems can prevent third party forgeries, but cannot settle disputes between the transmitter and receiver (e.g., a stock broker and his client) as to what message, if any, was sent. Solutions to this problem were first hypothesized by Diffie and Hellman[5] and found by Rivest, Shamir and Adleman[9] and Merkle and Hellman.[11]

PUBLIC KEY SYSTEMS

Merkle's public key system[8] is perhaps the simplest and least likely to yield to continued cryptanalytic efforts. Its disadvantage is that it is the most expensive. It depends on the existence of a one way function, a function that is easy to compute for all arguments in its domain but computationally infeasible to invert for almost all images in its range. Such functions have been discussed elsewhere[13-15] and are as easy to develop as secure cryptosystems of the conventional, as opposed to public key, type.[5] Merkle goes a step further and describes a method for generating one way functions of controllable "one wayness" or difficulty of inversion.

A mildly one way function can be used to generate a puzzle, a problem which is difficult, but not impossible, to solve and for which it is easy to check a supposed solution. User A generates m keys, $k_1, k_2, \ldots, k_m$, and operates on them with a mildly one way function $f(*)$ to obtain their images or puzzles, $y_1, y_2, \ldots, y_m$. These images are transmitted to user B who selects one of them at random, say y_i, and solves the associated puzzle to obtain k_i. The two users now share a key in common but A does not know which one it is. B therefore sends A the value $z=g(k_i)$, where $g(*)$ is a

true one way function. A then operates on k_1, k_2, etc. with $g(*)$ until he finds one which yields z. The successful key must be k_i provided $g(*)$ is one-to-one.

The cost to A is linearly proportional to m, the number of puzzles, because A must operate on m k's with $f(*)$—which is easy—to obtain the m y's; he must store the m k's; and finally must operate on approximately $m/2$ of the k's with $g(*)$—again an easy task—before finding z as an image. A's transmission cost is also linearly proportional to m since he must send m y's. B's dominant cost is in solving the one puzzle that he chose at random. By making the cost of solving a single puzzle proportional to m, the total cost to the two legitimate users is still only linear in m.

An eavesdropper, however, must solve $m/2$ puzzles on the average before finding k_i, so his cost is proportional to m^2. Thus as m tends to infinity the ratio of cryptanalytic cost to key exchange cost also tends to infinity.

This method's weakness is in the relatively small ratio of costs (m^2:m) and the fact that the key exchange cost is as much in transmission as in computation. (Transmission costs have not decreased as rapidly as computation costs.) The introduction of low cost, high bandwidth transmission media, such as fiber optics, may make this method more competitive. Merkle's paper[8] describes several very clever additions to this simple description, but the basic cost ratio is not changed.

Diffie and Hellman[5] propose a method of public key exchange which requires $2^{b/2}$ operations for cryptanalysis (using the best known algorithm) but only b^3 operations for key exchange, where b is the number of bits in the representation of the key. By choosing $b=400$, key exchange requires only 64 million gate operations and takes approximately one second in a special purpose LSI implementation. Cryptanalysis using currently known techniques requires approximately 10^{60} operations and words of memory and is therefore totally infeasible. This technique makes use of the apparent one wayness of the discrete exponential function $y=a^x \bmod q$, where q is a large prime number of appropriate form [16,17] and a is a fixed primitive element of the finite field $GF(q)$. Calculating y from x—with tacit knowledge of a and q—is relatively easy, and requires only three words of memory, each b bits long, and b^3 gate delays. Computing x from y is believed to be much harder, and the best known algorithm[16,17] requires memory and time proportional to $2^{b/2}$.

The two users and the cryptanalyst are assumed to know q and a. Each user generates a random number uniformly distributed between 2 and $q-2$. Call these values x_1 and x_2. The users keep these values secret, but compute $y_1=a^{x1} \bmod q$ and $y_2=a^{x2} \bmod q$ and exchange these values. The cryptanalyst therefore also learns y_1 and y_2, but cannot feasibly compute x_1 or x_2 therefrom. User 1 takes y_2 (which was sent to him) and x_1 (which he has kept secret) and computes $(y_2)^{x_1}=(a^{x_2})^{x_1}=a^{(x_1x_2)} \bmod q$. User 2 computes $(y_1)^{x_2}=(a^{x_1})^{x_2}=a^{(x_1x_2)}$. Both users are now in possession of a common number $K=a^{(x1x2)} \bmod q$ which they use as the key in a normal cryptographic system. The cryptanalyst cannot compute K as any obvious function of y_1 and y_2 (e.g., y_1y_2 or $(y_1)^y2$) without first computing either x_1 or x_2, which is an infeasible task using the best known algorithms. There may be better algorithms for computing x_1 and x_2, or there may be some nonobvious method for computing K from y_1 and y_2 directly. As with all cryptographic systems, this one should be studied further to increase our trust in it.

Merkle and Hellman[11] have proposed a public key method based on trap door knapsacks. Given a one-dimensional knapsack of length S and a set of n rods of lengths a_1, a_2, . . . , a_n, one version of the knapsack problem is to find a subset of the rods whose lengths sum to exactly S. Equivalently, find a binary n-vector x such that $\mathbf{a}^*\mathbf{x}=S$. (The dot product of two vectors is denoted by *.)

The knapsack problem is believed to be very difficult in general, and this belief is supported by its being an NP-complete problem.[18] In a loose sense the NP-complete problems are the most difficult problems of a cryptographic nature.[5] A trap door knapsack vector $\mathbf{a}$ is one which has no apparent structure which can be used to simplify the solution process, but which possesses hidden (trap door) structure which allows rapid solution for $\mathbf{x}$.

As a small demonstration example, consider $\mathbf{a}$=(5457, 1663, 216, 6013, 7439) and $S=1663+6013+7439=15115$, corresponding to $\mathbf{x}$=(0,1,0,1,1). It happens that if each component of $\mathbf{a}$ is multiplied by 3950 mod 8443 (the secret, trap door information) the vector $\mathbf{a}'$=(171, 196, 457, 1191, 2410) results. This vector has the property that each component is larger than the sum of all the preceding components. Transforming S in a similar manner (multiplying it by 3950 mod 8443) yields $S'=3797$. Some thought shows that the solution to the problem $S=\mathbf{a}^*\mathbf{x}$ is the same as the solution to $S'=\mathbf{a}'^*\mathbf{x}$, and that the solution to $S'=\mathbf{a}'^*\mathbf{x}$ is easily found because of the form of $\mathbf{a}'$. x_5 must be 1 because $S'\geq a_5'$—if x_5 were 0 then even if all other components of $\mathbf{x}$ were 1's the sum could not be large enough to yield S'. Subtracting a_5' from S' yields $3797-2410=1387$ which is the sum of a subset of the remaining components of $\mathbf{a}'$. Because $1387\geq a_4'=1191$ we know that x_4 must also equal 1. Subtracting a_4' from 1387 yields 196. This is smaller than $a_3'=457$ so x_3 must equal 0. It is equal to $a_2'=196$ so x_2 must equal 1 and x_1 must equal 0. The determination of $\mathbf{x}$ is now complete and, as a quick check will show, correct for the original problem $S=\mathbf{a}^*\mathbf{x}$ as well.

Of course the trap door knapsack vector $\mathbf{a}$ was not generated first. Rather $\mathbf{a}'$ was first chosen with the property that each component was larger than the sum of all preceding components and then transformed into the $\mathbf{a}$ vector by multiplying each component of $\mathbf{a}'$ by 2550 mod 8443 (2550 and 3950 are multiplicative inverses mod 8443). In a similar manner a program could easily be written to generate rather large trap door knapsack vectors from a random bit string. Any user of a computer system could then generate his own personal trap door knapsack vector regardless of his mathematical abilities. The program would also generate the secret multiplier and modulus which reduces the apparently difficult knapsack problem $S=\mathbf{a}^*\mathbf{x}$ to the trivial problem $S'=\mathbf{a}'^*\mathbf{x}$. This program is assumed to be public knowledge but, even so, there is no apparent way for a cryptanalyst to easily solve for $\mathbf{x}$ only from knowledge of S and the public vector $\mathbf{a}$.

After generating a trap door knapsack vector $\mathbf{a}$, the user

can place it in a public file. Then anyone who wishes to send him information can do so by representing it in binary blocks of n bits each, and using these as **x** vectors to compute the sums $S=\mathbf{a}*\mathbf{x}$ which are sent to the first user, who can easily recover the information **x** even though no one else can.

Note that this system is different from either of the first two public key systems in that a normal cryptographic system is not needed. This is because the first two systems each generated a number that the two legitimate parties to the conversation could easily compute, but neither of the parties could determine that number on his own. In the trap door knapsack system **x** is determined entirely by one of the users. While it is not necessary for **x** to be used as the key in a normal cryptographic system, in practice, the speed advantages of conventional cryptographic systems will probably cause **x** to be used in that manner. This same remark applies to all of the currently known public key systems.

The public key system due to Rivest, Shamir, and Adleman[9] can be regarded as a generalization of a conventional cryptographic system developed by Pohlig and Hellman.[16] Each user generates a pair of numbers E and n which are placed in a public file and which are used by others to encipher data they wish to send him. At the same time that E and n are generated, another number D is generated which is required for deciphering data. Clearly, it must be computationally infeasible to compute D from the public information E and n if the system is to be secure. As shown in Reference 9, computing D from E and n is equivalent to factoring n, and it is possible to choose n so that this is infeasible using the best known factoring algorithms.

First two large prime numbers p and q are chosen and multiplied to produce $n=pq$. Then Euler's function $m=\text{phi}(n)=(p-1)(q-1)$ is computed. Phi(n) is the number of integers between 1 and n which are relatively prime to n, and has the interesting property that almost any number between 1 and n when raised to the m power mod n equals 1 (the exceptions turn out not to affect the system and we therefore neglect them in what follows.[9]). E is then chosen as a random number between 1 and m which is relatively prime to m, and D is computed using Euclid's algorithm to be the multiplicative inverse of E mod m. That is $ED=km+1$ for some integer k. Enciphering requires only one exponentiation in modulo n arithmetic and is easily accomplished. Letting P denote the plaintext and C the ciphertext, $C=P^E \bmod n$. (The plaintext must be represented as a sequence of integers each between 0 and $n-1$.) Deciphering is also easily accomplished in one exponentiation, $P=C^D \bmod n$. To see that this really does undo the enciphering operation note that $C^D=(P^E)^D=P^{ED}=(P^m)^k P^1=P \bmod n$, because $P^m=1$.

The most recently developed public key system is due to McEliece,[10] and is based on algebraic coding theory. Goppa codes are highly efficient error correcting codes, both in their error correcting capacity and in the computation required to correct errors. The ease of error correction is destroyed, however, if the bits which make up a codeword are permuted prior to transmission. In McEliece's system a user's public enciphering key describes a scrambled Goppa code, chosen at random from a large set of possible codes. Anyone can easily encode information (scrambling the Goppa code does not greatly affect the ease of encoding because the code is still linear), add a randomly generated error vector and transmit this to the user. But only the intended recipient knows the inverse permutation which allows the errors to be corrected easily. McEliece estimates that a block length of 1000 bits, with 500 information bits, should foil cryptanalysis using the best currently known attacks. The main problem is the storage of a 500 by 1000 bit generator matrix, requiring 500 kilobits of memory per user.

SIGNATURES

Written signatures are essential to our current methods of conducting business. They serve to indicate accountability and agreement on contracts, etc. Before electronic means can fully replace physical (hardcopy) forms of information, a digital equivalent to a written signature is needed. A digital authenticator must be a number which is easily recognized without being known, because any number that is known can be forged by the intended recipient. While at first appearing to be a logical impossibility, digital signatures can be obtained from public key cryptosystems and probably in many other ways as well.[5]

Rivest, Shamir, and Adleman's system[9] yields signatures most directly, merely by interchanging the enciphering and deciphering operations, so we only describe that method. When a user wishes to send a signed message M to someone else, he operates on it with his secret key D to obtain $Y=M^D \bmod n$. The recipient can recover M through use of the public key E,n because $Y^E \bmod n=M$. The recipient saves Y as proof that message M was sent to him by the user whose public key is E,n. If the sender later disclaims having sent the message, the recipient gives Y to a "judge" who can access the public file and see that $Y^E \bmod n$ does in fact equal a meaningful message with the right header information. Only the user who placed E,n in the public file knows D and could produce such a Y.

In practice each block of the message will probably not be signed in this manner. Rather, to speed things up, the message will be sent in its untransformed state, and a one way hash total H of the message computed.[5] The signature will be $Y=H^D \bmod n$. The recipient can easily check that H results when the public key E,n acts on Y, and that it is the same H as obtained from action of the hash function H on the message.

The above discussion neglects the privacy problem which results if an eavesdropper may be listening. This problem is easily overcome by enciphering the message-signature combination in a normal or public key system.

CONCLUSIONS

Public key systems and digital signatures make teleprocessing systems vastly more useful for business and personal

use, but care must be exercised, both at the technical and legal levels, to ensure that these advances are not used in a detrimental manner. For example, a user's secret key will probably be stored on a magnetic card which is needed to transact any business on the system. If the system becomes all pervasive in daily life, people may be expected to carry their cards with them constantly. It is only a small step to allow the police to demand the card as a form of universal identifier, without which a person becomes a nonperson. There are clearly dangers in such a system and adequate safeguards must be built in. Even now, certain businesses (e.g., car rental, gas stations at night) will accept only credit cards.

Further research is obviously needed at a technical level. The security levels of the currently known systems need better evaluation and new systems should be sought. These may be more efficient than the currently known systems, or needed in the unlikely event that holes are found in all of them. A major research goal is the establishment of provably secure systems, conventional, public key, and signature. That goal is more ambitious than solving one of the premier outstanding problems in computer science (the P=? NP problem) and must be viewed as long term.

PART IV—PEOPLE AND SOCIETY

Area Director:
Susan H. Nycum
Chickering & Gregory
San Francisco, California

Legislation

OVERVIEW

Legislative and regulatory activity affecting the computer industry is on the increase. A recent computer search of legislation pending before the Congress retrieved 328 bills involving computers and/or communications. These bills and others pending before the fifty state legislatures supplement the numbers of existing laws that already affect the industry. Recent legislative and related regulatory activity has been in five general areas: communications including transborder data flow, privacy, protection of proprietary rights in software, personnel and security. (One specific computer application, electronic funds transfer, which is the subject of a related area, includes aspects of each of the above.) Lawyers and computer specialists will describe and analyze this activity and its impact on computing in the following sessions:

The session on communications entitled "Federal Policy And The Future Of Computer Communications Services" will focus on the present status of federal policy, regulation and legislation impinging on computer communications, as well as relevant anticipated developments and their impact on the data processing field. Discussion will include activity in the executive branch concerning international communications and the office of the Assistant Secretary of Commerce for Communications and Information. Considerations of the Federal Communications Commission in the ongoing FCC "Computer Inquiry" (Docket No. 20828) will be discussed and Congressional issues, particularly the possible revision of the Communications Act of 1934 and related legislation will be reviewed.

In a session entitled "Privacy: Practical Implications For Your Organization," a leader in the Federal Executive Branch Privacy Task Force will report on questions raised by that group's recent review of the privacy issues, an analysis of the technological implications of privacy laws, regulations and recommendations for organizations and projections of future development. Panelists will discuss the report from the viewpoints of technologists, individuals and business organizations.

The legal aspects of software protection will be discussed in a panel session in which the current status of patent, tradesecret and copyright law will be described by experts in the area—one of whom is also a Commissioner of the Federal Commission On New Technological Uses Of Copyrighted Works (CONTU). An industry executive will then comment on the kind of protection the software industry needs and inquire of the other panelists how current or proposed law responds to these needs.

Personnel issues in computing involve a variety of concerns.

Computer Crime: Sources, case studies and prevention will be the topic of the session in which three papers will be presented that describe and defend teaching EDP to prison inmates, detail a recent computer crime prosecution and suggest a new prevention strategy based on the differences between accidental and intentionally caused losses.

Software house in the big house

by WILLARD V. HANDLEY
Federal Prison Industries, Inc.
Winchester, Virginia

INTRODUCTION

At the United States Penitentiary, Leavenworth, Kansas, and the Federal Correctional Institution, Milan, Michigan, some fifty convicted felons are learning to be computer programmers. Inmates supplement academic training with experience by developing systems for the Veterans Administration, Department of Labor, and other Federal agencies. Programming services are sold to agencies at market prices to generate revenue for inmate salaries and other expenses. This custom software enterprise is, or course, managed and supervised by civil service staff.

A software house whose programmer staff are convicted felons must pay attention to the potential of computer fraud in its security program. But it is not enough to have a program deemed adequate by experts in the field. To the general public, the computer is still an awesome and mysterious device. Our operation, and indeed any computer operation susceptible to public opinion must, like Caesar's wife, not only be above reproach but appear above reproach.

We learned this fundamental lesson when an allegation was made that inmates were using our computers to defraud IRS. Nothing of the sort had happened, nor could happen, under the stringent procedures in force at Leavenworth. We knew it; but we could not convince our critics, because the explanation was too complex.

This paper explains how we subsequently changed our security program to make it more clearly obvious to any observer that inmates could not misuse our resources. It should prove useful not only to other prison systems with similar rehabilitation programs, but to any organization affected by public opinion. Everyone may not have inmates as programmers, but most have some form of Achilles' heel. The need to go beyond "secure" to "obviously secure" in your own sensitive area of security may be as great as was ours.

The IRS episode also resulted in criticism of the fundamental purpose of our program. There are some who argue that a skill so easily turned against society should not be taught to known felons. Although an inmate, once released from custody, is outside the scope of our security program, this paper would not be complete without an explanation of why we feel the program is a boon, rather than a bane, to society.

COMPUTER PROGRAMMING IN FPI

The Federal Prison System houses some 30,000 offenders in prisons located throughout the country. The Prison System has a duty beyond merely keeping *them* isolated from *us*. It is expected to afford inmates humane treatment and the opportunity for rehabilitation.

Humane treatment includes helping the inmate pass the endless hours without losing his sanity. This entails the need for meaningful work programs; ideally, these programs contribute also to rehabilitation by teaching a skill usable on the "outside."

"Rehabilitating offenders" is a phrase not now heard in the field of corrections as often as before. Now we admit the best we can do is provide opportunities for self-improvement. So, education, vocational training, religious opportunities, and work programs are made available, on a voluntary basis, along with close counseling by social workers. Some inmates sincerely avail themselves of these opportunities; others merely "do their time," and often it is these who come back to prison again and again.

The Leavenworth programming enterprise is only one of many self-supporting work/training programs operated by Federal Prison Industries, Incorporated. This wholly-owned government corporation was established by Congress in 1934 to operate as a private manufacturing concern, buying raw materials, producing products, and selling them to generate its operating revenue. Its management and supervisors are government civil servants; its workers, inmates. It was given freedom to develop and manufacture any product, but restricted to selling to other Federal agencies. It was capitalized with $4 million of machinery, equipment, and other assets with no provision for subsequent Federal funding.

Today, FPI, now operating under the trade name of "UNICOR," has seventy factories and shops in thirty-two penal institutions throughout the country. It is virtually a conglomerate, with six product line divisions and forty industrial activities. UNICOR makes textiles; several lines of office furniture; footwear; wiring harnesses for missiles, tanks and aircraft; operates print plants, sign factories, microfilming shops engineering drafting shops, and other graphic arts facilities; and offers data entry, systems analysis, and computer programming, and other commodities and services. It employs 5,900 inmates, 600 civilians, and has annual sales

of over $90,000,000. It has been self-sustaining for the forty-three years of its existence. Unlike some government corporations, and not a few private ones, it has never needed another infusion of Federal funds.

Probably the most ambitious UNICOR effort to provide inmates usable skills was the establishment, in 1972, of the Leavenworth computer programming industry. As with most UNICOR industries, its workers have little or no prior experience. A year of classroom training, taught by certified teachers, is provided to prepare carefully selected inmates for the program. Graduates then work in a closely supervised environment to increase their skills with live work.

Students are selected from among a usually long list of volunteer applicants who have been recommended by their counselors. The potential trainee must have a high school diploma or GED certificate, perform at the tenth grade level in general math and language arts, and score a minimum of 45 out of a possible 90 points on the IBM Programmer Aptitude Test. A panel of custody, counselor, and industry personnel reviews such documents as the inmate's prior criminal record, pre-sentencing report, caseworker's progress reports, and overall incarceration history to reach a decision on each applicant's suitability for the program.

The course consists of thirteen four-week instructional modules designed to provide the equivalent of vocational school programmer training. It includes hands-on training with an NCR Century 200 computer with 64k bytes of main memory, dual disk storage units, a card reader, and line printer. The system software includes the operating system, assembler, and both FORTRAN and COBOL compilers. The course stresses COBOL, although an introduction to the assembler language and to FORTRAN are included. One module introduces IBM JCL and operating system utilities.*

A new course begins roughly every six months to start a new class of fifteen students on the road to becoming programmers. By the end of the year, dropouts and elimination by rigorous testing has dwindeled the group to about 12. This number is adequate to maintain production staffing at about thirty programmers and eight analysts.

Production programmers are grouped into six or seven man teams, carefully staffed to maintain a balance of experienced and novice programmers. A non-working civilian supervisor, qualified by years of experience, heads each team. The leader is responsible not only for the quality and quantity of each team's production, but for each member's continued development and growth.

Additional staff required to operate the facility includes two Leavenworth-based analysts and two Washington-based analysts/marketing representatives. The Leavenworth analysts are augmented by a team of four inmate analysts each. An administrative officer and a computer room operator round out the staff.

The training program currently costs over $150,000 annually; operating costs for the production element bring the total to nearly $550,000. But with the potential for over 60,000 programmer hours per year, the industry is still capable of operating "in the black" despite the unusual need to extensively train every programmer.

When the program began in 1972, a customer was found conveniently close to Leavenworth: The Agriculture and Stabilization and Conservation Service in Kansas City. The ASCS sent Leavenworth detailed programming specifications which were reviewed and clarified by Leavenworth analysts before assignment to the teams. Leavenworth was soon turning out programs whose reject rate of 8.7 percent was deemed by the customer "much better than average." Inmates were honing their skills on live production work, and were beginning to find jobs in data processing upon release. By June 1976, twenty-four of the forty-eight released had become programmers or analysts in private industry.

It soon became apparent, however, that having one customer was not enough. To provide a continuous flow of work and keep all programmers busy most of the time, we needed several customers to fill in the gaps. Turning to other agencies, however, meant computer compatibility problems, since the Federal government, by design, has many different computers. Because of our proximity to ASCS/Kansas City, we had been able to use the customer's machine remotely; now we were looking at the distant market in Washington, D.C., where such arrangements might be impractical.

The obvious solution was commercial time-sharing. For each job, we would find a vendor who offered the same machine as our potential customer's, and an existing network to give us local access.

We started with Infonet and its UNIVAC 1108s. Inmates quickly learned to use time-sharing and the new tools it afforded, such as interactive programming. Infonet had not been chosen casually; it boasted more Federal customers than any other network. By contracting with these agencies, we could develop systems on the same computer as our customers thus eliminating compatibility problems.

That on-line access to computers shared with Internal Revenue, the Veterans Administration and others also posed the hazard of subversion was not overlooked. The initial, and as it turned out, only, terminal was placed in a secure room. Civilians made all telephone contacts, and observed inmates continuously as they used the machine. Plans for additional terminals included a PBX to be modified by the telephone company so that outgoing calls could be made only at the switchboard, in response to verbal requests by civilian staff. The switchboard would be located in the administrative area of the prison, outside the main security gates. All telephone lines would be disconnected at the switchboard at 4:00 P.M.

But we had not gone far beyond the training stage with this new tool before an unrelated incident occurred in another part of the prison that embroiled us in a national controversy, and eventually eliminated time-sharing as a resource of this program.

A CRISIS AND ITS IMPACT

Among Leavenworth's population at that time was an inmate busily defrauding the Internal Revenue Service.

* A copy of the curriculum is provided at the end of this paper.

There was nothing sophisticated in his operation; he was taking advantage of the commonly known fact that IRS does not crosscheck, except on a limited scale, the amount a taxpayer's W-2 form shows was withheld with what his employer reports. To his phony tax returns showing money he had not earned, the inmate simply attached bogus W-2 forms showing taxes that had never been withheld. IRS processed the returns routinely, and sent a refund check to his wife on the outside.

The inmate was eventually caught and prosecuted. Although he was not connected with our program in any way, it was perhaps inevitable that it would be assumed our computer was being used in this scheme. Overnight, the story spread and grew by leaps and bounds. In major newspapers, wire service reports, and national television news broadcasts, it was implied, and sometimes stated outright, that inmates trained by the prison were using computers to crack the IRS security codes, file hundreds of bogus returns, and embezzle millions of dollars.

Computer security experts' statements, such as "No computer system exists that cannot be penetrated" made it difficult for the press to understand our assertions that our inmates could not penetrate Infonet. No one wanted to hear that, as a practical matter, penetrating a system requires certain resources, such as a prior knowledge of the operating system and unlimited access to a terminal, neither of which our staff had. In the end, we suffered as much adverse publicity as had we been guilty.

FPI Security

The Leavenworth security program had to counter three distinct possibilities for computer fraud at the time of the IRS scandal:

1. *Client System Penetration.* An inmate might penetrate the Infonet system of controls and gain unauthorized access to sensitive data of the FPI client or other Infonet users. He might also modify copies of programs stored on Infonet so that they would produce something of value to himself at some future time. Likewise, he might penetrate the ASCS IBM 360 machine to which the Leavenworth computer was linked.
2. *Client System Exploitation.* An inmate might produce a program that, in addition to its intended function, secretly provided some benefit, such as issuing a check to the programmer, or indirectly benefited him by alerting the client's operating system to subvert his security controls for later unauthorized use.
3. *Unauthorized Use of Computer Resources.* An inmate might use the Leavenworth computer or the Infonet system to directly produce something of value for himself, such as an official-appearing transcript; or to run a lottery.

These same threats exist in most data processing organizations.[1] We felt at the time that, while we should do everything possible to reduce the probability that these threats would be carried out, we would be doing nothing more than any conscientious software house should be doing.

Our countermeasures at that time were based on controls that eliminated the personal freedom and access to equipment needed to carry out the threats previously described. A large measure of control was provided as a byproduct of being in a prison setting, and of having a staff comprised of trainees and "green" programmers.

An important factor in all publicized computer crimes to date, and indeed, in virtually all white collar crime, is the numerous privileges and freedoms enjoyed by the perpetrators.[2,4] But the incarcerated Leavenworth inmate leads a life of almost constant supervision. He is deprived of the usual freedoms, not out of fear he will commit a computer crime, but because his custody is the responsibility of some prison employee at all times. He must have express permission to move from one area of the institution to the other, and must always be in a prescribed place at a prescribed time. At night, he is locked away in a cellblock separated from the computer room by numerous barred doors and gates.

During working hours, he has the freedom to be in the computer programming area, but still the requirements of custody apply. His supervisor must be constantly aware that he is present and doing his assigned job. No "outside" programmers are so closely observed.

Few would contest the statement that in the usual programming environment, managers are not enough in touch with their programmers to constantly know what they are doing. Thus a programmer runs little risk of discovery in appearing to be doing legitimate work while actually utilizing the computer for fraudulent purposes.

A close relationship between team leaders and programmer is assured at Leavenworth because the primary mission is different from that of the public sector software house. The supreme goal here is to build each inmate into an accomplished programmer so that he can succeed in the field upon release, rather than to make money for the enterprise. The team leader works closely with the inmate from the initial stages of specification interpretation, through flowcharting, debugging, and testing. This is a well-recognized concept for promoting program integrity, which in turn helps to ensure that a program does only what it is intended to do, and nothing more.[1,3]

Thus, the environment in which this software house operates provides a degree of control not usually found in the public sector. But additional, more direct security measures were also in force at the time of the IRS incident to counter the three main threats:

1. *Management Control of Computer Runs*—All run decks are submitted to the inmate's team leader, who reviews each deck to ensure that the job is one assigned to the inmate, and that the JCL meets prescribed standards: Nothing is suppressed on the output listings, no permanent files are created, and only the test files prepared by civilian staff are accessed. Decks may be brought into the locked computer room only by the team leader, who also must retrieve the printed output.

Every listing is reviewed by the team leader before being turned over to the programmer.

2. *Limiting the Possibilities*—Live test data is never introduced into the prison, nor were inmates given access to live data when shared computers were being used. An unwritten policy at the time of the incident, since formalized, was to avoid accepting systems to be programmed that provided an opportunity for financial gain.
3. *Personnel Selection*—The screening process previously described for inmates being considered for entry into the program was designed not only to ensure that the man had the ability for the program, but, to the extent possible, that he had a sincere desire to change his life for the better. Admittedly, this judgment is subjective.
4. *Independent Testing and Review of Programs*—ASCS policy required that all programs be compiled and retested with their own test data against the program specifications and flowcharts. ASCS also ran each program through the Performance Monitor of METACOBOL, a product that helps in determining program integrity by listing unexecuted paragraphs.

Most professionals would agree that the above procedures, if consistly and conscientiously applied, would come as close to eliminating the possibility of computer fraud by Leavenworth inmates as possible, given the existence of the threats outlined. Indeed, a detailed analysis of this environment by the MITRE Corporation, well-known for its efforts in security on behalf of the Department of Defense, led them to state in their first report following the IRS incident: "The security procedures in use at this time are probably stronger than those used in most software development shops, and are more than adequate for the types of programs currently being developed and the current development system."[4]

Nevertheless, we realized that this was not enough to prevent a repetition of the incident and its consequence of adverse publicity. An indirect threat existed for which we had no countermeasure: The public outcry against a danger more perceived than real. It could spell the end of our program. A combination of a general belief that with computers, anything is possible, and the prejudice that everyone who has previously committed a crime will do it again, given an opportunity, meant the issue of computer fraud was extremely sensitive in our situation.

The conclusion was that countermeasures against the three threats was not enough; we had to go further and eliminate as many of the threats themselves as possible. Under the guidance of the MITRE Corporation, we moved to reduce all threats to the issue of program integrity, and then to maximize our countermeasures against it.

This is being accomplished by isolating the development process from the client or target system. We withdrew from Infonet and will sever the connection with the ASCS machine, and begin using our own dedicated machine for system development. Thus, the only thing that will flow between the development facility and the client system is the program itself, which will be moved manually. The 'dedicated facility' is a well-known security technique, recognized by Department of Defense.[5]

The residual issue of 'program integrity' was addressed by strengthening the procedures already in effect. The technique of structured programming was adopted to help expose faulty or malicious code. A comprehensive, but common-sense, set of procedures and controls was also adopted to protect the program from the time it is "cleared" by the Leavenworth staff until installed on the target system. To further reduce the threat of program integrity, we have defined a set of formal guidelines against which to screen future client systems to reduce as much as possible the chance that an inmate will work on a program that could benefit him. These exclude: Programs that directly update data files that are used as the basis of financial transactions; programs in any way involved in the disbursement or transfer of funds to individuals, organizations, or accounts; and programs that access files which contain classified or extremely sensitive data that could be used for immediate or future financial gain.

All of these procedures are designed to protect society from the inmate programmer still incarcerated. They of course have no effect of the inmate programmer once he is released. The IRS fraud scandal raised another issue that still appears from time to time: Is it proper for the Federal government to turn known criminals into computer programmers? It is interesting to note that in a report following its investigation of the Leavenworth incident, a Congressional committee criticized the use of timesharing and advised against FPI involvement in systems that disburse funds, but approved of the program itself.[6]

TEACHING PROGRAMMING IN PRISONS

The basic argument against teaching computer programming is that it provides criminals with tools to commit more rewarding crimes, with less effort and risk than their previous adventures required. If the saying "once a criminal, always a criminal" were true, this argument would be unassailable. But it isn't; nearly two-thirds of all Federal releasees have been shown to be "successes."*

Because we are dealing with something so complex and unpredictable as human beings, it is impossible to say just why some releasees succeed in remaining out of prison while others fail. But we have clues. We know that people who commit crimes have the same basic desires as the rest of us; security, status, and so forth. The main difference seems to be that the criminal is more impatient, wanting his desires met immediately. And they often lack the training to fulfill their desires through legitimate means.

The FPI data processing program is a long-term, rigorous ordeal. An inmate must apply himself diligently for twelve months of training to avoid being dropped from the course. After completing the course, he has to put in two or three

* From "Success and Failure of Federal Offenders Released in 1970," A Bureau of Prisons study which defines a "success" as having no parole revocation or new sentence of 60 days or more.

years of further training in live production work, steadily improving his skills, in order to land a job upon release. Many never make it through the first few months of training.

Earlier release is not the motivating factor for these participants. The Parole Board gives no consideration to the programs an inmate completes. But, over the years, inmates have watched our participants released to well-paying, interesting jobs, and they hear through correspondence about the satisfaction these people get out of their new lives. This is the predominant reason given for wanting to participate in our program.

The program itself, then, is self-screening. We feel it attracts and keeps only the inmate who has made a firm commitment to play by the rules. The attitude of wanting instant, effortless success would not carry a trainee halfway through the first course. It is difficult to imagine someone still caught up in the syndrome of instant gratification having the patience to undergo such a grueling ordeal.

We feel the program is worthwhile because it provides an opportunity for those suited for a data processing career, who otherwise might continue robbing banks, or stealing securities to change their behavior. We have clear indications, after six years of operation, that our successful participants do go on to lead productive lives.

While it is difficult under existing procedures to follow up individuals released from custody, we can tell from the FBI's National Crime Information Center Computerized Criminal History File whether a releasee commits a new offense. From a continual review of these records, we know that no former participant has ever been charged with a computer crime. Moreover, these records indicate that 85 percent of our successful participants have had no further involvement of any kind with the law.

Even sophisticated statistical studies (which the above is not) dealing with the issue of relating a releasee's rehabilitation to his custodial treatment are subject to attack. There are simply too many factors that account for human behavior. Because the data, as positive as it appears, is inconclusive, one has to look elsewhere for additional indications that the society is better served by continuing the program. One such indicator is the attitude of private firms who hire our "graduates."

I hesitate to list these firms for fear of possibly embarrassing ex-inmates now leading productive lives in their employment. Key officials in these companies are of course aware of the men's backgrounds, but peers in some cases may not be. These companies would be recognized immediately by name. They are national and international in scope and have become prominent through hardnosed decision-making. These firms have decided that hiring ex-inmates as computer professionals is good business, and send the same teams that conduct campus interviews to our "campus." Recurrent hiring by the same firm is not uncommon.

It seems, in the final analysis, that judging whether teaching inmates to program computers is wise is, and should be, in the hands of these companies that hire our releasees. It is they, after all, who stand to lose if our critics are right. If they felt that the program was dangerous, they could stop its effects, and the program itself, by simply refusing to hire participants. Instead, they urge us to continue; one firm tells us they get more from our experienced people than from fresh college graduates.

Computer programming in the Federal institutions will therefore go on. Our internal security procedures, and the attitudes of the inmate participants, are adequate to prevent inmates' misusing of this knowledge while in our custody. Because private sector employers have confidence in the program and its graduates, the data processing community as a whole should accept these individuals, not as criminals with new tools, but former offenders making a useful contribution to society.

APPENDIX—*CURRICULUM*

The one-year training phase is designed around behavior/skill producing modules which permit:

Flexibility in teaching and learning in a penitentiary;
Frequently measured goals which culminate in the PTU objectives, and,
Accurately defined functional areas of computer programming technology.

Thirteen modules are established as follows (each four weeks long, 160 classroom hours) with the objectives as stated.

Computer Programming Voctational Training by Behavioral Module

1. *The Computer and its Program, People, and Peripherals.* An introduction to computer programming as a technical science.
2. *The Scientific Programmer.* Learning and applying the FORTRAN programming language.
3. *The Business Programmer.* Learning and applying the COBOL programming language up through the use of tables and index-sequential files.
4. *The Systems Programmer.* Learning and applying the NEAT/3, Level 1 programming language.
5. *Operating a Computer for Fun and Profit.* Computer operations.
6. *The Computer Utilities and Maintenance Men.* The use of software utilities to perform discrete jobs, and the modification of existing computer programs.

7. *All De-Buggers are not Household Insect Sprays.* The art of writing a computer program from specification to completed program, without waste or futility.
8. *The Super Business Programmer.* Advanced COBOL through internal sorts, conversion to IBM from NCR, and beginning JCL.
9. *NCR versus IBM—How Does it work?* IBM utilities and advanced JCL and relationships to NCR's ways.
10. *Garbage In, Garbage Out.* Designing data systems, and test data.

Computer security differences for accidental and intentionally caused losses*

by DONN B. PARKER
SRI International
Menlo Park, California

INTRODUCTION

Research papers generally treat the problem of computer security as an intentional act to be solved by intellectually challenging methods such as encryption, descriptor-based systems, and program proving. Accidental and intentional acts are almost always referred to simultaneously; however, the safeguards are designed strictly to prevent intentional acts. It is generally thought that the same safeguards and strategies will be effective against both accidental and intentional acts. This is not necessarily true.

In a paper on security assessment by Glaseman, Turn and Gaines,[1] accidental and intentional differences are not stated but are made subservient to the question of exploitation of vulnerabilities. As with most research papers on security, important research issues are discussed but they are oriented principally to intentional acts. This is evident in use of terms such as "intruder," "attacks," and "exploit," but no discussion penetrates research needs for errors, omissions and other accidents.

In contrast, Courtney states in a paper on risk assessment:[2]

> *It is important that proper weight be given to the impact of errors and omissions. Data is more often destroyed or otherwise rendered useless or even harmful by people making mistakes than through dishonesty or malice. People whose loyalty and honesty are unquestioned but whose judgment and competence leave much to be desired are our greatest enemies. Data security consideration must not be limited to concern for the acts of dishonest people. Otherwise, it is very difficult to achieve proper cost justification of appropriate security measures. Weigh all potential security problems. . . The differences between accidentally and intentionally caused losses are many and profound.*

Unfortunately, he does not pursue these strong position statements to exploit the differences.

* The preparation of this paper was supported, in part, by the National Science Foundation Grant #MCS76-01242. However, any views or conclusions in this paper should not be interpreted as representing the official position or policy of the sponsor or SRI International.

The differences between accidental and intentional acts are profound. Accordingly, the requirements for the strategies and implementation of computer safeguards should respond specifically to each kind of act. Nevertheless, most research stops short of considering two security problems. It is therefore suggested that a more successful approach to the problem would be to regard the accidental and intentional acts as distinct entities requiring separate solutions. Treating each act separately would make the problem-solving process more manageable and more explicit so that combining the two derived strategies and safeguard applications will result in a more effective approach to both aspects of computer security.

The first step is to identify characteristics of the two problems. Each of the characteristics is discussed below.

CHARACTERISTICS OF ACCIDENTAL AND INTENTIONAL ACTS

Frequency

Incidence of errors and omissions is usually sufficiently high to support statistical analysis of loss cases in a computer service organization. A limited number of cases, however, is often tolerated because the expense of reducing incidence any further is not cost-effective. Analysis can be used to identify the major locations and sources of errors and omissions. Statistics on the incidence of accidents can be used to calculate the probability and expected loss from these problems.

Conversely, the low incidence of intentionally caused losses makes statistical analysis difficult. Only in limited cases, such as credit card and some other payment frauds, has the incidence been high enough to be subject to statistical analysis.[3] Most intentional acts, especially those involving significant losses, occur so infrequently that attempts to calculate probability, expected loss, nature, patterns of location, and source, are difficult if not impossible. Therefore, risk analysis at the present time must be more subjective and theoretical. The experience of victims that could be similar to experiences of future or potential

victims may be helpful in calculating statistical probabilities, but will probably not be sufficient.

Unsolved problems

There are few unsolved problems with regard to accidentally caused losses. Efforts to control unintentional losses have been made throughout the development of electronic data processing. Adequate solutions are known for most common errors and omissions. The causes of errors and omissions are mostly obvious and the solutions equally obvious. It remains to apply these solutions in a cost-effective manner. Nonetheless, despite the errors, computer operating systems, for example, are still effective.

In contrast, significant problems in security against intentionally caused losses remain unsolved. The technical security of currently available computer systems is inadequate against attacks from potential perpetrators (such as systems programmers) with sufficient skills, knowledge, and access to the systems. Moreover, computer operating systems are basically unpredictable. Therefore, proving the integrity of a system and guaranteeing freedom from unauthorized changes or enhancements are not possible at this time. Neither practical prevention nor adequate detection capabilities are currently known for such sophisticated attacks as Trojan Horse methods, salami techniques, data leakage, logic bombs, asynchronous attacks, or post system failure attacks.[4] Another problem yet to be solved is the adequate identification verification of legitimate remote system users. Where technical safeguards are inadequate, therefore, more difficult and costly methods of safeguarding must be developed for protection from intentional acts.

Act complexity

Accidentally caused losses derive from single, isolated acts. Each loss incident is usually independent of other loss incidents. On the other hand, an intentionally caused loss can result from sequences of dependent and independent authorized and unauthorized acts. The loss can occur from intentional efforts that capitalize on observed errors and omissions. Perpetrators often increase the complexity of intentional acts as a means of avoiding detection or apprehension.

Singularity of source

One person usually is responsible for an error or omission even though other people may cause extenuations, whereas more than one individual frequently perpetrates an intentional act. Half the known cases of computer abuse have involved collusion. Compared to manual, or non-computer related fraud, embezzlement, etc., there is much more collusion in perpetrating these crimes via computer. The reason for the high degree of collusion is that computer crime requires more skills, knowledge, access, time or resources than any one person usually possesses in the technically oriented environments of the computer systems. Security strategies and safeguards must be far more elaborate when one attempts to deal with the possibility of collusion.

Complexity of perpetrator behavior

Behavior of people causing errors and omissions is relatively simple. The behavior is related to the conditions at the instant of the act. After the act, the perpetrator need, at most, defend only his weakness that resulted in error. In contrast, the behavior of people performing intentional acts is often highly complex. Interviews with 23 people who intentionally perpetrated a computer crime revealed that these people had personal problems to solve or goals to reach preceding their search for vulnerabilities of a computer system or work environment.[3] Searching or studying a system for vulnerabilities is, however, only one facet of the complex behavior pattern of intentional perpetrators. Once motivated to penetrate and use a system to his own ends, a perpetrator plans, plots, gathers information, organizes, and conspires, and is left finally to rationalize all of his intentional acts. Effective security must address all of these issues.

Sources of security assistance

Accidentally caused losses have been extensively studied and reported in the technical literature for many years. As stated previously, however, most technical literature that claims to address both accidental and intentional acts effectively addresses only accidentally caused losses. Professional societies and governmental organizations dedicated to the prevention of intentionally caused losses have only recently attempted to examine the problems associated with computer technology. The American Society for Industrial Security, the U.S. Justice Department, the International Association of Chiefs of Police, National Crime Prevention Association, and Surety Association of America have barely, if at all, seriously or significantly addressed the criminal aspects of computer usage.

Security checklists

Much security literature relies heavily on checklist or cookbook approaches to computer security.[5,6] Strategy is based on the concept of implementing the well-known safeguards and controls identified in the checklists. Although this approach is particularly effective for handling errors and omissions, it is neither sufficient nor effective in dealing with intentionally caused losses. Perpetrators are aware of the safeguards and controls identified in checklists, thus their methods for compromising the system are designed to avoid them. Merely installing a named safeguard in a checklist is not necessarily sufficient protection from intentional acts. Moreover, the checklist rarely includes information

concerning the need and means of protecting the safeguard itself from attack or compromise.

Strategy and safeguard independence

Each error or omission possibility can be effectively treated in isolated ways, because one loss will be independent from any other loss. Thus, a safeguard against an accidental loss can be implemented without considering other possible losses. Basically, the formula of matching one error with one safeguard is reliable.

On the other hand, each intentionally caused loss possibility must be covered comprehensively, including all possible acts leading to the loss. A safeguard against an intentional act will often have impact on other types of acts or losses in that it may only partially supply adequate protection. A particular loss could result in a security strategy involving many safeguards or a defensive depth of multiple rings of safeguards which may be a desirable strategy. Further, the implications of imposing a safeguard must be considered in terms of its potential to open new possibilities of vulnerabilities. If a particular safeguard temporarily deters a perpetrator, he will simply seek ways around it or other vulnerabilities.

Safeguard compromise

In accidental loss situations, it can generally be assumed that the integrity of the safeguard will be ensured and sustained. Safeguards may be subject to failures from errors, but in general the errors will be independent of the errors that the safeguard is preventing. In contrast, safeguards are subject to intentional attack as part of the perpetrator's strategy in carrying out an intentional act. The compromise of safeguards becomes part of the total loss event that the safeguards are meant to prevent or detect. In this sense, a safeguard must be considered as an asset subject to protection if it is to perform adequately when needed.

Level of protection

Determining the level of protection that a safeguard from an accidental act affords is simple because of the one-for-one, act-safeguard relationship. Higher incidence of accidents can result in more easily calculated protection levels. In intentionally caused acts, the level of protection is determined by a combination of security measures associated with a given asset. Lack of statistics makes effectiveness difficult to determine.

Achievable protection level

Security from accidental losses can be achieved to a high degree or, at least, can be easily controlled at a wide range of loss levels. One reason for this is that the success of protection can be accurately measured from incidence statistics, and the security then can be changed on the basis of the need that is determined. Because there are few unsolved protection problems with accidental losses, it is possible to control incidents to any degree desired within the limits of economic considerations.

A high level of protection from intentionally caused losses is difficult to achieve because of incomplete knowledge of all vulnerabilities. An individual loss could be affected by many factors, including the difficult-to-determine completeness of protection. The one-upmanship escalation of protection and increasing sophistication of perpetrators' methods precludes reliable measurement.

Potential perpetrators

The population of potential perpetrators of accidental loss is easily identified. It consists of those persons having the access and authorization to perform an act that might result in an accidental loss. Conversely, the population of potential perpetrators of intentionally caused losses is difficult to identify. It includes not only those identified relative to accidentally caused losses, but also the often larger numbers of people who might gain the necessary skills, knowledge, and access to perform an unauthorized act. For example, in remote terminal usage, impersonation alone would account for a large number of people who might possess such skills to replace people in positions of trust.

Potential perpetrator capabilities

In accidentally caused losses, the minimum skills, knowledge, and resources of potential perpetrators are at issue. Access is a prerequisite. Beyond this, the security specialist is dealing with the minimum skills and knowledge of people that are the source of errors and omissions. With intentionally caused losses, the security specialist is dealing with people who potentially have the maximum possible skills, knowledge, access authorization, resources, and time to commit the act. The attack possibilities and matching protection activities constitute a game in which each side is pitting its maximum capabilities against the other side.

Loss limits

Accidentally caused losses are limited in size. Where the size of the loss can vary, the probability of detection and termination of the loss grows rapidly with the size of the loss. The victim is ordinarily able to observe, measure, and limit accidental losses in a timely manner. However, detection of intentionally caused losses in a timely manner is not necessarily related to the size of the loss. Exceptionally large losses can go undetected when the perpetrator puts forth significant effort to conceal the losses. Also, in increasingly automated criminal methods, the possibility of a large loss in a time scale measured in milliseconds before humans can react becomes more likely.

Detection

Perpetrators of accidentally caused losses have no conscious intention to err before and during their acts. Therefore, avoidance of detection occurs, if at all, after the act has occurred. There is generally less fear of detection or of reporting the loss and more cooperation with the victim in recovery in accidental loss situations as compared to the perpetrators' position relative to intentional acts. Interviews have revealed that perpetrators greatly fear unanticipated detection before, during, and after their acts, and often much of their efforts and resources go into prevention of detection. This makes detection of intentionally caused losses a much greater challenge than for accidentally caused losses and should occupy a greater amount of the security specialist's attention.

Theoretical approach

Support for claiming a difference in risk between accidental and intentional acts can be shown in mathematical terms, even though this procedure is highly theoretical and not intended for practical use. Given are an asset subject to accidentally or intentionally caused loss, its environment, and a population of potential perpetrators with known skills, knowledge, access, resources, time and motivation. The probability P of a particular type and size of loss L from any possible independent accidental acts a_i $(i=1,2,\ldots n)$ with probabilities of their occurrence $p(a_i)$ is $P(L)=\Sigma_n p(a_i)-\Pi_n p(a_i)$. This suggests that a safeguard that reduces the probability of an act a_i for any value of i will reduce $P(L)$.

The probability P of a particular type and size of loss L from any possible independent intentional acts a_i $(i=1,2,\ldots n)$ with probabilities of their occurrence $p(a_i)$ is $P(L)=\text{Max}_n\{p(a_i)\}$. This conclusion is based on the theoretical premise that any potential perpetrator will perform rationally in choosing the one act with the greatest probability of success. This suggests that an entirely different result would occur from installing a safeguard that reduces the probability of an intentional act a_i for any i. If it were the act with greatest probability, it would have the most significant effect on $P(L)$ by directly reducing it by the amount that would cause the act of next largest probability to determine the value of $P(L)$. If it were any other act that was affected, there would be no change in $P(L)$. Therefore, installing safeguards has no effect except for those that reduce the probability of the act with greatest probability of occurrence.

Two different security strategies are suggested by these theoretical conclusions. Optimum strategy for security from accidentally caused losses is to reduce the probabilities of that combination of acts that reduce $P(L)$ by the greatest amount to an acceptable level, given limited security resources. Optimum strategy for security from intentional acts that reduce $P(L)$ to an acceptable level is to reduce the probability of the act with maximum probability followed in sequence by reducing the probability of subsequently maximum probability acts until security resources have been expended or $P(L)$ is reduced to an acceptable level, whichever occurs first.

Applying any safeguard that reduces the probability of any accidental act will incrementally increase security. However, applying a safeguard that reduces the probability of an intentional act may not increase security unless it reduces the probability of the one act that represents the maximum probability of occurrence. Thus, security from intentional acts is no greater than the weakest link. This shows a major difference in the two kinds of problems.

The most obvious weakness in this argument is the assumption that the population of potential perpetrators is rational in always selecting the act with the greatest possibility of success. In addition, practical application of the theory implies that the population and all acts relative to loss of a particular asset are known.

Applying a strategy only for accident prevention or only for intentional act prevention would clearly result in suboptimization, because many safeguards, some with minor modification, serve both purposes. A combined strategy, although not fully optimized, offers significant advantages over the near random-based, currently used strategies that are organized around merely computer center functional approaches (physical, operational, procedural and system) to security strategy. The steps to be followed in applying a combined strategy are:

(1) Select the intentional act with largest probability of occurrence.
(2) Apply safeguards to reduce the probability.
(3) Identify the accidental acts also reduced in probability of occurrence.
(4) Repeat Steps (1), (2), and (3) with the newly identified intentional act with largest probability until probability of intentionally caused loss is reduced to an acceptable level.
(5) If the probability of accidentally caused loss is still not acceptably lowered, apply safeguards to reduce the probabilities of the combination of acts that reduce the probability of accidental loss to an acceptable level.

The alternatives of applying safeguards against accidental loss first or applying safeguards without regard to accidental or intentional act differences are less effective. Safeguards aimed only at accidental acts often will be ineffective or will not be the best safeguards against intentional acts. One reason for this is that the safeguards may be installed only with the intent of protecting against the compromise of assets and not with the intent of protecting the safeguards themselves against compromise. In addition, a particular order of implementation of safeguards may not be responsive to the strategies of the potential perpetrators who are looking for the simplest and safest route to achieving success.

Failure to use the recommended strategy results in the Maginot Line Syndrome: A monolith of obvious and traditional safeguards will be installed, and the perpetrator

merely bypasses it by finding the weakest link not yet addressed by the victim organization.

ILLUSTRATION

Implementation of access control by password to an on-line system from a terminal illustrates the problem. For purely accidental access prevention in a benign environment, identification verification by input of a minimal length password or name is all that is necessary. Prevention of intentional, unauthorized access to the system requires the following additional measures:

- Sufficient password length to reduce exhaustive search attempts.
- Assignment of randomly generated passwords to reduce guessing by analysis of dependence between password content and password holder characteristics or knowledge.
- Nonvisible input of passwords to avoid observation or scavenging.
- Frequent briefings of password holders concerning safekeeping of passwords.
- Safe password administration, including separation of duties; invocation of need-to-know principle; appropriate transport and storage of passwords; and specific authorization of duties to accountable and trusted employees to avoid spoofing, coercion, degradation of care, and unauthorized physical access attempts.
- Encryption of on-line system password files and password comparison in encrypted form in privileged mode computer operation to prevent technical compromise.
- Limit guessing attempts of unauthorized passwords by imposing time delays between input attempts and disconnect after n failed attempts.
- Record and verify password use periodically with password users to avoid password theft and unauthorized use.
- Analyze patterns of password use and failed access attempts for deviations from normal experience to detect unanticipated attacks.
- Test all protection mechanisms frequently and prepare and follow contingency plans to avoid attacks when system or operational failures occur.
- Perform frequent, random, independent, and visible audits to inhibit potential perpetrators and ensure safeguard integrity.
- Impose sanctions against violators.

These additional safeguards are not new, but it is difficult to find them all stated in a single source. Again, subsets of them have been implemented, but are not generally found in a single computer service organization. For prevention of accidental access, only a few are needed. For prevention of intentional acts, all are needed; however, total implementation of all safeguards still is insufficient protection in many high-risk environments. Many more detailed specifications are needed for such items as levels of encryption effectiveness, pattern analysis of password use, password length, and audit techniques.

CONCLUSION

Glaseman, Turn and Gaines conclude by stating two major requirements for progress in security assessment:

(1) Increased research aimed at the development of a better understanding of the informational elements of security assessment, and
(2) Experience at the level of individual computer installations, in the application of a broader and more accurate information base to the assessment of computer security.

A third requirement should be appended to those suggested above:

> Recognition and separate treatment of two separate and distinct computer security problems, accidentally caused losses and intentionally caused losses.

Anatomy of a computer crime*

by SUSAN HUBBELL NYCUM
Chickering & Gregory
San Francisco, California

INTRODUCTION

This paper describes the process of an investigation** into the technical and legal aspects of a computer abuse of alleged theft of programs stored in a computer. The goals of such investigation are to provide information to help make computers and computer systems more secure, to provide computer technologists and managers with data as to the potential exposure for a particular activity, and to provide law enforcement officers and prosecutors knowledge of whether and to what extent existing laws may apply to the case.

There is no wish on the part of the investigators to sensationalize a case or bring to the victims and perpetrators more notoriety or exposure than already exists from public documents and proceedings or prior press coverage. Therefore, the paper will not use actual names and will where possible, generalize rather than particularize places and organizations.

Methodology of investigation

To date the investigators have knowledge of over 500 reported cases of computer abuse. To investigate each of these is beyond the existing level of resources. The cases that are selected for field study are those which offer one or more of the following:

(1) a plethora of available detail;
(2) an interesting, yet typical rather than wildly bizarre modus operandi;
(3) a suspected or demonstrated significant gain to the perpetrator or similar loss or exposure to the victim;
(4) a nontrivial legal question as to what crime or legal wrong has been committed; and
(5) a nontrivial investigative question for the law enforcement agency.

These five topics are more fully developed as follows:

(1) The incident must be available for research. The project prefers to investigate an incident at the postresolution stage. This qualification more readily assures that the parties will candidly share their experiences. While individuals tend to rationalize their actions at all stages of an incident, postconviction interviews with perpetrators are more candid than pretrial or presentencing interviews. Similarly prosecutors and law enforcement personnel are understandably constrained from discussing a case before conclusion. Victims considering or in the course of civil litigation are normally uncommunicative.*

All aspects of the incident must be open to research to avoid the three common barriers to objectivity: bias, prejudice and interest of the parties thereto. In addition, each person involved sees the incident from a different perspective. As with the old anecdote about the blindfolded group asked to describe an elephant by touch, one at the trunk, one at the tail, one at the feet, each party to an incident "sees" the case somewhat differently and extrapolates the whole from his own experience. The investigator needs to put those various viewpoints together and can best do so from a wide variety of interviews.

(2) There are always unique approaches to the perpetration of computer abuses and there are always "old friends" of tried and true approaches. Since the project has six years of experience, many of the typical approaches have previously been identified, investigated and catalogued. If an incident looks like a good example of a known modus operandi, there is low utility, absent extenuating circumstances, in investigating that type again. At the same time a "far out" approach, dependent on a set of unique circumstances has lower utility than an abuse which could happen repeatedly to a larger set of victims, e.g., point of sale terminal users. This is not to say that new twists to old abuses or sophisticated efforts which thwart existing security are ignored. These may be the most critical cases from which to learn improved security techniques.

(3) The project does not chase the illicit makers of a

* The preparation of this paper was supported, in part, by the National Science Foundation Grant #MCS76-01242. However, any views or conclusions in this paper should not be interpreted as representing the official position or policy of the sponsor or Chickering & Gregory.
** As performed by Susan Nycum and Donn Parker pursuant to the above National Science Foundation Grant.

* However, many victims and perpetrators have given information to the project in confidence and that confidence is carefully guarded by the investigators.

snoopy calendar* any more than a traditional investigator is concerned with the typical business practice of taking pencils from the office for home use. The project prefers to spend time where the results of the study will help minimize exposure to nontrivial risks.

(4) From the standpoint of legal research, abuses to software and services are of greater significance than those to hardware. This is because hardware, however complex, is visible, touchable material, the generic equivalent of other materials the abuses to which the law has coped with for centuries. Software and computer services, e.g., computer time, are new forms of intangible property and less amenable to traditional legal treatment.

(5) How does one find out in what way the abuse happened, how does one prove what happened for the purpose of prosecuting the act and later implementing security against similar occurrences and implementing proper audit trails. This criteria can be evaluated with respect to inventiveness of the modus operandi or with respect to the rules related to evidence gathering, e.g., telephone traces.

Once an incident is selected for investigation, the project contacts the cognizant persons, the victim, perpetrator(s), law enforcement persons: prosecutors, and judicial personnel and sets up *personal* appointments with these people as nearly contiguous in time as possible at the interviewee's office or residence (including jail cells where applicable). (This helps to preserve the continuity of the investigation and to assure that similar questions and similar weighting techniques as to response are used.)

At an interview the researcher explains the project goal and invites a description of the event in the interviewee's own words. The approach is one of openness and professional interest. There is no attempt to intimidate or lead the interviewee. There is also a minimum level of sympathy or support for action taken. Experience indicates that rapport can be established with the interviewees without compromise to the interview—the project is not on one side or the other. New points that arise in a later interview are checked for comment by earlier interviewees on a call back basis. There are patterns to interviews but these vary with the type of abuse and the class of interviewee, e.g. victim, prosecutor, perpetrator. Notes of interviews are transcribed as soon as possible after the fact and details of the investigation rechecked and gaps filled in and authorities explained by subsequent contacts.

Results of case studies are added to an aggregate of data on several issues, project findings are never based on one incident.

*Selection of the Brown** case for investigation*

The Brown case was a theft of proprietary software from a private installation over telephone lines. It was investigated by the FBI, prosecuted by a U.S. attorney and the defendant pled not guilty. At a resulting jury trial the defendant was convicted on two counts and one count was dismissed. The facts were typical of a particular form of abuse which had not been previously investigated in depth. There were interesting legal and investigative issues and the motive of the perpetrator was in dispute at the trial. All parties were available for interview.

THE FACTS OF THE BROWN CASE

The facts of this incident have been undisputed since the perpetration was discovered and the perpetrator apprehended. The main and perhaps only contention is as to why the act was done.

The parties agree that the perpetration consisted of the unauthorized copying of a significant portion of a systems program from the installation on which it was running by means of remote terminal access over dial-up telephone lines.

The perpetrator ("Brown") was a former employee who had had supervisory status for technical conversion and operation of a data center, at the victim company. Brown had executed a confidential information and invention agreement at the time of hire which stated in relevant part:

> "I will not disclose to anyone outside of [Company] or use in other than [Company's] business any confidential information, information or material, including but not limited to any and all information, material, data or memoranda relating directly or indirectly to any technique, tool or method used and/or applied by [Company] in any computer program or project related to the business of [Company] or its subsidiaries, either during or after my [Company] employment except with [Company's] written permission."*

All the accessing of the system and copying of the program was done after Brown left the company.

The program copied was a heavily modified variant of a system originally developed by an educational institution and financed in whole or in part by government grants to that educational institution. No data was copied and no other program was copied.

Detection

The perpetration was originally discovered by an alert employee who noticed that an imposter was signed onto the system. The detection of the presence of an imposter was possible because the person whose identification was being used was in sight of the alert employee and not engaged in a terminal session. System capabilities were used to monitor the terminal session and telephone company traces specified the origin of the terminal use.

---

* Note, however, that S. 1766, The Federal Computer Systems Protection Act of 1977, makes such activity susceptible to a $50,000 fine or 15-year prison sentence.

** An actual case with names changed.

* Official Transcript, pp. 27-28 of Proceedings.

Prosecution

As the telephone access was across state lines, the FBI investigated the incident and the cognizant U.S. attorney prosecuted the perpetrator for violation of federal law, Section 1343 of Title 18 of the United States Code (wire fraud).* The indictment was summarized by the judge as follows:

> "That the defendant, [*Brown*], obtained the unpublished telephone access number to the computer systems operated at and by [Company] exclusively for [Government];
>
> That the defendant unlawfully and without authority obtained account numbers, user identification numbers, and other information which was necessary in order for him to access the said computer and computer systems;
>
> That the defendant, through the use of said information, gained access to the computer systems operated by [Company] for the exclusive use of [Government], including the system known as [X];
>
> That the defendant without authorization used said identification numbers and account numbers, and without authorization obtained information, including print-outs, from the computers and computer systems, then knowing that he did not have authorization to gain such access and to retrieve such information.
>
> . . . It is further alleged in each of Count I and II that for the purpose of executing said scheme to defraud, the defendant caused to be transmitted in interstate commerce by means of a wire communication, namely a telephone communication between the defendant in [Y State] and [Company in Z State], certain signs, signals and sounds. Count I alleges a transmission on our about _____, 1975 and Count II alleges a transmission on or about _____, 1975.
>
> In summary, then, the defendant is charged with devising a scheme to defraud and with using a wire transmission in furtherance of that scheme. The same scheme is involved in each count, although different transmission have been alleged."*

A third count which alleged receipt of stolen property, was dismissed by the judge who ruled that the electronic impulses transmitted by telephone line across state lines could not constitute stolen goods because they were not tangible items.

The defendant admitted the act of copying the system but argued first that the system was in the public domain and thus he hadn't taken anything proprietary from an owner and second that his intention was not to use the system for his own interests but to show the vulnerability of the company's systems security.

After a two and one-half hour deliberation, the jury found the defendant guilty on both counts.

Similarity to other cases

The fact pattern of this incident was close to that of an abuse which took place in California several years earlier. In the former case a programmer pled guilty to theft of trade secrets. These trade secrets consisted of a proprietary application program the perpetrator had copied over remote telephone lines to his employer's computer and then printed out a hard copy thereof on his employer's printer. The perpetrator in that case admitted that he intended to use the program for competition on behalf of his employer against the victim.

The contention of the perpetrator in the Brown case that his intention when he copied the program was to show the Company that its systems security was inadequate. This is most reminiscent of a 1974 Oregon case of computer abuse in which a student notified the console operator that he had taken control of the computer operating system from a terminal and had done so for the purpose of pointing out the security vulnerability of the system. The system in the Oregon case stored motor vehicle registration data including personal information. The system in the Brown case was targeted to contain government data classified "secret."

UTILITY OF THE CASE TO THE STUDY

The case was of great utility to the study of computer abuse from several aspects.

Security implications

The victim company described its systems access controls as a three part key number access: account number, associated user identification and password all of which had to be provided by the user and verified by the system before computer time could be used and files could be accessed. In their interview with the study the spokesmen were candid about their concern for the security breach but indicated the level of existing security was adequate to protect from external intrusion. Another employee of the company stated in a separate interview that steps had been taken after the incident to tighten the level of security. Testimony at trial indicated a security weakness in that passwords were infrequently changed:

> Q. How often are the passwords changed?
> A. Right now, they are changing once a week.
> Q. Well, up until the time of this little problem, how often were they being changed?
> A. At that particular time, I couldn't tell you, but it was not very often.
> Q. Well, I guess the next question obviously is, has the password been changed periodically as a result of this incident?
> A. They were supposed to be changed periodically before the incident.

* §1343. Fraud by wire, radio, or television. Whoever, having devised or intending to devise any scheme or artifice to defraud, or for obtaining money or property by means of false or fraudulent pretenses, representations, or promises, transmits or causes to be transmitted by means of wire, radio, or television communication in interstate or foreign commerce, any writings, signs, signals, pictures, or sounds for the purpose of executing such scheme or artifice, shall be fined not more than $1,000 or imprisoned not more than five years, or both. Added July 16, 1952, c. 879, §18(a), 66 Stat. 722, and amended July 11, 1956, c. 561, 70 Stat. 523.

** Transcript pp. 832-833.

Q. Well, I think that's clear, but I mean did this incident bring on a policy of changing those passwords?
A. No, the policy was there prior to that.
Q. Did this incident bring on an implementation of the policy of changing passwords?
A. Yes, it did change the password, yes.
Q. Okay, because they found that to be a weakness in the system, isn't that fair to say?
A. That's correct.
Q. And how about the identification numbers now, are they being changed more frequently?
A. The systems people's identifications are being changed more frequently.
Q. Are they becoming more complex?
A. The format remains the same.*

The prosecutor

The prosecutor stated that this had been the first exposure of that office to computer abuse and they felt hampered by the lack of adequate federal law applicable to the case and by their own unfamiliarity with the type of activity. (The FBI could not be interviewed without a many months' delay because of backlog of requests under the Freedom of Information Act. Their reports, however, had been used by the U.S. attorney who did share his experience on the case with the study.)

Impact on programmers

From the standpoint of programmers involved with programs developed other than by themselves entirely with their own resources, the case points out two critical matters.

Most programs are owned by someone; very, very few are actually in the public domain. Indeed, another paper by the study is directed to a discussion of the ownership of programs whose development was sponsored in whole or in part by government funds. If the perpetrator Brown thought himself innocent of any wrongdoing when he took a copy of the company program, he was woefully mistaken. That assumption, which is unfortunately widespread, is wrong. Programmers must assume, unless assured otherwise by the persons responsible for the program, that it belongs to someone and permission to copy or use the program must be obtained in advance of such use.

System security is a legitimate concern of all those involved with computer installations and programs running thereon. If Brown was truthful, his efforts to convince the company during his employment of its lack of systems security through memo and meetings were unsuccessful. His testimony was that having failed to achieve better security while an er ployee of the company, Brown intended to copy the entire program after termination and present the company with the evidence of a series of perpetrations and the significant results of such accesses. (In fact he accessed the system approximately 60 times without authority.)* The jury disbelieved Brown. His case might have been stronger had those noble intentions been documented or had he in any way enunciated his concerns to users of the facility or to law enforcement personnel. Computer people whose personal ethics require action similar to Brown must realize and acknowledge that the action carries with it the possibility of conviction of a crime.

Legal aspects of the case

The case was interesting from a legal standpoint for several reasons.

The Judge's dismissal of the count of receipt of stolen property was the second time a jurist had been faced with the unauthorized transfer of a copy of a computer program in the form of electronic impulses over telephone lines. In both cases the judges found this act to be outside the purview of the penal laws affecting asportation (carrying away) of personal property.

The prosecutors felt hampered in their conduct of the case by the lack of directly applicable law. They were fortunate that the alleged theft had been interstate and thereby subject to federal jurisdiction and the federal wire fraud statute. Had the incident occurred entirely intrastate, the laws of the particular state involved might not have provided the source of a prosecutable offense.

The character of the property involved, software, exposed the prosecution and the defense to the complicated and confusing issue of identification and protection of proprietary interests in software. This issue, as discussed above, was also a source of stated misunderstanding by Brown.

From a security standpoint, the methods of perpetration and detection were of value in determining how to make computer systems more secure, both technically and operationally.

CONCLUSIONS

Conclusions reached from a study of this incident include:

1. There is a need to educate prosecutors and defense attorneys about computer abuse. This was not the first or only instance of compromise of a computer system and a theft of a program and it was not the only instance of such a compromise being made purportedly not for gain. It would have been helpful to each side to have known of other occurrences.
2. Prosecutors and law enforcement officers need information about the environment and terminology of computer installations so that investigation and case preparation can proceed more independently of the victim's guidance.
3. Computer organizations need to know how to protect proprietary software, legally and physically.

* Official Transcript, pp. 88-89.

* Transcript p. 749.

4. Computer professionals need to be aware of their legal exposure for appropriation for their own purposes of software not owned solely by themselves.
5. Computer organizations need to realize that security precautions are an ongoing concern and that procedures must be kept current to remain effective, particularly vis-a-vis current and former employees who know the system.

Federal policy and the future of computer communications services

by PHILIP S. NYBORG
Computer and Communications Industry Association
Arlington, Virginia

Communications policy has long been a matter of direct Federal concern, based on the government's responsibility to regulate the monopoly communications industry. As computer technology becomes increasingly reliant on communications services, and as computers become increasingly utilized in the provision of communications services, the Federal government is faced with difficult policy decisions in executing its mandate to regulate communications services while at the same time refraining from regulation and inhibition of developments in computer systems.

In the intersection of the computer and communications industries, there are major new markets emerging for data communications services as well as hardware which arguably has both data processing and communications functions. Equally important, other regulated services which have traditionally been provided in paper media, such as postal service and banking, are now shifting to electronic form as electronic mail and electronic fund transfers. The technological possibility of all digital networks, in which a wide variety of services including voice could be distributed in digital form under computer control, further complicates the problem of regulating monopoly communications carriers while at the same time maintaining a competitive free enterprise market in the nonregulated data processing field.

Incoming Federal Communications Commission (FCC) chairman, Charles D. Ferris, while affirming the FCC procompetitive posture toward the provision of certain communications services has recognized the scope of the new technological opportunities. Ferris was recently quoted in the *Washington Post* as saying "I don't think its Buck Rogers to conceive of a system in the very near future of homes and certainly businesses having not only voice communications with each other but access to data banks, even video communications" and citing the possibility of computer terminals in each home and business for transactions ranging from banking to ordering groceries.

The panel will address the present status of Federal policy, regulation and legislation impinging on computer communications, as well as relevant anticipated developments and their impact on the data processing field.

The discussion will commence with a brief overview of multiple regulatory jurisdictions within the Federal government which affect computer communications in their various forms, including the Federal Communications Commission, the Congress and groups within the Executive Branch. The panel will then focus on the major issues within these forums, beginning with consideration of issues currently addressed by the Executive Branch; of particular importance will be international communications, as well as the newly created office of the Assistant Secretary of Commerce for Communications and Information. Following will be two closely related presentations on regulation of the communications industry, as implemented by the FCC and the Congress. Discussion of the Federal Communications Commission will address the trend toward a pro-competitive policy and the distinction between communications and data processing which is being formulated in the ongoing FCC "Computer Inquiry" (Docket No. 20828). Current issues before the Congress will be discussed as an extension of recent FCC decisions, and particular attention will be given to the possible revision of the Communications Act of 1934 as well as other related legislation dealing with industry structure in the telecommunications field.

Computing careers and education

The Technical Area of Computing Careers and Education offers those attending NCC-78 a state-of-the-art view of topics including Professional Requirements and Educational Alternatives, Accreditation of Information Processing Programs, Professionalism and Professional Development, Career Paths for Women, and Computers in Early Education. Viewpoints will be presented as to what educational skills and backgrounds recent graduates should have as they enter positions in industry and government. Needs will be identified for a formal evaluation program that will accredit the offerings of particular institutions and programs, similar to accreditation guidelines for computer engineering programs. Treatments of obsolescence problems through professional development for the computing professional, including guidelines for defining and conducting an individual professional development program, will be covered. It will, also, be postulated that women must more carefully design their careers in information processing. Finally, calculators and microcomputers are now cheap enough so that preschools, elementary schools and high schools can afford to give students quite good access to them, and better training and education with them.

A treatment—Professional development

by FRED A. GLUCKSON
National Bank of Detroit
Detroit, Michigan

"There's something going on here
but you don't know what it is . . ."
Bob Dylan

PREFACE

In the mid-1940's, the most advanced technology around was the Hydra-Matic transmission. The conventional wisdom among us kids was that the Hydra-Matic was so complex that no single person understood it all. A look at its valve body, which directed hydraulic pressure along various paths to effect gear changes, seemed to prove this. But the logical complexity of this valve was roughly the same as today's single-bit binary adder circuit. And such a circuit is an inconsequential component of today's most advanced technology—as exemplified by the Intel 8085 microprocessor, which has 6,200 transistors, can execute 770,000 instructions per second, and is housed on a chip .164 inch by .222 inch—smaller than Lincoln's head on a penny! In only 30 years the frontier of technology has surpassed anything we kids could have imagined. Most of us in this room will be alive in 30 more years. Where can the leading edge possibly be then?

Next, let us consider the career of Albert M. Diederich at the Ridge Tool Company. Mr. Diederich assembles wrenches. He has been assembling wrenches for 45 years. In that time, Mr. Diederich estimates that he has built 25,000,000 wrenches![1] He is, by all odds, the world's ranking expert at his trade; there is no problem beyond his knowledge or ability; no one can teach Mr. Diederich "a thing or two." Can anyone in this audience claim such expertise? Not likely! This is the nature of a career in information sciences: ours is a field in which experts disagree, where terms are ambiguous, but in which our achievements have been profound. We have used computers, in the Viking space program, to design and build a radio antenna so sensitive that it can perceive the energy radiated by a lighted match held on the surface of Mars.[2] We have designed a computer program that plays world-class chess and has beaten David Levy, an international chess master, at the computer's forte—speed chess—but not yet in regulation tournament chess. Mr. Levy described this program at ACM 77 in Seattle. "Chess 4.6 is fantastic. Nine years ago I wouldn't have believed it possible. It doesn't make tactical oversights. You can't fool it. But it can't make a long-term strategic plan. If it could, it would be a grandmaster."

Meanwhile, back in retail sales, a clerk waves a wand and the cash register prints the item description and price while inventory control systems a thousand miles away are notified of the transaction. In the classical sense, this is a magic wand. But for us, the data processors of today, the technology of such an application is well within our understanding. Or ought to be. Unlike Albert Diederich, we have chosen a profession that will leave each of us hopelessly behind if we do not search aggressively and persistently to stay with our art.

INTRODUCTION

It is my intention to suggest a program of self-development, aimed both at remedying known personal deficiencies and at keeping abreast of new applications of computing technology. There are many opportunities for self-development and I will point these out. But it remains for the individual computing professional to take the initiative to set up a program for himself or herself and to follow thru. It will require a commitment of time, and in some cases, money. But how could personal resources be better expended than as an investment in one's future?

One's career may be affected profoundly, as follows: employee appraisal forms usually have a section labelled "Job Competence". Other sections relate to personal traits such as "Leadership Skills" or "Interpersonal Relations". It is difficult for adults to change basic personality attributes such as leadership skills. So there is not a great deal that we can do about low ratings in non-technical areas. But we have no excuse for continuing to earn low ratings in technical knowledge.

When a computer professional takes a new job, his first performance appraisal may be lower than usual because of the new skill requirements. But having identified these deficiencies and established a program to remedy them, subsequent appraisals should improve. So there is little excuse for one's career progress being limited by technical inadequacy.

One large corporation strives to channel five percent of everyone's time into technical training. This comes to two

and one-half weeks a year, or two hours a week for formalized training apart from reading journals. If your organization is similarly enlightened, so much the better. If not, your five percent will have to come from personal time. Surely no one in this audience surrounds himself with TV and beer in free time. I suggest that you do not reduce the time spent with family—that is more important than career. Rather, you should defer some leisure time activities and substitute the pursuit of your own professional development goals. If this is too much of a burden, you may be in the wrong profession. The one resource each of us has in equal measure is time. Other facilities are not so evenly distributed. Personal wealth is not, nor is intelligence or good looks. But each of us has exactly 24 hours each day to be allocated as he sees fit. A major factor in success is one's ability to manage time to best advantage. The old cliche is: "If you need something done, ask a busy person to do it." You should not schedule yourself to be constantly busy. Relaxation is important to physical and mental health. But you should schedule your relaxation—not just let it happen. Do not drop in unexpectedly on a busy friend and expect a warm welcome.

Make a list of things to do and the priority of each. The first item on your list should be "make a list;" then when you finish the list you can immediately scratch off the first task and you have made progress.

OBJECTIVE

Perhaps an overall objective for self-development would be to help us distinguish good ideas from marginal ones. Not all ideas work; not all products are successful. Remember Corfam? Du Pont invested a king's ransom in this synthetic substitute for shoe leather. They ultimately wrote off this investment as a total loss. Does Viatron ring a bell? Ten years ago this company set about building a full-function terminal to rent for $21 per month. A good friend of mine, a computer professional, used pencil and slide rule (remember those?) to show that it could not be done. Viatron ultimately went into receivership. It takes years for the marketplace to render these judgments. A computer professional may be able to use intuition and analysis to render an informed appraisal. As of this writing the Commodore PET computer is described by its Project Manager[3] as selling for under $600, with volume projections of 5,000 per month. Service is to be handled by the retailer. Is this "viable"? What about conferencing by computer? Will this happen? Here is Dolotta on the subject:

> "We believe that over the next ten years the potential market for applications aimed at such 'offices of the future' may well equal the value of all of today's business data processing applications."[4]

Structured programming and distributed processing are current buzzwords. The computing professional ought to be well enough informed to have an understanding, and perhaps an opinion of these concepts. It is not sufficient to have written the world's tightest routine for converting 1401 five-digit operand addresses to properly zoned three-digit machine addresses. We're not doing this any more. So broaden and deepen your understanding so you can distinguish between good work and bad work in your sub-specialty of computing.

DEFINITIONS

Let's define our terms. We are talking about training, not education. Education is the business of elementary schools, secondary schools, and undergraduate liberal arts programs. In my opinion, the goal of education is to broaden the whole person, to develop logical thought processes, mental and physical discipline, communications skills, self confidence, broad awareness, and appreciation. In short, education prepares one for training. Without education, training can be self-limiting. Pre-med is education, medical school is training. Medical school prepares a doctor to diagnose illness or perform surgery; but pre-med enables him to grapple with concepts such as "health care delivery systems."

There is a growing trend in the lower schools that troubles me—the introduction of "computer labs" in secondary schools, and even in primary schools. Teachers are proud of turning their students on to computing at such tender years. No wonder the kids are excited and involved, and have to be peeled away from the terminals when the lab session is over. Programming and game playing are fun. Education is not. I was recently a guest lecturer to such a group of bright twelve-year-olds. They listened politely as I discussed how computers are used in banking—but when the compulsory lecture was done, they bowled me over to be first on the terminals. To be active, not reflective, and I am afraid, to *do* rather than *think*. Shouldn't these teachers be more concerned about kids' education than their training?

In a similar view, Sesame Street was designed to hook disadvantaged kids and those who had no tradition of studying. It showed them that learning can be fun. It hooked lots more kids and blurred the distinction between learning and fun; teaching them, by inference, that if it isn't fun, don't bother learning it. Not so. Education can be drudgery. Tedious hours of studying the classics. Is this why today's Johnnie can't read?

What is professionalism? The answer, as Tevya said,[5] is very simple. I don't know. But the main components are: defined body of knowledge of high intellectual content, defined standards of competence, examinations, code of ethics, and disciplinary capability.[6] These are present to a greater or lesser extent in the field of information systems. But to *be* a professional, you must first *consider* yourself a professional.

Then what is professional development? It is the continuing technical training necessary to attain or maintain professionalism. At present, podiatrists in New York State are required by law to take 35 hours of training and be recertified bienially. There is quite a stir among the legal profession in the same regard. The state is now considering[7] whether to require periodic refresher courses in four profes-

sional fields: those of physician, dentist, and optometrist, in addition to podiatrist.

I do not believe that training in managerial skills falls within the boundaries of professional development. The former is very important for those in management or aspiring to it but it is a different sort of problem and will not be addressed here.

OPPORTUNITIES FOR PROFESSIONAL DEVELOPMENT

So much for defining terms. Now to investigate opportunities for professional development. Let us consider degree programs, employer-provided training, and self-development efforts.

Degree programs

Technical degree programs may be considered the highest form of professional development. On the other hand, graduate business programs are aimed more at personal or managerial development, and are not within the framework of this discussion as defined earlier.

In passing, it is interesting to note the proliferation of new degree programs in Information Systems. Nunamaker[8] found in a recent survey that 77 institutions are offering a bachelor's or master's degree in IS, MIS, MS, or some variant. Apparently universities are finding wisdom in the excellent report by Bob Ashenhurst.[9] The content of these programs is positioned between business and computer science, and in my opinion, within five years will surpass both the MBA and MCS in importance. One department head I lunched with recently is so besieged by inquiries from industry for his graduates that he is considering retaining a telephone answering service.

Degree programs in computer science provide a lot of theory and analysis, and a little skills training. They are at the leading edge of such disciplines such as systems software for minicomputers, but they lag the user community in others, for example manipulating large data files. Thus an evening degree program in Computer Science may be undertaken as professional development by an applications programmer who aspires to work in systems software, rather than in systems analysis or management.

University Computer Science programs, while theoretical, provide the student the basis for understanding (and rendering value judgments) on technological advances. So a few evening university courses from the Computer Science curriculum may be a useful means of professional development even for someone not wishing to pursue the degree. Many colleges and universities offer Computer Science extension courses in non-campus locations for the convenience of computing professionals who are employed full time. As just one example, the New School for Social Research in New York offers a wide selection of evening certificate courses in computer science with a practical orientation—such as OS Debugging and Advanced Systems Analysis.

Most employers pay or reimburse tuition for job-related courses if good grades are attained. Bell Laboratories and other enlightened companies, as well as universities, may grant sabbaticals to staff members to pursue advanced degrees or research projects. There are a wide variety of computer-related professional development programs available thru colleges. The student must anticipate a major investment of time to attend class and to study—time away from home and family—but as with a financial investment, the return is proportional to the risk.

Employer-provided training

The employer benefits in many ways from offering good technical training to its computing staff. Obviously, technically proficient people work smarter instead of just harder. But also, turnover is reduced because professionals want to stay with an organization that offers technical growth. Recruiting is easier for the same reason.

The mere availability of in-house training facilities is not enough. It remains for each individual to take advantage of the opportunities afforded him. Indeed, the company should adopt an active rather than passive role by scheduling and monitoring attendance.

Technical training takes many forms depending upon size of company, rate of change in its computer installation, and degree of enlightenment. In a very large company or one with rapid growth or high turnover, classroom training is the mainstay. In a medium-sized or more stable installation, self-study courses on videotape are appropriate. And smaller or less advanced shops may rely strictly on sending people to external courses when and where they are offered. There is a place for all these modes of professional development in the typical company. If yours does not offer formal training, lobby for its adoption. Here are basic guidelines for an internal Professional Development program.

Establishing in-house training

It is best that job descriptions and responsibilities be formalized. If written job descriptions do not exist it could take many months until they are constructed to everyone's satisfaction. In any event, knowledge requirements must be defined for each position whether from job descriptions or from hearsay. "Before you prepare instruction, before you choose material, machine or method, it is important to be able to state clearly what your goals are."[10] Must Project Managers use Critical Path Scheduling Techniques? Are Senior Analysts responsible for discounted cash flow, or for statistical sampling methods? Do Lead Programmers prepare Warnier charts?

Next, sources for each level of knowledge are identified by reviewing multimedia courses or evaluating vendor courses. Alternatively, specific courses can be developed in-house—but there are three disadvantages to such courses. First, they are very expensive. For an experienced teacher to develop course material can require ten hours of prepa-

ration time for each hour of classroom time. For an inexperienced teacher working on new material the ratio can jump to 100 hours to one! Second is the effect of obsolescence. Consider a course in direct-access file design. For the course to be useful for programmers and technical analysts, it should be quite detailed and relevant to the facilities available. Student exercises should be directed toward the present installation. But when the direct-access devices or the installation access methods change, such training is instantly rendered out of date. The paradox is—the more specific the in-house course, the shorter its useful life. And a third disadvantage is the difficulty of assembling enough students and a qualified instructor in one place at one time.

Whatever the source of recommended courses, each job should have a list of recommended knowledge associated with it. Then present skills are rated and inventoried. Each member of the professional staff is asked to judge his proficiency in the technical skills important to this job—for training purposes only. New hires are asked to rate themselves similarly. Now, with skills required and skills available known, the training required by each individual can be planned in a cooperative effort between staff member and his supervisor. Another valuable resource in such a meeting is the systems project plan, which identifies the assignments each person will work on. These meetings to plan training should be held at least once a year. It is during such a meeting that the staff member should communicate his own goals for specific technical training. And it is very important that training be scheduled for specific times and should be considered just as important as project work. Training must not be allowed to slip because of problems on another assignment. Progress and performance in training must be measured and reported to management. It is not fill-in work and is not so treated by far-sighted organizations.

As stated previously, about five percent of available time should be spent in training. And about two percent of the department's salary budget should be allocated to out-of-pocket training costs. This sum will typically cover the cost of purchasing one or two multi-media courses as well as sending a number of people to external courses. Of course, the larger part of in-house training should use existing classroom or video courses at no out-of-pocket cost. The organization that is just launching in-house training should consider a rental agreement rather than purchasing courses outright. A more elaborate discussion of the entire in-house training process is available[11] and will not be repeated here.

Employer-provided external training

External training takes many forms. Obviously each vendor offers courses in use of its hardware and software. Unfortunately, some of the mini-computer vendors are suffering from growing pains as their marketing success surpasses their training capability.

Many private training firms offer good courses in systems methodology. Brandon Systems Institute, Ware Associates of Hudson Massachusetts, and Control Data Corporation's Institute for Advanced Technology come to mind.

One may measure the state of the economy by counting the number of such brochures that fill the in-basket. In lean times, external training is the first budget item cut by most user companies, so the provider companies go into suspended animation.

Even employers who make extensive use of in-house training facilities will continue to send selected people to external seminars. There is value in having Project Managers, for example, meet and socialize with their peers from other companies. They may pick up much of value from the successes and failures of other companies. And they may find out that things aren't so bad in their own shop after all.

The alert installation will collect, study, and file, written evaluations of all external (and internal) courses to be used in future planning. And the progressive installation will write the training firm to convey negative or positive views by attendees. This is appreciated by the vendor and helps to improve the breed.

Another form of external training that must be mentioned to this audience is the Professional Development Seminars offered by ACM, IEEE, DPMA, ASM, and other computer-related professional societies. Such seminars are offered both at the national and local chapter level. They are usually aimed more at benefiting members than at making money, and are usually less expensive and may be less formal than for-profit courses conducted by nationwide firms. Earlier in this paper, an annual training plan was discussed. Professional Development Seminars are rarely announced that far in advance. So the burden is on you to bring to the attention of your management any external PD seminar that supports your personal professional development plan. If no funds are available to pay the fee, ask for time off and pay it yourself. It will probably be tax-deductible. Under a liberalization of regulations, costs of training required to maintain or improve skills on the present job are a deductible expense (but training for a new job is not).

SELF-DEVELOPMENT EFFORTS

We have touched on the professional development offerings of universities, and have seen what employers can and should provide. Now let us consider what the individual can do for himself.

Establish a self-development plan

Consider your circumstances to the following questions:

1. Training taken in the last year
2. Books read in the last year
3. Current periodicals I read
4. Tasks that I perform on my present job
5. Personal qualities important on my job
6. Changes that I can see in the future
7. My strengths and weaknesses
8. Goals within one year
9. Goals beyond one year
10. Specific plans to accomplish these goals

Such plans might resemble the following:

(a) Read Weinberg's *An Introduction to General Systems Thinking* before September.
(b) Subscribe to *Computerworld* and *EDP Analyzer;* cancel subscriptions to *Sports Illustrated* and *Gourmet.*
(c) Begin a word list of all unfamiliar terms and their meanings. Carry this list and refer to it.
(d) Discuss ideas found in technical publications with coworkers. Practice active listening by restating your associate's view, in your own words, to his satisfaction.
(e) Find a professional development seminar on distributed data base.
(f) Seek an opportunity to give a short guest lecture on minicomputer applications in process control.

You should monitor progress on this plan and renew it periodically, at least annually. It is up to you; no one can do it for you.

Sources of professional self-development

Learning preferences and abilities differ. In our profession are found scholarly people and those who have come "thru the ranks." We differ in age, in temperament, and in experience. Thus training methods should differ. Some students respond favorably to video courses while others find them boring and would prefer to learn by studying reference manuals. Sources of the latter are well-known, and fortunately the former have also been documented.[13] The IEEE offers a wide variety of self-development opportunities to members, although not all in computers. For example there are self-study courses in engineering, on such subjects as Field Effect Transistors, and Digital Instrumentation; self-study courses in management, for example How to Start Your Own Consulting Business; approximately 100 field courses (to be held by your company); correspondence courses; and speed reading.

Many people learn by doing. "What I hear, I forget; what I see, I remember; what I do, I know." How to better learn about microcomputers than to build one? An IMSAI 8080 1K kit currently sells for $650, a saving of $350 over the assembled price. An expensive and time-consuming lesson, but one guaranteed to produce expertise and build a foundation for the future. (The 8080 chip, by the way, came out in 1974 priced at $300 in OEM quantities—at this writing, Radio Shack sells it over the counter for $18!)

Microcomputers may very well provide the at-home professional development wave of the future. Computer-assisted instruction has not yet become cost-effective except in special situations. But the Video Disk technology has prospects of providing huge quantities of read-only software, including course material, to microcomputer users—eliminating the traditional CAI requirement for large CPU connect time. The ACM Professional Development Committee is watching developments carefully.

Establish a reading program

Beyond any questions, the computing literature is overwhelming. The *ACM Computing Reviews* subscribes to 240 periodicals! Only a small fraction of their articles, and only a limited number of textbooks can be reviewed by *Computing Reviews*. But their staff of editors and reviewers does an admirable job—and the publication can be of great benefit to the reader. Clip or copy reviews of importance to you. File them and track them down when you have time or when your need is more urgent. Become a source of resource material to your associates. How can anyone be considered a professional who does not stay conversant with the literature of the field?

Each of the professional computing societies has a lead journal, most also have many special interest journals. They are far too numerous to list. Everyone ought to pick a few favorites and set aside time to scan them, marking or clipping articles to be read. Mine are *Datamation, Computerworld, EDP Analyzer, ACM Computing Surveys, IEEE Computer,* the *IBM Systems Journal,* and *Scientific American.* The September, 1977, issue of *Scientific American,* devoted to microelectronics, was a revelation to me. If sufficiently enlarged and studied, the Boolean logic of SLT circuits can be seen!

The *Honeywell Journal,* edited by Bob Bemer, had a fine format. It included microfiche in the inside cover, was multilingual in part, was printed on fine paper of the European standard size, and published significant articles with high quality graphics. Unfortunately it perished in the economic crunch a few years ago.

Take a rapid reading course and practice what you learn. One MBA student, overwhelmed with reading assignments, sat under the clock in the library and turned a page every time the clock's minute hand clunked. Even if he had not quite finished both sheets, he had the sense of the material. And 60 pages an hour is not a bad pace. Technical material may require more time, particularly if you own your books and write comments in the margin. There are several book clubs for computing professionals.[12] Membership will force you to set a reading schedule. However, many people believe in selecting their own books based on published reviews and personal recommendations, rather than reading books selected by committee. Discuss your reading and your opinion of it with your friends.

Other individual approaches

Your attendance here suggests two things: that you are a member of one of the AFIPS constituent societies, and that you are interested in professional development. If so, attend your evening chapter meetings. Practice your active listening skills on the speaker. Take notes ("what I do, I remember") and ask questions. Use the coffee or cocktail session to learn more, not to tell how you blasted out of a sand trap.

It is difficult, but useful, to find out what your coffee partner knows that may be interesting to you. Recently I learned, from a stranger, that the IRS master file consists of

1300 reels of tape! Such hearsay may not be totally reliable, but as a computing professional you have learned to render value judgments on incoming data.

Keep an audio cassette player in your car. Listen to speeches[14] you were unable to attend. Note-taking is a little more difficult here.

CONCLUSION

This paper has presented a variety of approaches to professional development. They range from formal university programs, to the semi-formal company courses, and the informal, personal endeavors in technical training. It should be apparent that there is enough variety and quantity of options that no one need to suffer from the malaise of creeping technical obsolescence. But it is an individual decision to construct an action plan and to persevere. No one can do it for you. Good luck!

DISCLAIMER

Professionalism in data processing management

by DELBERT W. ATWOOD, JR.
Utah State Board of Education
Salt Lake City, Utah

INTRODUCTION

Where do you stand as a member of the information processing community when the discussion turns to defining data processing as a "profession?" (Webster says, "One that engages in a pursuit or activity professionally." Webster also says, "Characterized by or conforming to the technical or ethical standards of a profession.") Professionalism is, "The conduct, aims, or qualities that characterize or mark a profession or a professional person." Black's Law Dictionary defines profession as:

> A vocation, calling, occupation or employment involving labor, skill, education, special knowledge and compensation or profit, but the labor and skill involved is predominantly mental or intellectual, rather than physical or manual. The method or means pursued by persons of technical or scientific training.

Black includes the following clarifying paragraph for the definition of a profession.

> The term originally contemplated only theology, law and medicine, but as application of science and learning are extended to other departments of affairs, other vocations also receive the name, which implies professed attainments in a special knowledge as distinguished from mere skill.

Occupational sociology literature suggests that modern technologically oriented societies indicate that the distinction once made between "Professional" and "Non-Professional" is blurred or vague.

ATTRIBUTES OF A PROFESSIONAL

In my opinion, the attributes of a professional are many. The qualities exhibited by a data processing professional place him/her above the "run of the mill" person. The professional:

- is knowledgeable, yet not overbearing
- listens, but does not always comment
- offers advice, but does not dictate
- works with people
- constantly strives to maintain technical competency
- is respected by his/her actions
- has extensive training in a specialized discipline supported by a body or research and theory
- supports a "code of ethics" developed by an association of colleagues
- performs a unique and essential service recognized by the community
- exhibits strong personal responsibility for his/her judgments and actions.

Individuals who score high on a professionalism measure exhibit a strong desire for implementing professional values among their peers.

One of the largest obstacles of any attempt in defining professionalism in data processing management is the lack of definite criteria as to what makes up a "professional" computer person. Some of these criteria might be:

- Education
- Knowledge
- Ethics
- Communication Abilities
- Public Relations Abilities

As we look back on *Webster's* definitions and characterize them as to our own particular situation, can we say that we are truly a professional, or merely standing on the outside looking in. Do we belong just for the sake of belonging, or do we belong so that we can be recognized as an individual who is knowledgeable about the profession and can be helpful to our management and companies as a result.

Leonard I. Krauss, in his book, *Administering and Controlling the Company Data Processing Function,* has a section on professionalism in the field. He states, "There are a number of factors which are characteristic of a profession. Rather than undertake a debate on whether data processing is a profession, the time could be better spent by discussing professionalism as it pertains to data processing. The aims and standards of data processing have been the concern of several data processing organizations, and also the USA Standards Institute."[3]

HOW TO ACHIEVE PROFESSIONALISM

A manager achieves a professional status from the actions of his peers and those who work for him. He is respected for his decisions. He is highly regarded by those who work for him and also those for whom he works. When a man is looked to for advice and counsel, and has gained the respect of others regarding the many aspects of the business he is engaged in, he is on the way to achieving the professional qualities described above. An individual can enhance his professional appearance through his training, education, association with others, his actions on the job as well as his personal life, and the activities to help others.

We, as managers of the information services areas of our companies or shops, have an obligation to our company, our management, our fellow employees, our staff, and also to ourselves to help make people understand our methods and procedures of operation, to advise our management so that sound, honest decisions can be made regarding our realm of responsibility. We must educate ourselves to be knowledgeable in the area of our pursuit or activity. We must work together to disseminate our knowledge to fellow workers and management, to realize the maximum benefit from our education. We must be loyal to our companies or firms, respecting the trust vested in us by them. We must conduct ourselves in an ethical manner at all times regarding the information processing profession and to any professional organization to which we belong. Your attitudes and actions mold for you the things that you are and the way other people see you.[1]

Are you a professional? Do you belong to a professional organization? George R. Terry, in his book *Principles of Management*, states "Active membership in a truly professional group can assist management development through attendance at meetings, informal discussions with other members, and the reading of the association's journal or official publication. Some associations stress individual self-development; others promote workshops, seminars and study groups. These experiences help to promote the important "develop yourself philosophy." Generally, most companies or employers wish to have their employees the most knowledgeable individuals in regard to their expertise. In order to accomplish this, they send them to schools and allow them to belong to groups that enable them to meet, share ideas, experiences and needs. They, in most cases, pay for the memberships and expenses. Companies and employers provide these additional fringe benefits to encourage professional development. This professional development should enable them to do a job better, quicker, and generally at a lesser cost.

When you are knowledgeable about a subject, your specialty, and you discuss and share this knowledge with your management, your peers and others, you become a professional. This recognition comes from others and can be helped by your membership in a professional group and your participation in all of the activities the professional group can provide.

Professionalism is sometimes associated with an honor society, or a certification of one type or another. This could also be in the form of an examination to license, to allow the individual to practice their specialty. This is characterized by the state boards to allow an M.D. to practice; the Bar to allow an attorney to hang out his shingle; the C.P.A. examination to permit the accountant who passes it to certify that his examination of a set of books is appropriate according to standards and acceptable.

Data processing, through DPMA, has constructed the certificate in Data Processing (CDP) as a test of knowledge in management, systems quantitative and qualitative analysis, programming, and other areas. Many professional groups joined together to form the Institute for Certification of Computer Professionals (ICCP). These groups recognized the need for a professional certificate to assist the individual in his personal development, recognition by his peers, his company or employer, and his development as a professional.

Many of the organizations have by-laws, codes of ethics, guidelines for professional conduct in information processing, and other written vehicles for the individual to follow to assist him in becoming a professional. Adherence to these precepts certainly would help us to be recognized as following a professional path.

Where do you stand in your own professional development and standing in your company, and within the organization to which you belong?

Are you going to classes to get your degree? Are you getting an advanced degree? Are you attending seminars to further your knowledge in your specialty subject matter? In our ever expanding field where specialized knowledge is mandatory, those individuals who demonstrate superior competence in the application of that specialized knowledge reap the rewards of progression.

The individuals who are looking for management recognition and who are looking for a greater professional posture in their work, may be selfishly motivated, but in the long run, they are on the road to becoming a professional. The knowledge and association developed in the process generally stimulates the individual to be more reflective about his work, and approach problems with a greater understanding and to bring to bear the new techniques and concepts learned to satisfy those problems.

Do you do your part? Are you becoming the professional your management would like you to become? Do you belong to a professional group, but never go to the meetings? You read they have excellent seminars and workshops, but when was the last time you attended one of them? Do you get a publication from the association? When was the last time you read it from cover to cover, or even selected articles? Can you quote from any of the articles about a particular subject matter that is coming up in a management committee meeting tomorrow? Can you refer to other publications, books, seminars, workshops, etc. to assist in helping to make management decisions?

Professionalism in data processing is beginning to emerge. It still may take a while to accomplish, but the tools are there, and if the right person or persons come along to guide the tools, the guidelines, ethics standards, methods of control and other details will be pulled together and be recog-

nized by all information processing personnel and organizations, and will be thus enforced by them or their peers who make up the organizations. The profession is growing by leaps and bounds, and some restraint or control is needed before it gets out of hand.

CONCLUSION

I believe that professionalism makes a difference, because an individual who is looked up to, respected by his associates and others, who exhibits the traits that place him a bit above, has a better chance for success and overall happiness in his life. A doctor, a lawyer, or an engineer work very hard to become educated and licensed to practice their specialty; likewise, data processing managers work very hard to become educated and knowledgeable in their specialty. Licensing is a way off, but maybe it will become a necessity before professionalism is a reality, certification is here now and is a step toward achieving the recognition and respect of our employers, our employees, and our peers.

Professionalism—A question of semantics

by EUGENE B. SMITH
U.S. Department of Agriculture
Beltsville, Maryland

INTRODUCTION

The topic of professionalism is of crucial importance to the ever-increasing group of individuals dedicated to the design, production, dissemination of knowledge, and application of the computer. There is a strong desire for professional recognition by large portions of this group. This paper focuses on the need for an appropriate definition for a computer professional. Questions are raised concerning the various requirements and related responsibilities which should be associated with recognition as a professional. The element of controversy over numerous issues will serve to clarify, if not resolve, the parameters which outline the future data processing professional.

PROFESSIONALISM DEFINED

In order to establish a baseline from which this dissertation can proceed, there is some value in presenting a "Webster's" definition of terms which are of fundamental importance to the topic. These terms include the following:

- Profess—To practice or claim to be versed in (a calling or profession).
- Profession—A calling requiring specialized knowledge and often long and intensive academic preparation.
- Professional—Characterized by or conforming to the technical or ethical standards of a profession. (Participating for gain or livelihood in an activity or field of endeavor often engaged in by amateurs).
- Professionalism—The conduct, aims, or qualities that characterize or mark a profession or a professional person.

The term professionalism has different meanings to different people. Ralston[1] defined professionalism by saying that ". . . a professional is someone dedicated to rigid training rather than immediate self-gratification. As such, "professional" bespeaks not elitism but a state of mind."

In an attempt to define the term professional by example, it would seem that there are at least two distinguishable groups. The first group might be called the "learned" professional and it might be categorized as having demonstrated a profound knowledge or scholarship. This group includes the universally recognized titles of doctor, lawyer, and engineer. Their professional recognition is based on an attained level of knowledge in a specialized field; a certification that they have reached a specified level of knowledge; and legal registration which gives them the right to practice their profession within certain constraints.

A second group of professionals may be categorized as the "other" professionals. These individuals may be identified as being associated with the second definition for professional which was given previously. That is, we may consider that they participate for gain or livelihood in an activity or field of endeavor often engaged in by amateurs. This group would include the professional bowler, the professional boxer, the professional football player, the professional golfer, and others. In addition to professional athletes, we might also include the professional politician, the journeyman electrician, and the journeyman plumber. The professional athlete has recognition based on his level of ability in his chosen field. In most cases this status is governed by membership in a professional association. The professional trades normally require an apprenticeship associated with a trade union. Advancement to the journeyman level implies the attainment of a reasonable skill. In some cases, local governments require that a licensed journeyman be responsible for the quality of work performed.

It may be helpful to associate the "learned" and "other" professionals on a continuum. In terms of respect or service to society, we may place the "doctor" at the high end of the continuum. In terms of income or monetary reward, we would have to place the boxer at the first of a continuum. In the case of either the "other" professional or the "learned" professional it is possible to identify the credentials associated with their professional status. In the case of the computer professional, it is important to identify the credentials associated with the achievement of a professional status. In addition to other things, these credentials are meant to insure a minimum level of competency and adherence to certain standard practices. If suitable credentials or criteria do not exist, it is important that these be identified or established to the satisfaction of the individual, his peer group, his employer, and society at large.

ELEMENTS OF DATA PROCESSING PROFESSIONALISM

In addition to identifying the various factors associated with the achievement of a high level of professional recognition in the field of data processing, it is important to pursue the parameters or limits associated with each factor. It must be possible for individuals to work toward achieving the status of a professional and know when they have obtained it. Such recognition must extend beyond the peer group to the employer and to society as a whole. Once a high level of professional recognition is possible, it may be that many individuals in data processing may not be suitably motivated to try to achieve it.

Perhaps the first question to be resolved is why we wish to achieve a professional status. What is our purpose? Is it to satisfy some personal ego requirement which would allow one to be a member of an elite group? Do we wish to improve our monetary status within our group? Do we wish to improve the moral and ethical level of our peer group? Are we interested in improving our level of service to both our employer and society as a whole? We are associated with the use of a technology which can have awesome implications to all of mankind. It is important to give consideration to the underlying motivation for our desire for professional status.

The term profession implies the existence of a certain level of specialized knowledge. One might question the make-up of this body of knowledge and how it can be validated. The Institute for Certification of Computer Professionals[2] identifies the content of the Certificate in Data Processing (CDP) examination as containing sections on Data Processing Equipment, Computer Programming and Software, Principles of Management, Quantitative Methods, and Systems Analysis and Design. The CDP eligibility requirements consist of the equivalent of 60 months full time related experience. An academic alternative allows a substitution of designated academic work for up to two years experience. This sets an example for a test that, to some extent, validates a level of knowledge at one point in time. Is this "the" common body of knowledge which the computer professional should have? Are there several specialties as there are in medicine or engineering?

If we could assume that this is "the" common body of knowledge that is desired and that the eligibility requirements are suitable, there are still many other factors which must be considered. Is there a need for periodic re-certification? Both DPMA and ACM have Self-Assessment programs under way which should help an individual identify his weak points and provide references for correcting them. Continuing education in many forms is available on almost any topic. The mechanism for maintaining a current knowledge of the state-of-the-art is present but the verification vehicle is missing.

Consider the ethical implications of professional status and how they might apply to this situation. In terms of loyalty, Pletta and Gray[3] point out that ". . . the professional's primary loyalty may be to: (1) society; (2) his peer group; (3) employer or client; or (4) himself. Only if he is free to elect the first of these does society confer upon his peer group the status of a profession." Loyalty will greatly influence a course of action when a question of conflict of interest arises. Questions involving privacy and security are also related to ethics.

While each major professional group has a code of ethics associated with membership, one might question the adequacy of the requirements. It would seem that the enforcement provisions and mechanisms leave something to be desired. Even the old line professional groups such as the doctors and lawyers have great difficulty in adequately enforcing their respective codes.

The legal implications of professional status are primarily related to a licensing process. Municipal, state, and federal agencies often have a role in licensing. The various legislative groups must enact specific laws to create the license mechanism. Lord[4] goes to great lengths to distinguish between the licensing and certification processes. The licensing process must also have a sound basis for enforcement.

It is appropriate to identify the various players and their role in the question of professionalism. The list includes the following:

Academia—The majority of the formal training will be done in the numerous colleges and universities. These institutions have a responsibility to provide training in an accepted common body of data processing knowledge. The curricula must be kept current with the changing technology. In addition to a well rounded education they must attempt to instill a sense of responsibility, morality, ethics, and general professional awareness in the students.

Professional Groups—The role of continuing education carried out through professional meetings, quality publications and innovations such as the self-assessment programs is a primary responsibility of these organizations. Their role in certification, and/or some accepted vehicle for determining the minimum level of knowledge is crucial. An organization such as the ICCP, which receives wide support from most related professional groups, is needed to serve as the testing and enforcement agency. The professional group must strive to represent and provide a unified voice for the membership.

Employers—If a significant professional status is to be achieved, it must be recognized and supported by business and industry. This recognition could take the form of consideration in the hiring and promotion processes.

Governmental Agencies—In the event that some form of licensing or registration is appropriate, the government agencies would be expected to establish the requirements, procedures, and control mechanisms for enactment of legislation.

Society—If society does recognize a professional group through general acceptance and the enactment of legislation, it has the right to expect a high level of moral and ethical responsibility. Society also has the responsibility to speak out when the actions of the professional adversely affect segments of the public.

The Individual—When an individual achieves the status of a professional, he must accept certain responsibilities along with the related benefits. Some of these responsibilities are legal and some are social. In the event that he fails to meet the responsibilities, his peers must be willing to take appropriate corrective action.

Each player has a role and associated responsibilities in progress toward professional recognition for the Data Processor. The failure of any player to assume his proper role and responsibility will impede the progress.

SUMMARY

Professional status will be achieved in the data processing area. The speed and degree to which this is accomplished will depend on the dedication of the individual and his level of support for the data processing professional societies and related groups.

Continuing education opportunities—A mark of a profession

by ROLAND D. SPANIOL
Eastern Illinois University
Charleston, Illinois

INTRODUCTION

Authorities indicate that one of the marks of a profession is the availability of continuing education to its members. Education that will tend to keep the members current with their technology and skilled in applying it in their work. It seems reasonable this should be a requirement of information systems if it is to be designated a profession.

AN INTERPRETATION OF PRESENT CONDITIONS

Educational products for people in information systems occupations come from a variety of sources including hardware manufacturers, software houses, government regulated industries, universities and colleges, profit motivated schools, businesses, etc. Based on the large number of advertisements in the mail each day, it is easy to identify the variety of educational offerings that are available. There are many; they are offered in many big cities; and they cover a wide range of topics.

The present situation with respect to educational offerings is summarized in the following paragraphs.

The enormous number of group and self-instructional courses presently on the market cover the majority of the subject areas revealed in the DPMA Education Foundation's "Survey of Educational Needs and Desires."[1] For example, 25 of the 34 most frequently mentioned subject areas in the survey are covered by one or more current promotional brochures.

Is the demand for these courses so great that the needs of the information systems practitioners cannot be met? Is the demand being driven by a desire on the part of the information systems practitioners to be professional? Do you think the courses would be as heavily advertised as they are if this were the case? In short, most of what the information systems practitioner says he needs is probably available; but to be blunt, much of it is probably the "paper tiger" variety.

At the present time prospective registrants have no feasible way of evaluating the quality of an offering beyond the general reputation of the firm that markets it or the personal recommendation of past participants with whom they may have had some chance contact.

Many private educational offerings are priced well beyond the reach of those who probably need them the most. This unfortunate situation is due, of course, to the high cost of producing and delivering an educational product in combination with too few buyers spread over too many sellers.

To summarize present conditions, it can be said that most of what information processing professionals say they need is available. It may not be in the precise form they would like it to be, but it is available. Their problem is to find it among the plethora of offerings while avoiding poor quality and figuring out a way to pay for it.

If it is true that the information systems practitioner's educational needs can generally be met with current offerings in a variety of big cities, but that the cost is high, what is the solution? The one obvious solution that comes to mind is to cut the number of offerings, teach to a larger group at a time, and lower the tuition for each student. Those of you involved in higher education in recent years will note this is not an original solution. Those of you involved in offering the courses from the private sector may be curious how this can be accomplished.

EVALUATION TECHNIQUES

What I am suggesting is not new either, it is supply and demand aided with market analysis, evaluation of the offering, publicity, and a booking service.

Market response to an educational offering is a good indicator of the worth of the offering. If the course is popular and makes money, it can be repeated; when it loses its appeal, enrollments decline, and profit wanes, it will be dropped. This is not an unknown phenomenon (except maybe in public education). As a matter of fact, for educational offerings from the private sector it is principally the law of supply and demand that decides whether a course is to be repeated. Demand and enrollment are the required measures of the quality of the offering.

Reaction to an educational offering is a commonly used indicator of the quality of the offering. The technique is familiar to you; the attendees each receive an evaluation form near the end of a course and the attendees rate the presentor, the presentation, the content, the facilities, etc.

Since it is easy to do and results are quickly available, it is often used with market response as the way to improve the offering, to determine whether or not it should be offered, which instructor is getting the best evaluation, type of facilities most desired, etc. Later, you will see that it leaves room for improvement as an evaluation instrument, but it is an important measure of how well the program was accepted.

Learning that has taken place because of an educational experience is a better measure of an educational offering. For this situation, suffice it to say that learning is the ability to recall a concept, knowledge, technique, or item of information in a testing situation. Comparing reaction to learning, it can be seen that learning is a better measure of the success of a program than reaction because with learning we know that the program message is getting through to the enrollees.

Learning is more difficult to measure because if we are to be precise, we must test before we teach and then test after we teach so we can develop a statistical correlation and/or confidence level. Because it is more difficult may be the reason we rarely see testing done in courses offered by the private sector. What do you think?

Behavior changes in an individual that are perceptible to others as the result of an educational experience is an excellent measure of the value of that experience. But, measuring behavior changes is much more complex, difficult, and costly than measuring learning or reaction. It usually requires experts in testing, is usually administered to a special group or groups at a time, is usually done on contract, etc. Though difficult, measuring behavior changes is certainly a valid evaluation process and should be considered in special situations.

Results is what everyone wants. Why not measure the contribution of educational programs based on whether the enrollees get satisfactory results from implementing their new found knowledges, techniques, skills, etc.? Probably because results are more difficult to measure than market response, reaction, behavior, and learning combined. Not only that, but it is difficult to be sure that the results achieved are related to the instruction. Much more work needs to be done relative to measuring results.

IMPLEMENTATION OF A NATIONWIDE PROGRAM

Catalog of programs

Initial efforts should be directed at facing the formidable tasks of identifying programs and materials currently in existence that will meet the members professed educational needs. Indeed, the greatest contribution may be in seeing that an ongoing cataloging process is set in motion to identify to the membership where and when they can enroll in programs they feel they require to keep them abreast of current technology. A catalog of these program offerings could be made available on a subscription basis to libraries, businesses, individuals, etc. In order to be kept current it would have to be updated no less than monthly. The listings should be complete with course outline, presentor, dates, places, costs, etc.

Booking service

A natural byproduct of a catalog of programs is a nationwide booking service, a centralized office where persons could enroll in the courses of their choice. This office could be the central point for all tuition, enrollments, evaluation activities, etc.

EVALUATION PLAN

Evaluation of the programs cooperating in the project would be a major activity. It is recommended that reaction evaluation be the first method used. This method should be used for all educational offerings made a part of this service. The courses in the top 10 to 25 percent should be given special publicity such that they would be widely recognized as popular courses.

As the project matures, the testing for learning process should be initiated. Attempts should be made to see if learning does take place. In the programs where learning is greatest, the courses should be given special publicity so they would become widely known as good programs to take to learn the needed information.

In some special cases, attempts should be made to determine changes in behavior. Because this evaluation method would be difficult to implement and would have marginal influence on this project, it will not be dealt with in this paper.

Results evaluation is an interesting method and in a broad sense could make some real contributions on a nationwide basis. Initially, or in the foreseeable future, there does not seem to be much results evaluation can do for this project and will not be dealt with in this paper.

On a nationwide scale, however, it would be interesting to see if the information systems professionals could identify the knowledges of the citizens about an issue such as privacy. Then, after implementing a large scale public education program on the issues of privacy, follow this up with a post test. Enough said.

WHO COULD MANAGE THIS CONTINUING EDUCATION PROJECT?

Possibly the DPMA Education Foundation. Or maybe any of the professional organizations. How about AFIPS? Perhaps because of my prejudices, I think the DPMA-EF is best suited for the job. They are an IRS 501 (c) (3) not-for-profit corporation. They have no members, and they were organized with the major objective of providing education to the information systems practitioners. Why not let them know how you feel about having them sponsor such a project.

WHAT WOULD MOTIVATE COOPERATION WITH THIS PROJECT?

Have you ever sat through a two or three-day course or a semester one for that matter and felt you were wasting your time? Do you think that experience was unusual? Would you like to do something about it? Of course, we have all had bad experiences on occasion. And, if there was a formal process where we could input our thoughts about a course, we would have done so. The primary motivation for an individual to cooperate in the evaluation process is improved education. The more information systems practitioners we can get to evaluate the course offerings they take, the better chance we have to weed out the less effective courses.

Getting cooperation from the presentors may initially be more difficult than getting cooperation from the individuals taking the instruction. After all, what is in it for the presentor? Of course, it depends upon the management of the project, but I would hope the presentors would soon see the merits and become the proponents of the process.

The project incentives which will engender presentor participation will be positive incentives. If the project is to be successful, the presentors must want to participate, must strive for the opportunity to be listed in the catalog, must encourage enrollees to participate in the evaluation, etc. What will encourage this eagerness?

The possibles include the following:

An honor roll of blue ribbon presentations. A panel of judges selected by the participating presentor organizations would select a limited number of offerings for special recognition. The top two or three presentors would be selected from this group for a special award or prize.

The opportunity of participating in a cooperative nationwide publicity activity. Through advertising in the trade press and other publicity, the offerings of the cooperating presentors would be made available to the information systems practitioners.

A catalog of the offerings of all the presentors. The listings would be by presentor organization, by subject, by city, and by date, for example. This catalog would be made available on a subscription basis. The subscription price would be low enough to be attractive to public libraries, companies, and certain other training organizations, and governmental agencies.

The opportunity of participating with experts in the process of developing evaluation techniques. It is anticipated that the number of presentors involved would be great enough that they could employ testing specialists to work with them on the evaluation processes.

Altruistic as it may sound, I hope some of the presentors would want to participate for the simple reason that they would like to improve their offering. Just because they want to do a better job.

Then, there are other kinds of reasons. Some information systems practitioners would like to show that they have the trappings of a professional. These might include a college degree, a certificate such as the CDP, and some would even prefer a license to practice.

In any event, it seems reasonable that if a profession offers continuing education opportunities to its members, its members may want to have a formal method of showing they are taking advantage of this education.

There is such a system where courses are evaluated and are then assigned whole or fractional units of instruction. These units are called Continuing Education Units and are known as CEU's. It seems reasonable the programs cooperating with this project could be dealt with in a similar fashion and the record keeping for the participants could be kept as part of the project.

SUMMARY

In this paper the surface of an idea has been presented. What we need now is someone who wants to develop this idea into a reality. I hope you will agree that there are several prevailing reasons for our industry to formalize and strive to improve the continuing education aspects of the industry. We in the industry will be the last to know we are in a profession or when we became a profession. Let's make sure we have taken every opportunity to be as professional as we can be now that we are a part of that group.

So you think you are a professional?

by G. GARY CASPER
Weber State College
Ogden, Utah

INTRODUCTION

The human ego provides continuous opportunities to explore the richness and variety of human perception. It is capable of excruciating truth and insight as well as delusions of grandeur that obscure truth and reality. The maturity of an individual can be defined in relation to his ability to differentiate between these extremes.

The computing practitioner, being human, is no exception. His existence in a rampant technology substantially lacking established codes of standards, conduct, and practice accentuates his capability to delude himself and makes more difficult a clear understanding of the reality of his experience in a complex environment. He can to a large degree establish his own criteria of accomplishment, yet must feel some concern of exposure as he realizes the effects of the rapid change forced upon him by his technology.

This paper postulates two resulting classes of behavior observed in the industry, one which could provide considerable benefit to the individual in coping with his anxieties while the other appears to be counter productive.

The first category can be described as behavior reflecting a desire to be identified as a "professional" and as such be associated with practitioners characterized as possessing competence, integrity, contribution, and esteem.

The second category represents a potpourri of behaviors generally designed to avoid exposure of the anxieties experienced from the self-doubt engendered among those responsible for the implementation and control of rampant technological change.

The purpose of this paper is to investigate the current level of maturity in the industry which has been defined as differentiating between reality and protective delusions, and to make recommendations upon the conclusions drawn.

One cannot but be impressed with the frequent and pervasive use of the objective "professional" in reference to the many authors and speakers represented in the trade press and at various computing conferences. It appears that the proverbial "Everyman" considers himself a professional although considerable debate exists as to exactly what is the meaning of the term. In fact, one might express curiosity at the apparent egotism evidenced in the employment of the term. While clearly proposing their own professional status, most express serious doubts about the credentials of any others. What then are the essential criteria of a professional?

To begin, professionalism in the computing industry cannot be understood unless one first clearly understands what a profession is generally and the environment in which the professional finds himself.

The age in which we live has been characterized as one suffering from "Future Shock," a term defined by author Alvin Toffler as the effects of ". . . too much change too fast." As our world, environment, institutions, our very lives and personal values reel under the onslaught of pervasive change, we respond in dazed, often ill-defined, and inadequate ways.[1]

As practitioners of the computing arts, we are thrust into the forefront of this technological revolution facing the constant realization of technological obsolescence. Ours is a young industry with few if any age-old standards or solutions to an ever increasing complexity of opportunities and challenges. How are we to survive for a career that may span fully four decades?

Certainly education is offered as a possible solution, but who is to prepare and disseminate appropriate state of the art courses for an increasingly diverse and specialized body of knowledge? Are we not facing a dilemma of enormous magnitude whose solution will require the resources and commitment of significant numbers of us? What will be the cohesive force to organize and coordinate our efforts?

Has not our answer been to some extent to join together with peers of common interests to develop programs, materials, and vehicles with which to attack such problems? In fact, are we in this regard much different from other industries which have experienced similar needs? I believe not, and anticipate the increasing need for a developing, responsible, and viable profession.

What exactly is a profession, or more specifically, a learned profession? To understand the concept, one can look to other so called professions for criteria. One of the more common is tradition. For example, the story is told of a doctor, engineer, and politician arguing about whose profession was the oldest. The doctor said there was little doubt that medicine was the oldest profession because humanity was preceded by the first medical operation—the removal of Adam's rib. However, the engineer objected arguing that engineering preceded medicine by virtue of the

great project of creating the world from chaos. To this the politician inquired, "And who do you think created the chaos in the first place?"[9]

While data processors may not have a claim to old age for their profession, it might be observed that many feel we certainly have a legitimate claim for creating chaos.

Perhaps some light might be shed on this matter by looking at the definitions of a profession and a professional.

The simplest definition Webster offers is that a professional is one "following an occupation as a means of livelihood or for gain." Such a definition qualifies virtually anyone and everyone. Somehow, though, the lack of distinguishing criteria diminishes the concept and leaves it less than useful.

Hardly satisfied, definition two catches the eye. Professional is . . . "pertaining or appropriate to a profession." Further investigation reveals that a profession involves . . . "a vocation requiring *knowledge* of some department of *learning* or science." Here at least are some minimal criteria beyond merely holding a position in the industry (i.e., knowledge and learning). A professional is one "engaged in one of the *learned* professions," and is also one . . . "RESPECTED BY THE PROFESSION."

In this more lofty view of professionalism, one discerns other criteria pertaining to . . . "professional character, spirit, or methods," and again, the . . . "standing practice, or methods of a professional as distinguished from an amateur."[10]

Clearly there is a world of difference between the perceptions of a professional conveyed by these later definitions from the extreme of mere employment.

One might conclude then that to be professional is merely a matter of definition and clearly that a definition could be devised to cover anyone desired. However, to do so seems hardly productive as it serves only to camouflage any real differences among practitioners. What is sad is that such a strategy appears to be effectively implemented in the computing industry. At best passive, yet more often active resistance to any attempt to differentiate significant variables among computer practitioners is prevalent in the industry. One must ask why?

A complete answer would have to consider many possibilities among which would be the desire to avoid exposure of the incompetent, insecure, paranoid, and even the amateur. However evident such motivations and the real need to address the problems of such people, the intent here is to investigate the competent practitioner to attempt to understand his apathy in such matters and his reluctance to identify the characteristics of his own competence. Such serious deficiencies betray an absence of maturity among such practitioners.

Maturity is a state of being; an expression of the full development of an individual's ability to differentiate reality and delusion. If one can demonstrate a serious deficiency in such development of a person or groups, then one has the basis to challenge its maturity.

This is precisely what is proposed here. Since the computing industry is seriously neglecting the critical need to differentiate professional development among its numbers in that it tolerates a simplistic blanket usage of the term professional that masks the incompetent and amateur in its midst, then in that respect it lacks maturity. It is guilty of ignoring the reality of differentiating criteria among practitioners and of deluding itself into believing no such discrimination is necessary.

Not all practitioners of the computing arts are guilty of such lack of maturity. Many have addressed the problems, have worked diligently to devise sound definitions, and have tried to accomplish the identification of professional characteristics, but unfortunately many more have chosen to negate or compromise any achievements obtained. For the most part such contributors have been ostracized for their efforts and bullied into silence by the masses whose comfortable but erroneous self-image would be shattered by a glimpse of the truth.

Frankly, there is no such thing as a data processing professional! At least, not in the sense most people in this industry seem to use the term. We have no clear example of a professional directly comparable to a doctor, lawyer, or CPA. It is suggested that the term is being misused and in reality twisted to meet the ego needs of an immature industry.

However, the potential of a profession exists and could easily be established through the efforts of significant support from practitioners. What then would be required to qualify as a profession?

Richard Canning, in the EDP Analyzer (December 1968) listed a number of criteria by which any group could judge if it would qualify as a profession.[9]

1. A profession has a defined body of knowledge of high intellectual content acquired by training-in-depth.
2. A profession has defined standards of competence and certification that the professional meets those standards.
3. A profession has a code of ethical behavior.
4. A profession has at least one professional society aimed at advancing the welfare of its members.
5. A profession has responsibility to society to perform in a competent, ethical manner.
6. The members of a profession generally are not under the control of non-professional management (with regard to professional decisions).
7. The members of a profession have a loyalty to their profession which may transcend their loyalty to their employers.
8. The members of a profession may be licensed by the state to practice the profession if it affects such things as public health, public safety, property rights, or schooling of the young.
9. A profession has the right and ability to eject someone from the field for being incompetent or unethical.

Now the question is . . . Does the computer field qualify?

Certainly a body of knowledge in the computer field is being defined. Academic programs, educational programs of professional societies and an increasing body of literature are continually refining our understanding of minimal knowledge requirements. However, the technological and infor-

mation explosion will require diligent attention to the maintenance of these knowledge requirements. Who is to fund and man these efforts?

We have a certification program through the Institute of Certification of Computer Professionals (ICCP) which is being seriously developed, expanded, and implemented. But still there are few if any clearly defined standards of competence, although efforts are under way to attempt their definition. Who should be responsible for such standards definition?

The ICCP has a published code of ethics as do most of the existing professional societies. However, most of these codes are "Mother and Apple Pie" documents with no enforcement capability. Who must take on the continuing and sensitive task of defining ethical behavior, and more critically, who will be responsible for the enforcement of such codes? Only ICCP has an enforcement mechanism in place but it has yet to be exercised.

Most data processors are not independent decision-makers, nor has there been much indication of a willingness to transcend their loyalty to the company and their paycheck. Furthermore, many argue that one ought not take responsibility for questioning the propriety of their management or employers. What reinforcement should and could be provided to encourage responsible professional behavior in the public interest regardless of potential company reprisal?

Notice the need for the recognition of a legitimate and perhaps necessary licensing role. In spite of such recognition by increasing numbers of responsible leaders in the industry as well as the private and public sectors of our society, an overwhelming majority of practitioners now reject the concept.

Finally, no one to my knowledge has ever been ejected nor disciplined by any society for being incompetent or unethical.

What all this means is that the computing profession, if there is one, is only an emerging profession and much needs to be done if in fact it is ever to achieve a legitimate status.

Many practitioners argue and act as though such a situation were desirable and that there is no need for concern. With many of the benefits of a profession emerging anyway, why be concerned with the legitimate recognition of the profession? Let things take a slow, natural course and all will come out in the end. In the meantime no one need be threatened and all can use the term "professional" as they please at no cost to anyone.

Here again is a manifestation of immaturity, for the satisfaction of the ego need to be regarded as a professional is accomplished through the delusion that such a choice is within the power of the computing industry alone. Ignored is the reality that the public, legislatures, the courts, employers, and other professions are expressing an entirely different point of view. While naively awaiting recognition of professional status, events are occurring that may well forever deny such status to computing personnel.

In December of 1971, the U.S. Department of Labor's Wage and Hour Division decided that programmers were not exempt and should not be considered professionals.[7]

This precedent supported a January 1976 decision handed down by a U.S. District Court judge in Tennessee that again ruled programmers not exempt since they did not satisfy the provisions of the Fair Labor Standards Act of 1938, Section 213 which specify that "any employee employed in a bona fide executive, administrative, or professional capacity" is exempt from overtime pay.[1]

Seeking professional recognition, programmers have organized professional societies, sponsored professional activities, and encouraged professional development of the practitioner, but also all to no avail.

What happened? Where did they slip up? First of all, in their lack of attention to the necessary legal definitions and secondly, because of divergent motivations among their numbers.

Lacking a defined and recognized professional status sealed the fate of programmers who now face legal precedence in their struggle to achieve a profession. Are the rest of us likewise to be denied?

Close upon the heels of this bombshell has come the controversy in several states during 1976-77 concerning the tax status of computer software. The battle continues and the Data Processing Management Association (DPMA) as reflected in an August, 1977 position statement is arguing, ". . . whether data processors will receive equal treatment under tax laws as services by other professions."[8] This is an interesting argument considering the status of the so called computer profession, and it certainly puts the industry on notice to its exposure unless its professional status is established.

But the question now becomes, how long will this process take? A corollary is how much time is available for completion?

The answer depends upon projections of current and future events now evident and believed to be inevitable. Among these are governmental intervention such as has occurred with legislation involving privacy and electronic funds transfer systems.

Concerns that the public interest must be protected is causing legislatures to become increasingly sensitive to the impact of computer technology. How long are they going to tolerate the technology without regulation?

If one accepts the inevitability of such regulation within limited time frames, the argument becomes compelling for accelerating formation of the profession and regulation within it. In fact, the passage of regulatory legislation could make all the prior concerns empty rhetoric.[5]

It is in the belief that such would happen, and especially that it would come in a relatively short time frame, that has prompted many of the need to address the controversy. However, such legislation is not without peril and inadequate preparation must be avoided if possible.

Such has been the appeal of this author in the past who has been concerned that the industry is faced with potential for the establishment of a profession, and that it would seem prudent to prepare for it.[2–6] The argument has been made that certain things must be done to prepare. In particular, identification must be made of who would be a professional, what he would do that would differ from non-professionals, and how he would perform those activities.

Therefore, the real issue is the formation of a legitimate profession, regulated to protect the public interest, to insure the quality of the professional, and to provide him with the working tools with which he will perform.

If it maintains a head in the sand attitude, the industry is likely to find itself one day regulated by government established in desperation to control a technology the public perceives as much too powerful, self-serving, and threatening.

Such control may even exclude a DP profession and relegate it to the role of technicians employed by and regulated by some other profession such as accounting, or even worse, give rise to unionism. There are ample reasons to fear these eventualities.

If the computer industry is to participate in this regulation of computer related areas rather than perform as technicians under the guidance of other professions, then we must establish ourselves as acceptable professionals and in short order. Are we going to accept technician roles to other professionals? Or worse yet, unionization as technicians of the laboring class?

Let it be again perfectly clear that the use of the term professional in our industry is merely a dream or hope for the future. True, many are working for the reality but the vast majority are either apathetic or actively opposed to the concept. It is this apathy and opposition which must command our interest, for a lack of understanding of the motives of such opposition may well spell out doom to the efforts to legitimatize a computing profession. What then might we do to create a legitimate professional in our society?

One formal effort to achieve such professional status is the certification movement. Here is attempted a clear and comprehensive articulation of peer evaluation and approval with attendant subscription to a continuing practice of ethical behavior. This, of course, is the realm of the Institute for Certification of Computer Professionals (ICCP). This effort is essential to the development of a professional group of people and represents the most significant industry effort to improve and regulate itself. At this level one finds most of the generally mentioned and accepted attributes of the definition of a profession.

Culminating the work of many these past years, the certification movement promises the industry its best potential of achieving a profession and the practitioner his best chance to aspire to a truly mature professional status.

Full definition and development of a computing profession under the umbrella support of most of the significant computing societies is possible through the Institute for Certification of Computer Professionals (ICCP). Charged with the task of identifying significant discriminating characteristics among practitioners and certifying against such gives rise to hope for a profession. Definition of and attention to the characteristics of such a profession in addition to programs directed toward their achievement remain the best hope of the industry. However, while these efforts are often spoken of and are of interest, such is again not the purpose of this presentation. What is critical here, is the serious lack of support for these efforts.

The trade press ranks with superficial and often foolish criticisms of the serious attempts to improve the situation of computer professionals. Rarely, however, rises a thoughtful defender to spoil such attacks.

Rarely do we call our employers attention to these credentials or encourage our colleagues to acquire them. Rarely are such credentials rewarded. Rarely do we volunteer the time or effort to assist those making the sacrifices in our behalf. How then can we truly consider ourselves mature professionals, if indeed we are professionals at all?

Finally, why do we continue to tolerate those who use the label of professionalism itself to attack any serious attempt to achieve such? These people become especially agitated by any hint of assessment, certification, licensing, or any other potential measure of their credentials, yet we tolerate their frequent attacks of those seriously attempting to establish legitimacy for that which these critics take for granted for themselves. Their arguments against an elite class of practitioners also appears weak. If being elite means being concerned, involved, improving ones knowledge and skills, and contributing to the profession, then hooray for the elites. The cry of "ego trip" is no more valid for the achiever than it is for the non-achiever. Is it not much more ego involved to attribute characteristics to oneself without the verification of peer group evaluation?

What is suggested is that the industry begin to show maturity in at least three ways: First, that all assist in obtaining credentials reflecting clear definitions of distinguishing professional characteristics. Second, participate in implementing and acquiring legitimacy for these credentials. Third, cease to tolerate the distracting and demeaning attacks upon efforts to develop and mature the profession by actively responding to those who would diminish or destroy the efforts to improve our industry and performance within it.

Surely, tradition, common sense, and responsible self-interest dictate the formation of such a recognized computing profession.

The decision rests with us in the industry. All are urged to become concerned, to get involved, and to make commitments such that many voices and talents will be engaged in finding solutions to the challenges of the future toward the profession.

In this spirit remember the visionary words of George Bernard Shaw as he wrote:

> Some men see things as they are,
> and ask why?
> I dream of things as they might be,
> and ask why not?

Designing and debugging careers for women in the computer industry

by THELMA ESTRIN
Brain Research Institute, University of California
Los Angeles, California

Women's pursuit of careers in the computer industry is consistent with our national commitment to equal opportunity and with our national need to utilize all available talent in support of scientific research and industrial efforts.

Computer science education and immediate employment on the first steps of the career ladder are readily available for women but after these initial steps women still face cultural, educational and institutional barriers which block them from advancement to the top. Women are finding, as men have, that superiority in technical knowledge and competence are not sufficient to guarantee advancement. In addition, women must carefully plan their careers and remain alert to those societal attitudes, the hidden "bugs", that prevent them from successfully implementing their long-term career goals.

The concept of career planning is receiving much attention by professionals in all fields, but the rapid rate of technological and methodological innovation in the computer industry gives special urgency to the need for computer professionals to use planning techniques to combat technical obsolescence and to aid upward mobility. Career planning deals with the identification of ones goals, skills, and priorities and the designing of a career with alternative options. It involves deciding if one wants to pursue a technical or a managerial career and poses questions such as: What type of a job do I want in the next years? What is the knowledge base? What are the skills needed and at what level of competence and experience? What types of inter-personal relationships are important?

Many factors that relate to professional development apply equally to men and women but career planning is especially important to help compensate for the distinct problems women encounter with upward mobility, and for women who want to combine career advancement with family life. There are very few women at the top in any business or profession and the lack of role models serves to discourage women who might consider working towards leadership status in the computer field. Qualified women are often reluctant to move ahead because upward mobility requires significant deviation from social norms. In other cases, women may be hindered by the attitudes of men, who are their peers and supervisors. Withholding promotion of women may not be overt, but due to unconscious discrimination based on sex-role stereotyping and societal conventions.

The panelists will discuss various approaches to career planning. The opening panelist, a career development consultant, will present a model of career stages based on accepted theories of adult development. The other panelists, computer professionals in the areas of software, hardware and technical marketing, will discuss factors and strategies which they have found useful in advancing through career stages in the computer industry. They will also discuss barriers to women's full and equal participation which should be considered in career planning.

This panel is not for women only and men are encouraged to attend. In addition to benefiting from those aspects of career planning which are of value to all professionals, men can gain insights to improve their working relations with female colleagues from an awareness of the special problems professional women encounter in pursuing non-traditional careers.

A panel session—Computers in early education

SESSION CHAIRMAN—ORLANDO S. MADRIGAL
California State University, Chico

Panel Members

Alan Kay—Xerox Palo Alto Research Center
David Moursund—University of Oregon
John Maniotes—Purdue University
William G. Lane—California State University
A. M. Banks—Beyer High School

PANEL OVERVIEW—Orlando S. Madrigal

This session will have five panelists/speakers who will discuss the use of computers at the pre-college level. The speakers will include topics related to:

- The cost-effectiveness of the use of computers for high school education, by William G. Lane—California State University, Chico.
- Computer Science education for preservice elementary school teachers, by David Moursand—University of Oregon.
- Programming for children on a personal computer. To include a brief movie that will demonstrate the speaker's experiences with children who are taught programming at an early age. By Alan C. Kay—Xerox Palo Alto Research Center.
- The teaching of micro-computers in high school, by Amberse Banks—Beyer High School, Modesto, California.
- The state of high school data processing programs, by John Maniotes, Purdue University.

SPEAKERS AND TOPICS:

(1) Professor David Moursund, University of Oregon
Title: Computer Science Education for Preservice Elementary School Teachers
Abstract: Calculators and microcomputers are now cheap enough so that elementary schools can afford to give students quite good access. Thus this equipment could be playing a major role in the curriculum. But progress to date has been slow. A major cause is lack of suitably trained teachers. Preservice elementary school teachers need to receive a substantial introduction to computer literacy, teaching using calculators and computers, and teaching about calculators and computers. The author has been involved in the development of courses of this sort, and is currently teaching such a course. This paper includes a detailed course outline and discussion. References to the text used, as well as supplementary material, are given.

(2) Professor John Maniotes, Purdue University, Columett Campus
Title: The Interface Between High School Data Processing Students and the Two-Year Community College Programs in Computer Science
Abstract: Data and problem areas will be presented to explore the transition of high school students, with data processing background, to a formal 2-year curriculum in Computer Science. More and more high schools teach computer-related courses. Students in these programs are able to phase into a college program in computer science including the exemption from the basic courses including introductory programming and concepts. A high school data processing program that is well articulated with college level programs will greatly benefit the students in the program. There will be less course duplication and students will be able to obtain advance placement in the Computer Science area.

(3) Professor William G. Lane, California State University, Chico
Title: Cost-Effectiveness of the Use of Computers For High School Education
Abstract: As more and more high schools start offering computer programming courses, the cost of high school education will greatly increase. And with the trend towards a "no increase" in school budgets, new avenues of educational financing will have to be pursued in order to allow school districts to pursue the addition of basic computer science to existing high school curricula. It will be shown that various avenues of cost-sharing among computer users in a given area can reduce the "per student cost" for computing use to a level that will be within the budgetary restrictions of most school districts. Another area that will affect cost is the need for high school teachers who can qualify as teachers in the Computer Science area. The

current move to establish high school credential programs in various states will be discussed.

(4) Dr. Alan Kay, Xerox Palo Alto Research Center
Title: Experiences With "Small Talk" and Pre-Schoolers

Abstract: The author has been involved with the development of personalized computing systems including both hardware and software. A major result of his work is the "Small Talk" system which utilizes a mini computer that can be used interactively to train preschoolers in the use of computers. The system utilizes a specially designed terminal that will allow the user to perform interactive color graphics without prior training in the use of computers. Hundreds of preschoolers have gone through the "Small Talk" system, and interesting observations have been noted including the users response to a unique computer environment and eventually relating these experiences to the classroom.

These systems, although not yet commercially available, can be considered as the forerunner to personalized computing where users can gain exposure to computing at an early age.

(5) Mr. Amberse Banks, Beyer High School, Modesto, California
Title: Augmenting a High School Curriculum With Microcomputer Education

Abstract: Microcomputer education can be paralleled to the traditional electronics training for television and stereo systems. However, microcomputers are more complex since computer programming must be included in the students work.

The author has devoted two years to the development of high school courses which train students in the intricacies of building and programming microcomputers. More and more students are getting involved in these courses. A number of these students have aspirations for college-level training in Computer Science and eventually enter the field as computer professionals.

PROGRAMMING FOR CHILDREN ON A PERSONAL COMPUTER—Alan Kay

The "Small Talk" system utilizes a mini computer with an attached terminal that can be used interactively to train pre-schoolers in the use of computers. The system utilizes a specially designed terminal that will allow users (preschoolers) to perform interactive color graphics without prior training in the use of computers. Hundreds of preschoolers have gone through the "Small Talk" system, and interesting observations have been noted including the users response to a unique computer environment and eventually relating these experiences to classroom learning.

These systems, although not yet commercially available, can be considered as the forerunner to personalized computing for children where users can gain exposure to computing at an early age.

COMPUTER SCIENCE EDUCATION FOR PRESERVICE ELEMENTARY SCHOOL TEACHERS—David Moursund

Calculators and microcomputers are now cheap enough so that elementary schools can afford to give students quite good access. Thus this equipment could be playing a major role in the curriculum. But progress to date has been slow. A major cause is lack of suitably trained teachers. Preservice elementary school teachers need to receive a substantial introduction to computer literacy, teaching using calculators and computers, and teaching about calculators and computers. This talk includes a detailed course outline and discussion of course requirements for such training.

THE STATE OF HIGH SCHOOL DATA PROCESSING PROGRAMS—John Maniotes

In recent years, computers have had a profound effect on all of the institutions of society, including early (and late) education. If we, as educators, are to prepare students for the future, we need to participate fully in the computer evolution/revolution and to teach our students to use, understand, and live with these logical machines that will exert such a significant influence on the rest of their lives.

The number of computer and data processing related courses and programs a high school has to offer depends upon the size of the school, the availability of experienced EDP or computer science teachers, the attitude of the school's administrators, and above all the amount of funds allocated to the EDP program. Although some schools continue to overlook the impact that computers have had in the business and scientific world, others have found economic ways to incorporate some kind of computer-related courses in their curriculum.

Several programs that have been categorized according to the equipment available to the students are described. These programs include the:

- Textbook concept programs
- Input/Output terminal programs
- Centrally located computer concept programs
- Home-based computer concept programs

For those schools which lack the aforementioned programs, all sorts of extracurricular activities can be found intermingled with the obligatory academic subjects. In particular, the role of the ACM computer clubs, science and math clubs, and the explorer posts are described.

Finally, some of the major problems facing high schools in implementing vocational data processing programs are

explored. In particular the problems associated with:

- Curriculum objectives and guidelines
- Recruitment of qualified instructors
- On-going teacher education in EDP
- Instructional materials
- Computer oriented aptitude tests
- Funding to support the EDP programs
- Physical facilities for computer hardware
- Computer software and application packages
- Recent impact of microcomputers, intelligent terminals, and programmable calculators
- Interfacing with 2-year BDP and 4-year CS programs at colleges and universities.

COST-EFFECTIVENESS OF THE USE OF COMPUTERS FOR HIGH SCHOOL EDUCATION—William G. Lane

A decade of program development in elementary and secondary education has been characterized by oversell, underdelivery and poor timing. CAI projects, which promised to raise the overall class growth "X" grades, while letting everyone proceed at his own pace, ran into a number of problems:

- Parent taxpayers, whose only probable previous experience with the computer was in trying to get a credit card purchase error corrected, raised much concern over "turning the education of our children over to a computer."
- Teachers were resistant to adopting new methods that too frequently were perceived as having a potential for lowering the number of faculty positions and that had the effect of reducing their status to a regulated learning manager rather than an independent learning deliverer.
- Curriculum personnel and school administrators were asked to operate in a new environment for which they had little or no training.
- Marketing analysts had underestimated the cost and length of the development effort and over-estimated early market, causing computer companies to become disenchanted and to withdraw support.
- Low cost hardware technology required for broad acceptance had not yet been developed.

Given these problems, it is not surprising that computers in the elementary secondary education areas have not even begun to reach their potential. But times have changed; hardware costs have lowered, TV games and microprocessors have become a major factor in the home market, the computer is no longer perceived as a job-eating monster and, as such, we are now probably ready to again access the feasibility of installing computers at all levels of our school system.

Several pilot studies are evaluated and analyzed for their potential:

- The use of computer graphics in the teaching of mechanical drawing at the junior high level.
- The use of modularized instruction and computer-based testing in lower elementary levels.
- The use of a computer in handicapped education.

Each of the above studies showed a need for differing systems and peripheral architectures, as well as responsibility for the classroom teachers. These led to the requirement for differing architectural concepts and approaches.

TEACHING MICRO-COMPUTERS IN HIGH SCHOOL—A. M. Banks

In view of the impact of computers upon our society, few people would question their inclusion in the secondary school curriculum. But why should it be done by using micro-computers? Can such curricula be of value to students? While it is true that such small systems do have more limitations than do larger systems, they also offer many new options to the high school program that only have access to micro-computer systems.

Most computer courses in high schools are arranged to suit the type of equipment that is available to the students. Terminals are the most common form of computer access at the high school level; however, in many cases, the students are assigned as low priority users. The restrictions that are thus placed on high school programs curtail, prevent, or even discourage students. Also, the increasingly bleak financial situation of most school districts makes the acquisition of systems large enough to support more sophisticated time-sharing a virtual impossibility. Also, the rising costs of telephone lines makes the use of district-wide systems more and more difficult.

Highly flexible, expandable micro-computers now cost the same as terminals did a year ago. The newer self-contained, assembled systems cost so little that shcools can afford to build up a laboratory with several machines. Multiple machines offer variety and protection against system-wide downtime.

Can the computing work that is possible on a micro-computer compare with that possible on larger systems? Yes and no. First there is the matter of the languages that are available. Currently, there are several excellent BASIC interpreters and some reasonable assemblers available for each of the microprocessors used in micro-computer systems. In addition, there are versions of PILOT, APL, Pl/1 and FORTH available for some chips. While the lack of COBOL, for example, is a handicap if we are training professional programmers, these available languages are more than adequate for high schools. Software advances are being announced every month for those who do not wish to write their own. This is an area where interested students can do advanced work on micro-computer systems but not in larger systems.

There is an additional aspect of computers that can be covered using micro-computers which cannot even be attempted with larger systems. It is possible to have students do hardware work, including maintenance and hardware configuration. It helps the student to view a computer as a tool to be used rather than as a shrine into whose presence only a privileged few are permitted. Instead, they find new ways and new places to put it to work. This kind of attitude is not generated when students use larger computers or even mini-computers.

Thus, we see that micro-computers can match almost every service offered by a larger system to high school classes, and can offer additional opportunities to students that are just not feasible with larger systems.

Computer education in higher education—status, alternatives and needs

by JOHN W. HAMBLEN
University of Missouri-Rolla
Rolla, Missouri

INTRODUCTION

The cause of many of the problems associated with computer usage is the "overutilization of undereducated people." The reason being, of course, that properly educated people have not been available. Bootstrapping by training existing personnel and pirating whatever other centers had trained was the only way that staff could be obtained during the late fifties and the early sixties. The late sixties saw the tremendous growth in the one and two-year programs aided by large infusions of federal monies via the Office of Education programs. The production of these programs crested around 1972 at a peak of nearly 28,000 during that year. The seventies might well become known as the decade of the recognition of the value of the college graduate to effective and efficient computer usage. Based upon my estimate of need and the present average rate of growth (about 10 percent) in the production of graduates of four-year programs it would take nearly twenty-four years to match the need and production.

The main point here is that it will be some time before we need to worry about a "glut" in the market for four-year graduates in the computer related areas. At the master's level, the rate of growth is about half that of the four-year production rate and it will take nearly twice as long to match production with need. At the doctorate level fifteen years will be required to match production with need based upon my estimates of need and current rates of growth in the doctorate production.

All of my estimates are based upon the expectation that the professors in colleges and universities will seek out the advice of representatives of industry as to industries' needs and keep the educational programs aligned with those needs. They cannot afford to do otherwise.

In the following I present my estimates[7,9] of computer manpower based upon the best, though limited, data available classified by job classifications and level of education which I believe will be required for replacement of current personnel and to fill new positions. Better data is available on manpower production than on utilization through the efforts of SREB Computer Science Project[1-3] and the American Federation of Information Processing Societies[4,5] with support from the National Science Foundation. Data from the Bureau of Adult, Vocational, and Technical Education of the U. S. Office of Education[6] are also utilized. Manpower production is then matched against estimated needs.

Although the need for computer manpower education is great, there is at least an equal need for most people to become "computer literates" as a minimum. This can be easily accomplished if all teachers and other college graduates can become a little more than just "Computer Literate" (e.g., at least one course involving some programming).

BACKGROUND

During the period 1966-72 while I was Project Director for Computer Sciences at the Southern Regional Education Board (SREB), I conducted three surveys on Computers in U. S. Higher Education including their utilization and related educational programs. These studies were supported by the National Science Foundation and resulted in three publications.[1-3] The first was published by the SREB and the latter two by the National Science Foundation.

The first study was a survey using a stratified random sample of 739 institutions, from a population of 2219, selected by systematic random sampling within strata by the U. S. Office of Education. Six hundred sixty-nine or 92 percent of the institutions in the sample responded.

The base year for data collection was 1964-65 and projections were requested from the institutions for 1968-69. The data collection instrument was designed by the Mathematical Sciences Section of NSF to meet their existing program needs for planning. Consequently, emphasis was placed upon the financial aspects of college and university computer center operations and only limited information was gathered with regard to manpower training and utilization.

The second survey was much more comprehensive and was sent to all institutions of higher education listed on the U. S. Office of Education's Higher Education General Information Survey (HEGIS) file. Nineteen hundred sixty-five or 79 percent of the 2477 institutions responded. The data collection forms were designed with the advice and counsel of thirty or more national professional and institutional associations and government agencies. The base year for reporting data was 1966-67.

Extensive modifications were made in the data collection forms for the third survey. The base year was 1969-70.

In 1972 I was commissioned by the SREB to do a paper on Computer Manpower—Supply and Demand—in SREB states. Using this as a starter, I prepared a similar report for all states.[7,9] Manpower production estimates were based upon the NSF supported surveys[1-3] and data from the USOE.

During 1974, I sent questionnaires to 2,520 institutions of higher education (seminaries, conservatories and special schools were not included) to update the data obtained on degree programs in the 1969-70 survey. A 61 percent rate of response was obtained and the production estimates for 1973-74 and 1974-75 were added to previous estimates.[7,9]

Another survey covering the 1976-77 year is nearing completion and comparable data will be supplied at the NCC in Anahein for all tables in this paper.

COMPUTER EDUCATION LEVELS AND ALTERNATIVES

It is generally recognized that there is a definite need for some degree of computer education for all college graduates. This can be accomplished at several different levels.

- Non-Credit Survey or Programming Short Course—This may consist of 8-16 hours of lectures and demonstrations and should be provided for faculty and staff on a continuing basis. Response by students is usually spotty. Very poor coverage can be expected from this approach.
- A Unit on Computers and/or Programming Introduced in a Required College Course—This is the best way to insure a minimum introduction to computers for all students. Faculty can be trained for this teaching through short courses, provided good training outlines and materials are made available to them.
- Integration of Computer Techniques as Tools in Most Disciplines—This part of the program requires an enlightened faculty. It will be several years before faculties exist which are able to do this on a college-wide basis. However, there are several fields in which this can be accomplished now. Among them are business, economics, statistics, mathematics, physics, chemistry, engineering and the social, behavioral and biological sciences. If handled properly, the use of the computer can serve to motivate the student and to permit the instructors to use more realistic examples in their instruction.

TABLE I.—Numbers of Colleges and Universities Offering Computer Appreciation Courses with Enrollment

	1969-70	1976-77 (Est.)
No. Institutions	152*	300
Enrollment	18112	50000

* Fifty-six other institutions reported such a course on the books but not yet offered during 1969-70.

TABLE II.—Courses and Enrollments in "Introductory Courses in Some Computer Language such as FORTRAN, PL/1, BASIC, ALGOL"

	1969-70	1976-77 (Est.)
Courses (Institutions)	971*	2,000
Enrollment	132,462	300,000

* Two hundred and six other courses were reported as being on the books but not offered yet during 1969-70.

COMPUTER APPRECIATION COURSES

Courses, such as Computer Appreciation, Computers in Society, Computers and Society, etc., have been popular for some time at many colleges and universities as is shown in Table I.

INTRODUCTORY COURSE IN SOME COMPUTER LANGUAGE SUCH AS FORTRAN, PL/1, BASIC, ALGOL.

These courses should consist of a minimum of two hours of lecture and two hours of laboratory each week. If handled carefully with regard to problem selection, this kind of course could be conducted as one multi-section course. However, better results can be obtained if some stratification is introduced when more than one section is needed. Such a course requires an instructor who has had some experience in programming in several computer languages. These courses will be required in some curricula and elected in others. The numbers of institutions (possible duplications) offering such courses and their enrollments are shown in Table II.

VOCATIONAL TRAINING PROGRAM

This is usually a one-year or two-year post high school curriculum. Several vocational training institutes initiated such curricula with federal and state assistance under the NDEA Title VIII program. Table III shows the estimated number of two-year programs offered and the number of degrees awarded.[7,9] Fifty-five (55) of these programs were in four-year and higher institutions offering the associate degree in data processing, computer programming, or computer technology.

TABLE III.—Estimated Number of Two-Year Degree Programs and Number of Degrees Awarded

	1966-67	1969-70	1973-74	1976-77

No. Programs*	58	98	90	100
No. Degrees	174	307	369	500

* Includes options in Math, Electrical Engineering, etc.

FOUR-YEAR DEGREE PROGRAM FOR COMPUTER PROFESSIONALS

Although there is now a recognized need for many majors in computer science, information systems, etc., not many colleges can afford to properly staff such a program for several years to come. For one thing, the competition is very keen for new Ph.D.'s in Computer Science and very few exist in Information Systems.

One hundred thirteen bachelor's degree programs in Computer Science were reported in operation with 8000 majors and 1537 graduates for 1970-71. In addition, another 69 bachelor's programs were reported going with nearly 7000 enrollees and 1000 graduates. The latter included 28 programs in Data Processing, Information Sciences, and Computer Science as options in various academic areas, with the most being in mathematics and electrical engineering. All 28 of these programs were offered in institutions granting a master's degree or higher. Table IV gives estimates[7,9] of the numbers of bachelor's degree programs and the number of degrees awarded.

MASTER'S DEGREE PROGRAMS

A perennial debate is whether the M.S. degree should be professional or research oriented. Where possible those who want to go on for a doctorate should do a thesis option otherwise little distinction should be made. The number of M.S. programs and degrees continue to grow as can be seen in Table V.

DOCTORATE PROGRAMS

Conte and Taulbee[8] are gathering information annually on the "Production and Employment of Ph.D.'s in Computer Science" as a Subcommittee on Manpower of the Computer Science Board. Prior to 1976 their data was collected only from Ph.D. granting departments of Computer Science, Information Science, etc. Sixty departments reporting for 1976 graduated 246 Ph.D.'s and estimated that 310 would complete the degree in 1977. Considering the number of departments reporting these numbers are well in line with my estimates given in Table VI.

TABLE V.—Estimated Number of Master's Programs and Degrees Awarded

	1966-67	1969-70	1973-74	1976-77
No. Programs	98	155	157*	200
No. Degrees	742	1442	2854	4000

* 192 for 1975-76.

MANPOWER NEEDS

In References 7 and 9, I present a model which I developed to produce estimates of computer manpower needs. The results are given in Tables VII and VIII.

The post-secondary vocational institutions' production figures are added to the associate degrees to obtain the final "post-secondary and two-year" estimates.

These estimates say that we are close to producing enough two-year/post-secondary graduates in the computer field, but only one-half of the needed doctorates, one-eighth the number of bachelor's and one-eleventh the number of master's levels needed. This reinforces my earlier statement that we are overutilizing undereducated people in the computer related fields. Others may wish to take exception to the assumptions which led to these results. If so, I hope that I have made the procedures transparent enough in Reference 7 that they can produce their own estimates. Even if my estimates are off by 50 percent, we still would have severe shortages indicated at the four-year and master's levels for some years.

The master's degree, quite common in the management analysts and systems programmers categories, and not too uncommon among applications programmers. Some top supervisory positions in operations attract M.S. graduates in the computer and information sciences.

Table VII gives my estimate of the distribution of computer staff by level of education that I believe to be desired for replacement if an adequate supply of manpower is available at these levels. During the past years, companies have had to take what staff they could get and train or retrain them. This is an expensive route and therefore, I believe that given a choice, industry would prefer to hire trained personnel. In terms of formal education, I believe that we are overutilizing undereducated people in the computer related occupations.

COMPARISON WITH BLS ESTIMATES AND PROJECTIONS FOR 1980

In the 1972-73 Occupational Outlook Handbook published by the Bureau of Labor Statistics, it was reported that there were over 100,000 systems analysts in 1970, over 200,000

TABLE VII.—Estimated Distribution of 1973 Computer Staff by Level of Education Required or Desired for Replacements

	PS VOC and 2-year	4-year	M.S.	Ph.D.	Total	Percent of Total
Teaching	200	1,500	2,000	2,200	5,900	.6
Management	3,000	37,000	60,000	5,000	105,000	11
Analysts	1,000	62,000	100,000	2,000	175,000	18
Systems Programmers	2,000	33,000	70,000	—	105,000	11
Applications Programmers	10,000	200,000	35,000	—	245,000	25
Operators	100,000	100,000	10,000	—	210,000	22
Other Operating Personnel	100,000	12,000	—	—	112,000	12
Total	216,200	445,500	287,000	9,200	957,900	
Percent of Total	23	46	30	1		

programmers and over 200,000 operators. Assuming a 10 percent annual growth factor (Gilchrist, Computerworld, McGovern of International Data Corporation, and U.S. Department of Labor in the U.S. Economy in 1980, Bulletin 1673, p. 47) we can expect these numbers to double by 1980. This extrapolation would give 200,000 systems analysts, 400,000 programmers and 400,000 operators for 1980. However, the 1970 estimate for systems analysts does not agree with the 1968 figures given in the U.S. Economy in 1980, p. 59, which gives 150,000 systems analysts for 1968 or when extrapolated to 1970, 180,000 systems analysts for 1970 and 240,000 for 1973, as compared to my estimate of 175,000. The projections for 1980 are presented on the same page and are 425,000 for systems analysts, 400,000 for programmers and 400,000 for operators. Some of the differences result from definitions. I would guess that some of what I call systems programmers are counted by BLS as programmers and others as systems analysts since no such category as systems programmers appears in BLS publications referred to above. It is of interest to note (p. 59, also) that systems analysts, programmers and computer operators were expected to be the fastest growing occupations in the 1970's.

Management personnel are most likely to be counted under "Managers" in the BLS classifications and on page 293 of the 1972-73 Handbook there is an indication that what I call other operating personnel (excluding card punch operators) are included under Office Machine Operators. In particular, operators of tabulating machines and related equipment, where such equipment is an integral part of a computer installation, would fall under my classification of "other operating personnel."

In BLS Bulletin 1673 referred to above it was estimated that there would be 120,000 computers in use by 1980 and that the number of process computers would reach about 17,000. I believe that the 120,000 figure is conservative, depending upon one's definition of a computer. In the same publication, it was estimated that for the period 1968-80 there would be annual openings for 23,000 programmers, 27,000 systems analysts and 20,400 operators, or a total of 70,400 in just these three classifications. Since these three categories account for about two-thirds of my total estimates, extrapolation of the 70,400 figure gives about 105,000 annual openings per year. This number compares very well under the circumstances with my estimated need of 117,000 per year.

TABLE VIII.—Future Computer Manpower Needs Per 1000 Estimated 1973 Personnel

	Education Level			
	PS Voc and 2-yr.	4-yr.	M.S.	Doctorate
Cause:				
Replacement:				
Deaths	5	5	2	2
Retirements	17	17	17	17
Growth	100	100	100	100
Total Rate	122	122	119	119
Total New Openings	26,376	55,571	34,153	1,095
Estimated 1975 Productions	19,286	6,996	3,236	493

COMPARISON WITH HEGIS DATA

Gilchrist and Weber[5] refer to classification differences which exist between the HEGIS data and the data which I collected at SREB. The main reason for differences in number of graduates reported is that HEGIS data, in general, reflect graduates of so-named departments only. For example, graduates of mathematics departments with computer science options would be classified as mathematics (or a subheading) and not computer science. The same would, in general, be true of graduates of other departments (EE, IE, etc.) with computer science options. Likewise, graduates of departments in business with options in systems analysis would not be reported under systems analysis. For this reason, the data reported in the inventory conducted by me at SREB and my updates for 1973-74 and 1974-75 should be considered to reflect more closely the actual numbers of graduates being produced in these computer related fields.

SUMMARY

Large numbers of personnel have been able to enter the computer manpower pool in the past with little training. The

proprietary schools had a "heyday." Only the best and largest have survived. Large amounts of federal and state funds were poured into the vocational and two-year programs. I question the value of those operated at the secondary level and have indicated[7,9,10] that there should be a weeding out of the weakest post-secondary vocational and two-year programs. I differ with Gilchrist and Weber[4,5] in that I do not think that secondary schools will be significant producers of computer manpower. On the other hand, computer education at the secondary level should not be neglected. Secondary schools should provide enough computer education so that the student can learn to live comfortably in a computer assisted environment and also enough so that students pursuing post-secondary education can judge whether or not they wish to pursue a program of study which will prepare them for entry into the computer manpower pool.

Computer science and computer engineering— A review and overview of curriculum development

by GERALD L. ENGEL
Old Dominion University
Norfolk, Virginia

and

OSCAR N. GARCIA*
National Science Foundation
Washington, DC

INTRODUCTION

The introduction of the digital computer into the academic environment created a situation that would lead to impact on how teaching and research are conducted at virtually all levels, and in virtually all disciplines. The further combined evolution of semiconductor technology with software practice and methodology has resulted in a new field which has developed at an astounding rate. The impact of this rapid change in the academic environment has forced universities to modify their classic attitude of slow change on curricula and research matters to yield to external demands for education and research in computer related topics.

Though the implication of the computer has been present in all areas of the academic institution, this paper will be directed to education about the computer; that is, computer science and computer engineering. Within these areas the changes that have occurred can in some way be observed by the changes that have occurred in pedagogical hardware. Initially, most programs in these areas relied on a "large" central computer resource of the institution, and perhaps, a modest logic design laboratory. With their introduction, minicomputers were acquired in increasing numbers and it became common for a major department to have its own system. More recently, low priced microprocessor systems are placing significant computer power in the hands of almost any department.

An equally significant development went on in the classroom as in the laboratory. Initially, programming classes were presented often by the computer center staff. These quickly moved into more academic settings within mathematics and electrical engineering departments. From this point options and minors developed. These, in turn, developed into degree offering departments, which included in their offerings the tool courses but also moved up to more abstract courses, such as switching and automata theory, computability and formal languages.

In the sections that follow, the development of the academic concepts of this area of education will be considered, with primary emphasis on the more recent developments.

THE DEVELOPMENT OF CURRICULUM IN COMPUTER SCIENCE

The single most significant document in computer science education was the report of the Curriculum Committee on Computer Science (C^3S) of the Association for Computing Machinery, most commonly known as "Curriculum '68."[1] The report gives detailed specifications for twenty-two courses fundamental to the study of computer science, as well as putting these courses into a prerequisite structure that also involves mathematics.

While the questions of definition and justification of computer science are not addressed in the report, the subject matter is classified into three areas of computer science and two related areas. A core program is defined, and based on this core area the undergraduate program is detailed involving computer science courses, mathematics courses, and technical electives.

Graduate degree programs are mentioned but not detailed to the extent of the undergraduate program. The master's program is outlined in terms of areas while doctoral programs are only mentioned in general terms, with ideas put forth for further work. Additional topics which received some attention in the report included service courses and minors, continuing education programs, program implementation problems, and facilities.

"Curriculum '68" may be seen as an expansion and refinement of the 1965 report of C^3S[2]. This earlier report spent a great deal more time on the definition of computer science as a discipline, and its relationship to other disciplines, especially mathematics.

The 1965 report of C^3S was, in turn, an outgrowth of a panel presentation at the 1963 ACM national meeting that was reported in 1964 in *The Communications of the ACM*

* On leave from the University of South Florida, Tampa, Fla.

by Perlis,[3] Arden,[4] Forsythe,[5] Korfhage,[6] Gorn,[7] Muller,[8] Keenan,[9] and Atchison and Hamblen.[10] In these reports one finds a definition and specification of computer science; courses and program description emphasizing the first course, numerical analysis, logic and logic design; and descriptions on programs then existing in the United States. Within the courses and program descriptions emphasis was placed on the role of programming projects and exercises as an integral portion of the programs, and the close ties of computer science education to mathematics, at that time, was noted.

COMPUTER ENGINEERING

While the more theoretical aspects of computing machinery was being addressed by C³S, the improvement in economics in the computer industry opened new areas in logic design. Not only was computer design the main objective of studying combinatorial and sequential circuits, but also new areas in process control, data communications, systems analysis and simulation required this knowledge. A trend was initiated in colleges of engineering and particularly among electrical engineering departments to create the discipline of Computer Engineering.

In September 1967 the COSINE Committee of the Commission on Engineering Education published recommendations for an undergraduate course program.[11] Though originally designed as an enhancement of an electrical engineering curriculum this report was, in effect, the initial development of the area of computer engineering.

The report presents a series of subject areas in a computer science program in electrical engineering consisting of basic subject areas including programming principles, computation structures, discrete mathematics, and machines, languages and algorithms; and recommended elective areas including digital devices and circuits, switching theory and logical design, programming systems, numerical methods, optimization techniques, circuit and system theory, information theory and coding, functional analysis, combinatorics and applications, probability and statistics and symbol manipulation and heuristic programming.

The COSINE Committee did not regard its mission as the same as C³S and did not equate electrical engineering and computer science. Nonetheless, it is of note that much of the material recommended parallels that of "Curriculum '68." The main differences appear in the advanced areas, and in a lack of a course or area corresponding directly to compiler construction. The core of the two programs are virtually the same, however, the work reported on by the COSINE Committee does not place the area of data structures in the fundamental position given by C³S.

The COSINE Committee issued eight other reports dealing with the first course in electrical engineering,[12] computer organization,[13] digital subsystems,[14] industries' reaction,[15] a computer engineering option,[16] digital system laboratory courses,[17] operating systems,[18] and the minicomputer in laboratory programs.[19] Perhaps the lack of a stable operating organizational base such as a professional society prevented the COSINE reports from having the broad impact of the more integrated report of C³S. An effort following in the steps of the COSINE Committee has been the DISE Committee, funded by the National Science Foundation, and with some of the same problems. It should be noted, however, that the efforts of the DISE project are more directed at dissemination of materials than at the definition of programs.

CURRICULUM DEVELOPMENT SINCE "CURRICULUM '68" AND THE COSINE REPORT

Subsequent to the publication of "Curriculum '68" and the COSINE Report, considerable work has gone on relating to computer science education. A significant development in this period was the formation of the ACM Special Interest Group on Computer Science Education (SIGCSE), which provides a continuing organization for the presentation and exchange of ideas in the field.

C³S has continued its activities following the publication of "Curriculum '68." Under the sponsorship of this Committee, a series on doctoral programs was published, a summer institute program for smaller colleges was conducted, course recommendations for smaller schools were prepared,[20] and guidelines for masters programs were prepared.[21]

Additional curriculum work has been conducted within ACM by the Curriculum Committee on Computer Education for Management (C³EM). This Committee has prepared guidelines for both graduate programs[22] and undergraduate programs[23] in information systems which integrates materials associated with computer science with materials associated with business.

As was indicated in the previous section, the COSINE Committee was active in this period, and in addition to the publication cited, the Committee also conducted a series of workshops to assist in the interpretation of their work.

The Committee on the Undergraduate Program in Mathematics (CUPM), also published recommendations in the area of computational mathematics[24] during the period. This work represented an extension of earlier work describing a mathematics program with work in computing.[25]

In addition to these efforts, the literature of computer science education contains numerous references to specific courses and topics providing an expansion of the course material given in the curriculum studies, and presenting something of a dynamic updating of the recommendations. The more recent work of this type emphasizes the area of software engineering and has been addressed in a recent volume.[26] A comprehensive survey of the post "Curriculum '68" literature in computer science education has been published,[27] and thus will not be further addressed at this time.

NEW CURRICULUM RECOMMENDATIONS IN COMPUTER SCIENCE AND ENGINEERING

The Education Committee of the IEEE Computer Society has been meeting regularly for over two years to design a

curriculum which may serve as a model for both the computer science and computer engineering approaches. This work led to the publication of a report of the Model Curricula Subcommittee of the Education Committee in February 1977,[28] although a preliminary report on the work had appeared earlier.[29]

Two aspects of this report should be taken into account for its correct interpretation:

1. The total curriculum as presented probably exceeds the resources or time allocations of most undergraduate programs and, as a result, needs to be adapted to regional needs, local resources, and departmental orientation.
2. A central "core" of subject matter is outlined that is considered the kernel of an undergraduate program in computer science and engineering.

There is no pretention that the report is either exhaustive, complete or definitive. It is claimed that it does represent the views of representative segments of the educational community acting in a committee mode with suitable compromises.

The general distribution of the recommended course modules is divided into five areas as follows:

(a) Digital Logic—5 courses
(b) Computer Organization and Architecture—5 courses
(c) Software Engineering—8 courses
(d) Theory of Computing—4 courses
(e) Laboratories—7 courses

The titles of these courses are given in Figure 1. For catalog descriptions and more detailed information, the interested reader is referred to the full report referenced above.

It should be noted that from the number of courses, the software engineering area is the predominant area in the curriculum; thus, giving the curriculum a pragmatic and applied flavor. In the theory of computing area, a modest amount of course work is recommended which presents a number of very abstract principles in an introductory fashion.

Of particular note is the laboratory sequence. Most laboratories in present computer science and engineering programs, whether they are a part of a given course or a separate course, deal with a specific subset of hardware or

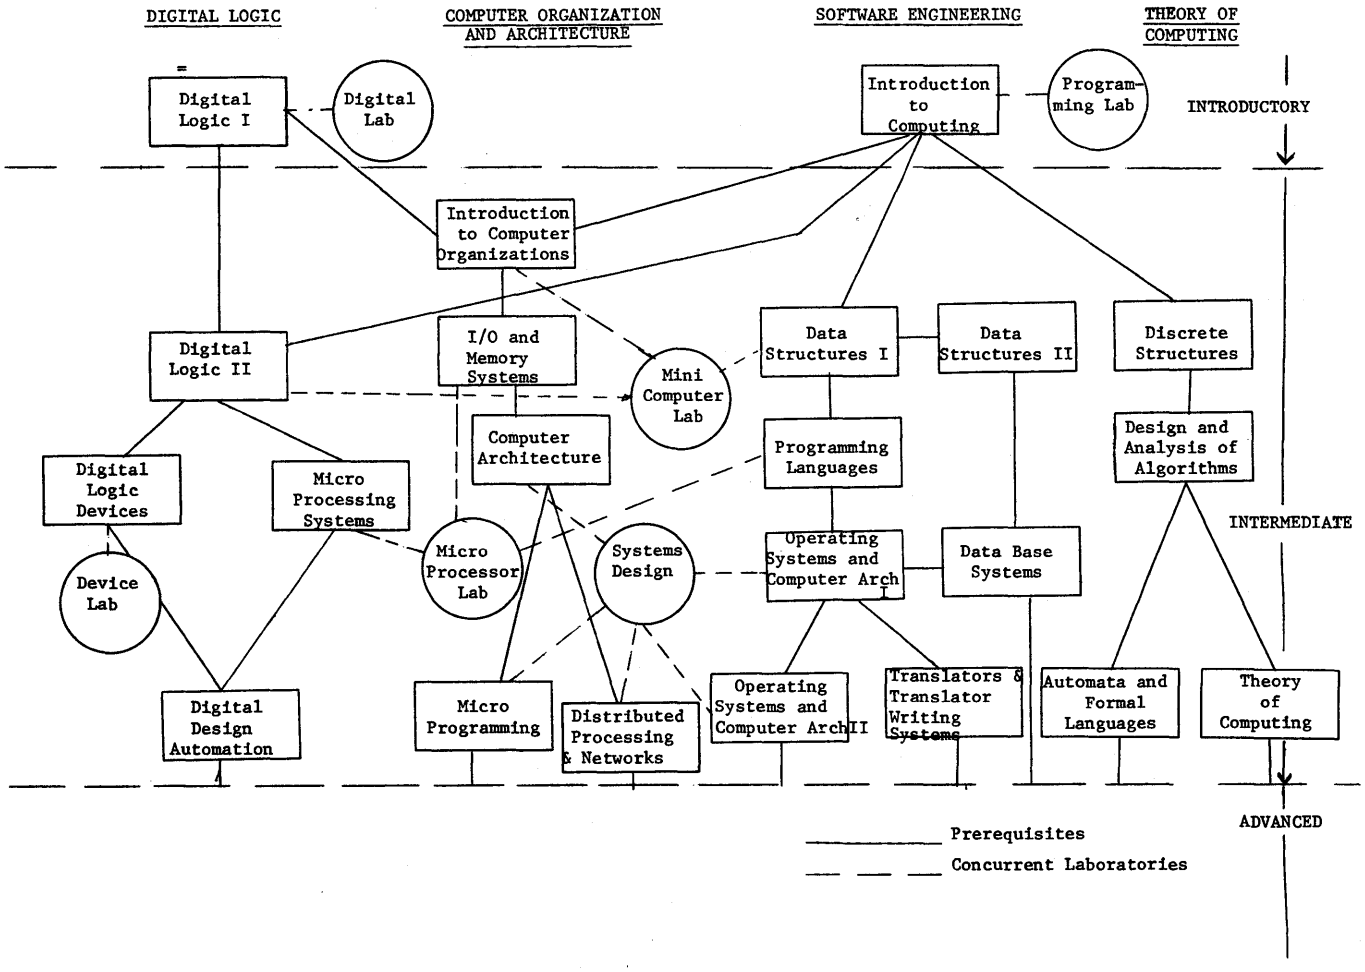

Figure 1—The courses of the IEEE/Computer Society curriculum recommendations

software problems. Therefore, a laboratory sequence should allow a student to become familiar with current technology to apply theory and to solve problems. Thus, the main objective is to expose the student to methods applicable to the "real world," to enhance creativity, and to develop problem solving skills. In the process, the student needs to learn a variety of techniques for designing, implementing, debugging, and maintaining a project.

The approach suggested here has a two-dimension organization.

1. *Vertically,* the labs are organized in a series of graded courses in which the student advances gradually from well-defined experiments to more sophisticated projects.
2. *Horizontally,* the labs are used as media to apply hardware and software principles in an integrated form.

The value of such experience becomes clear when the student realizes that the solution of a hardware design problem requires considering its software implications and vice versa.

The prerequisite structure for the program is given in Figure 2 which indicates the positioning of both the courses and the laboratories.

THE NEW RECOMMENDATIONS OF THE CURRICULUM COMMITTEE ON COMPUTER SCIENCE (C^{3}S) OF THE ACM

During the same period that the Computer Society was developing recommendations, C^{3}S was preparing an update and modification to "Curriculum '68." This appeared in draft form in June, 1977.[30] Though it will not be covered in this paper, it should also be noted that a subcommittee of C^{3}S prepared draft recommendations for a program at the two year level at the same time.[31] These reports were published in this way as working papers to obtain maximum input regarding their content prior to publication of the final committee reports which is anticipated in 1978.

The C^{3}S report is broken down into the general areas of the core curriculum, Computer Science electives, the undergraduate program, service courses and other considerations including facilities, staff and articulation.

The core material is considered to be at both the elementary and intermediate level. The material at the elementary level is first presented as a list of topics in the areas of programming, software organization, hardware organization and data structures and file processing. It is anticipated that many implementations are possible from this listing of topics, and it is emphasized that programming projects should be stressed throughout the course sequence. As a guide to implementation, but certainly not the only implementation, a five course sequence is proposed at this level: CS1-Computer Programming I, CS2-Computer Programming II, CS3-Assembly Language Programming, CS4-Introduction to Computer Organization, and CS5-Introduction to File Processing. Three intermediate level courses are then proposed to complete the core or that material required to provide minimum requirements common to all computer science undergraduate programs. They are CS6-Operating Systems and Computer Architecture I, CS7-Data Structures and Algorithm Analysis, and CS8-Organization of Programming Languages.

Following the core material illustrated in Figure 3, two intermediate level electives are proposed, as are nine advanced courses, and provisions for special topics courses. The course prerequisite structure in the report is given in Figure 3, and the interested reader is referred to the full report for more detailed information.

It should be particularly noted that the intermediate level core courses are recommended to contain a strong emphasis of fundamental concepts exemplified by various types of programming languages, architecture and operating systems, and data structures. Neither theoretical treatments nor case study approaches in and of themselves are adequate or appropriate at this level. Advanced level courses may be used for such treatments. Special topics courses are suggested and it should also be noted that which of the special topics are offered will be dependent on the resources of the department, however, it certainly is the case that in time, some of the material listed under this category, should be integrated into the courses more fully specified, or replace entire courses in the curriculum. Monitoring this phase of the program will be a continuing activity of C^{3}S.

Tied into the prerequisite structure of the program are six mathematics courses:

MA 1 Introductory Calculus
MA 2 Mathematical Analysis I
MA 3 Linear Algebra
MA 4 Discrete Structures
MA 5 Mathematical Analysis II
MA 6 Probability and Statistics

Descriptions of the courses MA1, MA2, MA3, MA5 and MA6 may be found in the 1965 CUPM recommendations.[32] MA4 represents a more advanced course in discrete structures than that given in "Curriculum '68," and builds on concepts developed in the study of calculus and linear algebra, emphasizing applications of discrete structures to computer science. The complete prerequisite structure is given in Figure 4 which includes all the courses mentioned, except CS 10, Computer and Society, and the Special Topics courses whose prerequisites will vary depending on circumstances.

The major will normally consist of the eight courses of the core material plus four additional courses selected from the recommended computer science intermediate and advanced electives with no more than two from any one specific subfield of the discipline. It is further recommended that the student take mathematics courses MA1, MA2, MA3, and MA4, and depending on computer science electives selected, MA5 and MA6 may be required.

As has been indicated, further details are available to the reader in the report, and in fact, this paper has only addressed those portions of the report dealing with the under-

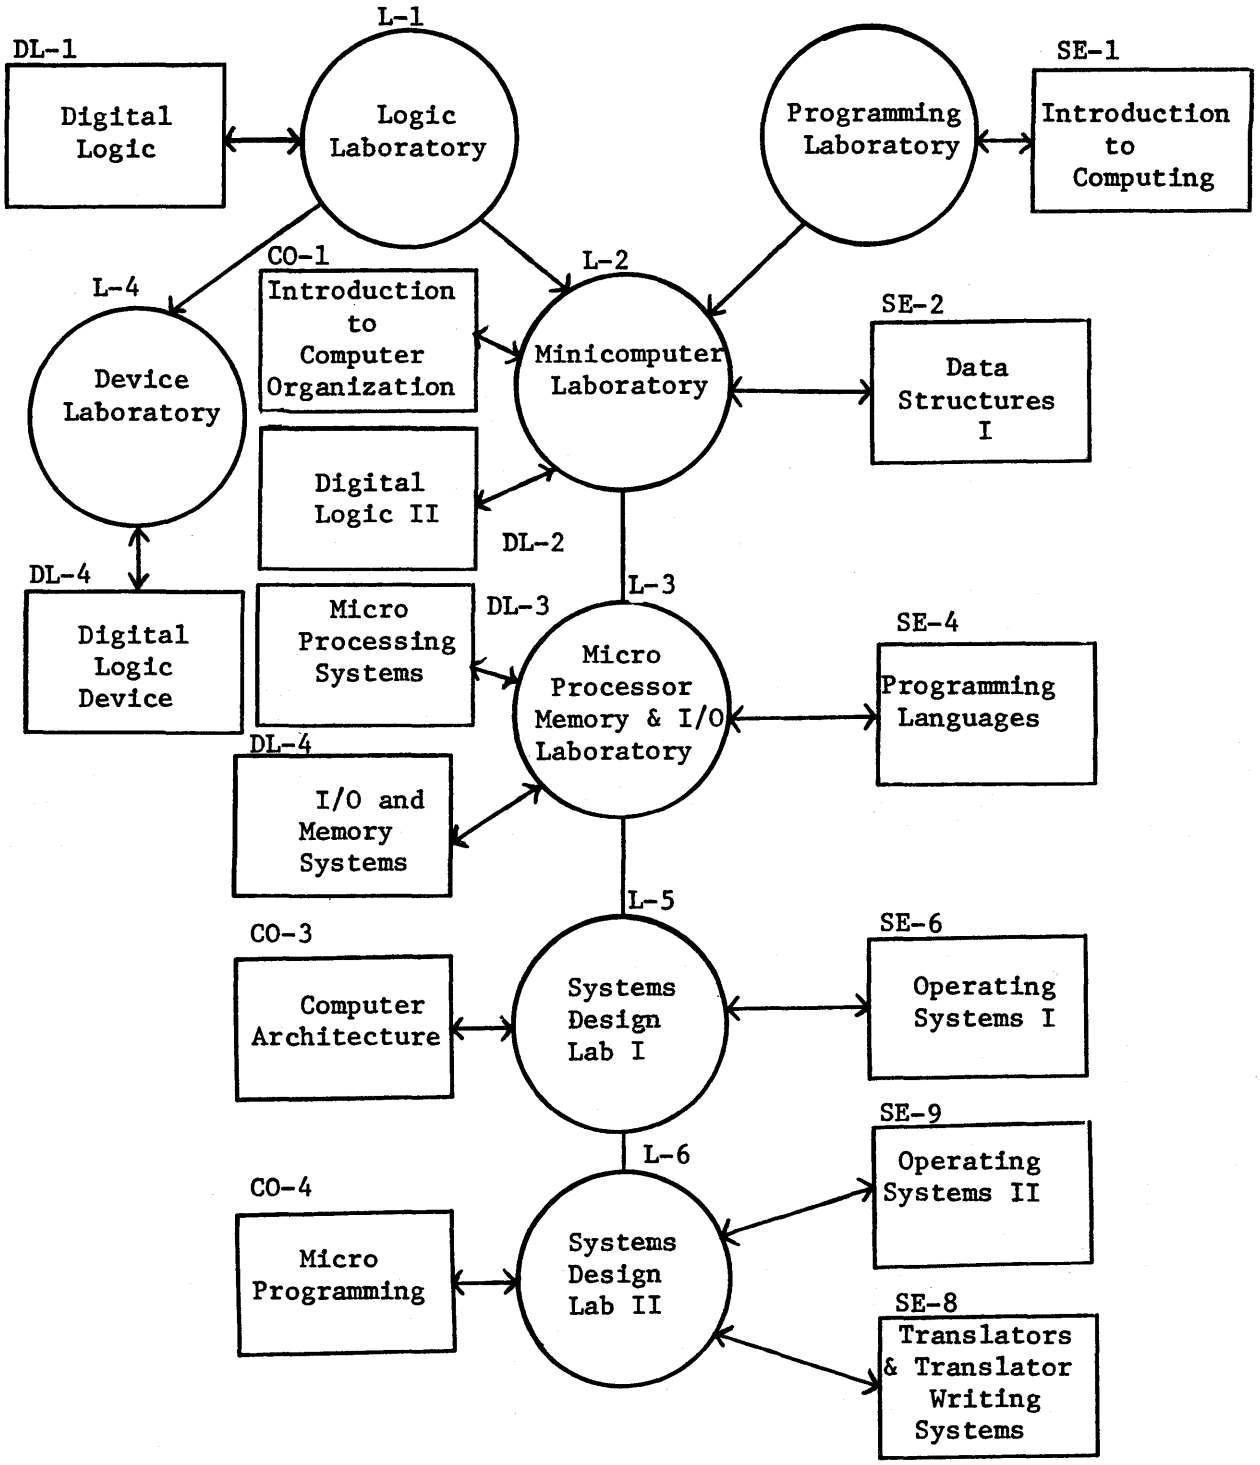

Figure 2—The prerequisite structure of the IEEE/Computer Society laboratory sequence

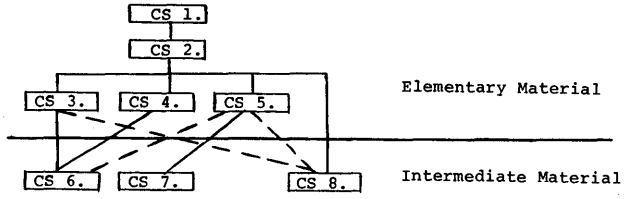

Figure 3—The core courses of the C³S recommended curriculum

graduate major. It should be noted, at this point, that the minimum requirement for the major, as specified, requires 48 semester hours which is certainly less than half the typical undergraduate program.

CONCLUSIONS, OUTLOOK AND PROJECTIONS

As has been shown in this paper, computer science and computer engineering have grown considerably in the past ten years. It would appear significant that it took ten years from the publication of the COSINE recommendations in 1967 to the publication of the model curricula of the Computer Society, while it also took ten years from the publication of "Curriculum '68" to the final version of the report updating that document.

What is perhaps most significant, however, is the convergence that can be seen occurring between the groups. Though working almost in total independence of each other, the two committees prepared guidelines remarkably similar in philosophy and content.

This similarity may be best seen in considering the core material of the two programs; CS1 Computer Programming I is similar to SE-1 Introduction to Computing, CS2 Computer Programming II is similar to SE-2 Data Structures 1, CS3 Assembly Language Programming and CS4 Introduction to Computer Organization cover much the same material as CO-1 Introduction to Computer Organizations, CS5 Introduction to File Processing is similar to SE-3 Data Structures II, CS6 Operating Systems and Computer Architecture I is similar to SE-6 Operating Systems and Computer Architecture 1, CS7 Data Structures and Algorithm Analysis covers much the same material as TC-2 Design and Analysis of Algorithms and SE-5 Data Base Systems, and CS8 Organization of Programming Languages is similar to SE-4 Programming Languages.

As one would expect, there are differences in the recommendations. The recommended core of the Computer Society program more strongly emphasizes the hardware and engineering areas, while those of C³S more strongly emphasize software and theoretical areas. But while these differences exist, the similarities strongly point to the fact that the discipline of computer science and engineering is approaching a well defined state.

It is fortunate that the two committees produced their reports at essentially the same time. This gives the educator the opportunity to study both documents, and select those parts that best fit his institutional needs in constructing a

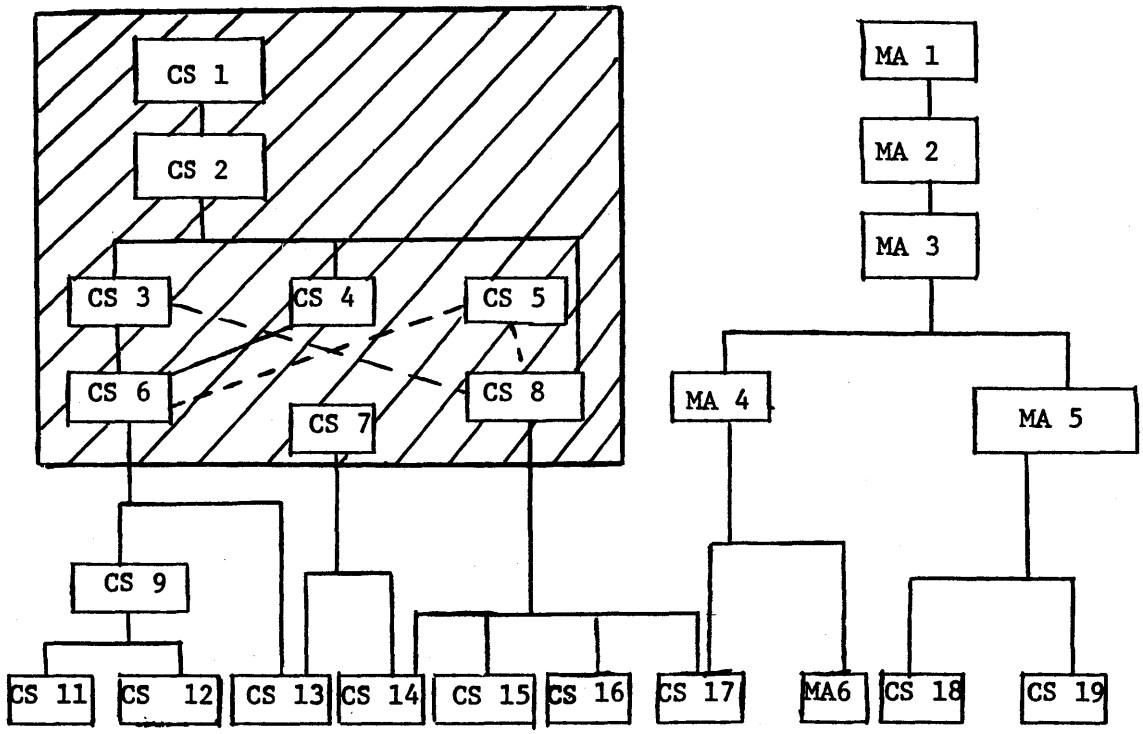

Figure 4—Prerequisite structure of the C³S curriculum

program, for it must be emphasized that these are only guidelines.

Coursework may be outlined on paper, however, more critical questions of feasibility of implementation in a variety of settings exists. While it is not anticipated that there will be complete agreement on courses and curriculum design on the part of all interested parties, by continued interchange of ideas, at least a consensus of the critical issues to be covered may take place. To foster this interchange, both committees welcome input from all interested parties.

The status of computer education in the community and junior colleges—Needs and alternatives

by JOYCE CURRIE LITTLE
Community College of Baltimore
Baltimore, Maryland

INTRODUCTION

The community and junior college is usually a multi-purpose, comprehensive, open-door institution, offering traditional transfer programs, career programs, continuing education courses, and community service courses. Each college is usually funded by both state and local taxes, and serves the citizens of a local geographic political division or sub-division. They offer access to higher education by means of generally lower tuition and by being within commuting distance of the citizens they serve. They are not often residential campuses, generally having a clientele who work part-time and maintain their role in their regular family situation.[1,2]

Although the first public community and junior college was established in 1901, it was not until the 1940's that the President's Commission on Higher Education called for making education more generally available through the establishment of two year colleges. Later commissions, in 1960 and 1970, recommended that a college be within commuting distance of almost every citizen of the United States. By serving as the "open-door" of opportunity to those who had no chance for higher education before, the two-year institutions have been credited as the "social leveler" in our society, and have brought this country closer to the goal of universal higher education.[2]

COMPUTER EDUCATION

The earliest programs in the computer field in the two-year colleges were those offered in California in the late 1950's. These early programs were generally built around unit record equipment and computers acquired through substantial discounts from IBM, in conjunction with support from the federal government. Because *business data processing* is the name generally used for record-keeping activities of a business or industry, most of the early programs carried this name and were offered through the auspices of the Business or Business Administration department. Many of these programs still exist, and often are named *Data Processing Technology, Information Systems, Computer Programming,* or *Computer Science.*

A typical career program in a two-year college offering an Associate in Arts or Sciences includes anywhere from 62 to 70 semester credits of coursework. This generally includes 24 credits of general education work, including English, Mathematics, and Social Studies, 12 to 15 credits in subjects in Business, and 18 to 24 credits of computer courses. Most of these programs generally include: three credits of an introductory data processing, three credits of an introductory computer programming language, as many as eight credits of COBOL programming, perhaps three credits of RPG programming, and six credits of systems analysis and design. Students sometimes have an opportunity to take one course in operations, and in some instances are included in an internship or work-study program. The mathematics requirement is generally either Business Mathematics or General College Mathematics, sometimes including a course in Elementary Statistics.

Additions to the offerings of the two-year colleges included, in many instances, a "scientific" option. These programs emphasize the use of the computer in the programming of statistical and data-gathering applications, in forecasting, and in mathematical and engineering work. Many of these programs are offered under the auspices of the mathematics departments; some of them are called *computer science.* More recently, two-year colleges near four-year programs have initiated the first two years of a transfer program, also generally entitled *computer science.* The scientific option generally differs from the business data processing or commercial option in these ways: classical mathematics up through the calculus is substituted for the courses in business, statistics is required, emphasis in computer language is on FORTRAN, and assembler programming is stressed in more depth. The transfer program, however, generally offers a course in data structures, one in computer organization or architecture, and a course in numerical methods.

A few schools offer an option within the Engineering or Electronics Departments. Students learn fundamentals in digital and analog computer logic and circuitry, and often

are employed by the manufacturers of computers to be further trained as customer service engineers.

Certificate programs are offered in some two-year schools. These are generally one year in length, but sometimes are one semester. Most computer operations certificate programs are one year, while certificate programs in data entry are generally shorter. In many states, these types of programs are offered by the secondary vocational-technical schools rather than in the community and junior colleges.

Many of the community and junior colleges offer courses about computers as a service to other departments and programs. Students majoring in Business or Accounting generally take one introductory course, as do students in medical records and paraprofessional health programs. Some schools offer "professional development" courses for industry, although the popularity of these courses has decreased at the community and junior college level as states have begun to limit the number of credits that may be transferred from these institutions to upper division colleges. Community service courses for no credit or for continuing education units (CEU's) remain popular with local community groups, especially within off-campus centers in local industry.

CURRICULUM GUIDELINES

Several curriculum guidelines for two-year programs have been prepared by the U.S. Department of Health, Education and Welfare Office of Education. A business data processing curriculum was prepared and released in 1963,[3] covering a broad range of careers in the computer field. In 1964, a report for electronic data processing in engineering, science, and business[4] gave suggested techniques for use in courses of study. A report on scientific data processing technology was released in 1970,[5] and in 1973, the earlier 1963 report was revised.[6] The 1963 publication was perhaps the most important influence on the establishment of programs during the 1960's.

In 1969, the American Association for Community and Junior Colleges (AACJC), sponsored the publication of two reports, with the assistance of a grant from Hewlitt-Packard Corporation. One concerned curriculum;[7] the other concerned college-wide computer usage.[8] There are currently no plans to update these reports by AACJC.[9]

A report giving recommendations and guidelines for a career program in computer programming for community and junior colleges was recently released by the Subcommittee for Community and Junior College Curriculum of the Association for Computing Machinery (ACM).[10] This report is based on the results of extensive discussion held between June 1975 and February 1977 with community college educators, industry representatives, and professional society representatives. The report appeared as a working paper in the SIGCSE Bulletin, along with a working paper for an undergraduate program in computer science, prepared by the Committee on Curriculum in Computer Science of the ACM, to receive reactions and comments before final publication.

This report represents the first set of curriculum recommendations to be produced for the community and junior college level by a professional society. In earlier ACM curriculum reports, however, providing educational programs for applications programmers is credited to the community and junior colleges.[11,12] The 1977 report is intended for the preparation of entry-level or trainee computer programmers who will work in an applications setting to support the general, administrative, and organizational functions of industry, commerce, business, and government service. Even though it is designed to prepare students for jobs, it emphasizes the need for a sufficient foundation for continued learning and advancement in the field. It is hoped that this report will encourage the re-evaluation of existing programs as well as serving as a guideline for the creation of new programs.

The ACM Community and Junior College Curriculum Report gives 14 objectives of the program, covering technical and non-technical skills. Instead of providing one sample or recommended curriculum structure, if offers guidelines for the local institution to adapt to the needs of their local community. It provides a detailed topical outline of the content of the program, and recommends that each college teach this content by giving depth instruction in a major procedural language (such as COBOL), some additional instruction in a second, or minor, language (such as RPG), and a foundation of concepts based on whatever assembler language it has available to use. It is recommended that the program include an "applied area" of study to be the major applications area. This feature of the curriculum recommendations allows the purpose of the program to be toward the commercial or business field, toward the scientific area, or toward any applied field of interest to the institution or to the student.

The report recommends laboratory experiences of a variety of types, with one type in one course, and perhaps another type in other courses. It is recommended that immediate turnaround of computer runs be provided during the scheduled laboratory sessions with the instructor present, with several additional turnarounds provided for open laboratory use. The report suggests an increased use of timesharing access, with experience in interactive programming provided. It recommends increased emphasis on concepts and usage of an operating system during coursework, increased emphasis on data and file structures, and increased use of pre-programmed packages and utilities.

The report offers a real challenge to those two-year institutions interested in maintaining an up-to-date, viable program. It will perhaps serve as an incentive to review and re-examine equipment, facilities, and programs.

EMPLOYMENT NEEDS

Students who complete the two-year Associate in Arts or Associate in Sciences degree program are generally capable of working as a junior computer programmer or programmer-trainee. Most graduates go into commercial applications work, into banks, insurance companies, small business, etc. Others go into statistical data centers, service bureaus, or local government data processing. Although most commu-

nity and junior colleges are required to perform student follow-up studies, most is done on a college-wide basis rather than for any particular curriculum. Therefore little has been documented on graduates of two year programs in computer education.

Most two-year educators feel that placement of graduates has been good. Many graduates have, within three years, moved up the promotion ladder into a variety of jobs, ranging from senior programmer, systems programmer, to management in a small company. Often, within five years of graduation, almost a third have not only been promoted on the job, but have acquired a baccalaureate degree, generally by continuing to an upper division institution on a part-time basis. Employment practices are, however, often criticized by these community and junior college program coordinators, to the extent that many local businesses and industries require that the entry level position be that of an operator, sometimes even a peripheral equipment operator. This mismatch of training to the job is usually "corrected" once the applicant has proven valuable.

More and more baccalaureate programs are becoming available in computer education, with the number of them recently passing the number of associate level programs.[13] Many companies now show a definite preference for the four year graduate, as does the U.S. Government. Two year college graduates generally have their best opportunity, in their first job, with the small systems shop. Recently, several colleges have specifically attempted to outline a separate option within their program to fill that need.

OPPORTUNITIES AND CHALLENGES

Students interested in the computer field as a profession have opportunities at the community and junior college level to learn about the field, gain good technical skills in computer programming, and get a good general education. This initial investment is usually enough to give a talented person enough foundation to allow continuation in further learning while working in the field. Community colleges generally cost less, do not require students to move away from home while going to school, and in most cases provide a somewhat more personalized atmosphere than do the large state colleges and universities.

However, certain problems do exist. Many center around the problems arising from the lack of well-qualified faculty. It is difficult to find, and keep, faculty with good academic credentials, several years of experience doing computer work, and several years of teaching experience. With the declining enrollments forecast by professional educators, administrators are hesitant to hire new full-time faculty, and are, instead, promoting "cross-training" of those faculty in other departments whose enrollments have already declined. This can be done, and can be done well, but it requires more time than is generally given. Secondly, problems arise, and are increasing, from the lack of proper equipment, or lack of proper access to the equipment to be used, or lack of control over the types of activities to be done on the equipment. Thirdly, problems exist in the lack of commitment on the part of the institution to ensure a quality program. It is difficult for instructors teaching full-time to properly revise and maintain both a facility and a curriculum, without needed released time from course instruction. Fourthly, problems exist in the lack of understanding of the students about what the career field is, and the types of skills and talents that success in the field requires. The mystique of the "computer" has not been disspelled from entering students. Lastly, problems exist in the transition of the student from one level of schooling to another, commonly called the "articulation" problem. It occurs between secondary schools and community colleges as much as it does between community colleges and upper division institutions.

NEEDS FOR THE FUTURE

Developments in the computer field continue to occur at extremely fast rates. The boom in minicomputer and microprocessor technology is having a profound effect on business and industry. The growth in small diskette and cassette computers has led to an increased need for personnel who can serve as a combination of operator, analyst, data entry operator, and programmer. The effect of data base management inquiry systems and the creation of the position of data base administrator will change the way the conventional computer programmer performs work.

Educational institutions often react slowly to the need for change. Curricula established a decade ago are, in many instances, in need of attention in both the content area and in the physical facilities being used. Several rather urgent needs, given here in prioritized order, exist:

1. A return to the philosophy of attempting to do those things that are "academically" better, rather than doing merely those things that are the absolute minimum for retaining the program. We should be looking for the best teachers, the best in facilities and the best access to them, and strengthening of the content of the programs, both technically and otherwise. Getting this is NOT always a matter of increasing costs.
2. An emphasis on a well-qualified, kept-up-to-date faculty, given time for curriculum development as well as for teaching. There should be opportunities for "cross-trained" teachers to gain experience by working under the auspices of the college, perhaps, before being placed technically "over their heads" into a classroom. Special programs should be considered for community college instructors, perhaps on a state-wide or regional basis. Opportunity to interact with other teachers, as is possible in the ACM's Special Interest Group for Computer Science Education,[14] should be found. Access to recent computer literature should be planned, by means of journals, newsletters, etc.
3. More imaginative use of the monies spent on computer equipment. Recently decreased costs of equipment can make an older five-year lease very expensive. Alternative types of computers should be studied and con-

sidered for use in an entire curriculum, or in one course. Access to this equipment should be planned under the philosophy recommended in 1. above.

4. An increased emphasis on career education in the computer field, from the middle school level, at least. Better advising and counseling is needed in both secondary schools and community colleges. Encourage professional societies to revise career leaflets as they become dated, and urge students and counselors alike to use career books presently available.[15,16]
5. Availability of a "certification" examination suitable to the requirements of the entry-level computer programmer. Such an examination would give potential employers a reference point for the evaluation of the knowledge base of the entry-level applicant. It would provide a means for continuous professional over-view of what the entry-level person should know, as continuing re-evaluation of the examination occurs from year to year. It would provide the community and junior colleges with some statistical data on the scores of their graduates for continuous evaluation of their program.

OUR ALTERNATIVES

Community colleges have experienced explosive growth over the last few decades. Programs established during that period are in need of attention. Those that get it, and a rebirth of commitment, should survive, and will perform a service to society in the preparation of well-qualified persons for the use of computers in the future. Those programs that continue without changing to meet industry requirements will, in due time, slowly fade away. The needs will be met somewhere else, perhaps by a program at the four-year level, in the state colleges or universities. The decision, and the challenge, is ours.

Business/computer science curricula—A survey

by KATHRYN L. SCHENK and JAMES R. PINKERT
California State University, Chico
Chico, California

INTRODUCTION

The use of computers in business is increasing dramatically, both in the diversity of applications and in the number of smaller firms now employing them. Hence, one would expect a corresponding increase in the number and extent of combined business/computer science programs in undergraduate college and university curricula. In an effort to explore this increase, and to provide one resource for their work on a combined program at California State University, Chico, the authors did a survey of such programs in the United States. This paper is a report on the results of that survey.

METHODOLOGY

The survey was conducted during the 1976-77 academic year. Program directories, departmental brochures, catalogs, professional journals, mail inquiries, and personal discussions were used to compile an initial "candidate" list of schools and their programs.

Sub-minimal crossovers were eliminated during this compilation; "minimal" was arbitrarily taken to mean "a combined program in which the degree area required at least 75 percent of the units normally required for a minor in the other area;" e.g., if a typical minor was 20 units, then a business program which required fewer than 15 units of computer-related courses was considered sub-minimal.

As indicated above, this cutoff was arbitrary. It was unfortunately necessitated after initial work indicated a very large candidate list, but one in which a significant number of supposedly combined programs required only two or three courses in the non-degree area.

It is interesting to note that during the search process the perspective of the survey changed. It was originally intended to have two aspects: computer science majors with business options and business majors with computer science options. However, the authors were able to identify very few of the former; hence, the focus is on the latter.

After compilation of the candidate list, work was begun on an in-depth analysis of each program and the courses in it. At this stage some programs were unfortunately dropped from consideration because precise requirements and/or descriptions for course numbers were not available in time. The final sample consisted of 56 schools offering a business degree with a minimal option in computer science.

Results were tabulated according to a course list derived from the union of all the samples' courses. Since emphasis here is mainly on content rather than quantified amounts, it was decided not to distinguish between quarters, semesters, 4-1-4, etc. Similarly, only two status categories were used: required and elective. Required courses are those explicitly and individually specified. Elective courses comprise all others, including such listings as "select two of the following six," etc.

The percentage of schools having each course required, elective, and either required or elective is shown in Appendix I. Appendix II is a selection of those courses most often required. Finally, Appendix III shows several of the more comprehensive programs.

COMMENTS

It must be stressed that the fundamental orientation of this survey has been the general composition of computer science options in business curricula. Ideally, of course, an advisor from every school would have been interviewed with regard to the program in his/her department. Limited resources, time constraints, and the number of programs involved made this impossible. Therefore, although every possible effort was expended to insure accuracy and completeness, no claims can be made as to the inclusion of all programs or the exact specification of programs included.

The survey results have proven very useful for the authors' purposes. It should be of similar use for others designing combined programs.

In closing, two sidelights were of interest to the authors. First, the large number of courses coupled with the small percentage of schools requiring many of these courses seems to indicate considerable diversity of opinion as to which topics should be part of such a program. Second, the topic "security" was automatically entered at the start of the tabulations. Given the concern with computer crimes and abuses, it was surprising to find that none of the programs included a course in security as either a requirement or elective.

APPENDIX I—REQUIRED AND ELECTIVE PERCENTAGES

	REQUIRED	ELECTIVE	TOTAL
I. Introduction and Languages			
1. Introduction to computers	85.7	1.8	87.5
2. Flowcharting	3.6		3.6
3. Documentation	1.8		1.8
4. Basic	1.8		1.8
5. FORTRAN I	37.5	3.6	41.1
6. FORTRAN II	5.4	3.6	8.9
7. R.P.G.	8.9		8.9
8. COBOL I	51.8	7.1	58.9
9. COBOL II	10.7	5.4	16.1
10. PL/I	7.1	3.6	10.7
11. Assembly I	30.4	8.9	39.3
12. Assembly II	1.8	1.8	3.6
13. Survey of Languages	8.9	7.1	16.1
14. Programming Applications	23.2	5.4	28.6
15. Advanced Programming	5.4	1.8	7.1
II. Foundations			
1. Data Structures	19.6	5.4	25.0
2. Numerical Analysis	1.8	1.8	3.6
3. Discrete Structures	5.4		5.4
4. Information Theory	1.8		1.8
5. Automata Theory	1.8		1.8
6. Symbolic Logic	1.8		1.8
7. Analysis of Algorithms	7.1		7.1
8. Formal Languages	3.6		3.6
9. Systems Theory	1.8	1.8	3.6
III. Hardware and Operations			
1. Computer Organization	5.4	3.6	8.9
2. Hardware Systems	3.6	3.6	7.1
3. I/O Devices	1.8		1.8
4. Systems Programming	12.5	1.8	14.3
5. Compilers	1.8		1.8
6. Operating Systems I	8.9	3.6	12.5
7. Operating Systems II		3.6	3.6
8. Real Time Systems	5.4	3.6	7.9
9. Selection of Hardware Systems	3.6		3.6
10. Use of Software Packages	1.8		1.8
11. Analogs	1.8		1.8
12. Minicomputers	1.8		1.8
13. Management of Data Processing Systems	8.9	1.8	10.7
14. Person/Machine Interaction		1.8	1.8
15. Security			
IV. Information Systems			
1. Information Systems I	17.9	1.8	19.6
2. Information Systems II	3.6		3.6
3. Accounting Systems	5.4	1.8	7.1
4. Management Information Systems	21.4	3.6	25.0
5. Systems Analysis	46.4	5.4	51.8
6. Systems Design	41.1	1.8	42.9
7. Files and Data Management	16.1	3.6	19.6
8. Information Retrieval	7.1	1.8	8.9
9. Database Management Systems	8.9	1.8	10.7
10. Case Studies		1.8	1.8
V. Probability and Statistics			
1. Probability	14.3	1.8	16.1
2. Statistics I	28.6	3.6	32.1

3. Statistics II	14.3	3.6	17.9
4. Sampling	1.8	1.8	3.6
5. Regression	3.6		3.6
6. Non-Parametric Statistics	3.6	3.6	7.1
7. Multi-Variate Analysis	1.8	1.8	3.6
8. Statistical Experiments		1.8	1.8
9. Reliability Statistics	1.8	1.8	3.6
10. Queing Theory		1.8	1.8
11. Decision Theory	10.7		10.7
12. Forecasting	1.8	3.6	5.4
VI. Operations Research			
1. Operations Research I	23.2	5.4	28.6
2. Operations Research II	5.4	8.9	14.3
3. Optimization		1.8	1.8
4. Linear Programming		1.8	1.8
5. Non-Linear Programming		1.8	1.8
6. Dynamic Programming		1.8	1.8
7. Integer Programming		1.8	1.8
VII. Simulation and Modeling			
1. Simulation	21.4	19.6	41.1
2. Simulation Languages		1.8	1.8
3. Modeling	5.4	1.8	7.1
4. Deterministic Modeling	3.6		3.6
5. Stochastic Modeling	3.6	1.8	5.4
6. Continuous Systems		1.8	1.8
7. Discrete Systems	1.8	1.8	3.6
VIII. Computer Science Topics			
1. Symbol Manipulation		1.8	1.8
2. Natural Language Processing	1.8		1.8
3. Computer Assisted Instruction	1.8		1.8
4. Artificial Intelligence	3.6	1.8	5.4
5. Pattern Recognition	1.8		1.8

APPENDIX II—TOP 18 REQUIRED COURSES

Name	% Requiring

Minicomputers
Systems Analysis
Systems Design
Statistics I and II
Simulation
Deterministic Models
Stochastic Models

A brief survey of computer science and engineering education

by C. V. RAMAMOORTHY
University of California
Berkeley, California

INTRODUCTION

In this paper we shall attempt an overview of some significant developments that have taken place over a span of three decades in the Computer Science and Engineering (CSE) education and to discuss some very critical issues that face the educators and the professional societies. Unlike other technologies, the computer technology has been in a state of explosive evolution. It has never been easy to define or even agree upon what should constitute an essential core of knowledge a student should obtain (learn) during a four-year period of undergraduate study of the computer technology.

With the development of the first electrical computers,[22] Harvard (1937), Bell Telephone Laboratories (1937) and the University of Pennsylvania (1946), the computer industry has grown by leaps and bounds. Computer sales *currently* amounted to more than 10 billion dollars in 1975 and it is predicted that the industry will experience a 19 percent growth in revenues by 1985, with more than two million people employed in computer related jobs. One cannot forget that we as a nation are wholly dependent on the computer. It becomes therefore, very important for us to study the role and trends of CSE education especially as it attempts to satisfy the growing need for well-trained professionals in this area.

HISTORICAL DEVELOPMENTS

It is not easy to trace the evolution of CSE education. Universities such as Harvard, MIT, Pennsylvania, and Illinois were probably among the first to include CSE courses in their regular curricula. Two types of courses were most prominent; the logic design courses primarily emphasizing the computer design techniques based on the switching theory and circuit design, and programming courses emphasizing machine and assembly language programming. While the former were generally taught by electrical engineering professors, the programming courses were taught usually by the specialists of the university's computing center under the auspices of the mathematics department. As the need for computer engineers and computer programmers increased, more and more courses were added and a distinctive pattern emerged in the administration of these courses. Electrical engineering (EE) departments naturally included computer design courses in their curriculum whereas the mathematics departments generally handled programming and numerical analysis courses.

The early computers such as Harvard Mark I, ENIAC etc., were built through the support of the U.S. Army and were intended to calculate the ballistic trajectory tables. This heralded the increasing use of computers in scientific computations, which in turn placed demands for more college graduates with numerical analysis and computer programming backgrounds. Consequently, mathematics departments initiated scientific programming courses in their curricula, and expanded their numerical analysis programs. Computer science (CS) departments began to appear in the middle sixties generally as off-shoots of mathematics departments in the Colleges of Arts and Science. Stanford University's Department of Computer Science under the late Prof. Forsythe was among the earliest. At present, the CSE education in major universities and colleges are administered mainly either by separate Computer Science and Electrical Engineering Departments, or by a combined Electrical Engineering and Computer Science Department. The former pattern can be seen in universities like Illinois at Urbana, Stanford, and Texas at Austin. The latter plan of a combined department is credited to be originated at University of California at Berkeley and at MIT,[19] and is followed at universities like Columbia, Northwestern, etc. The hardware design oriented courses are taught very naturally by the EE departments whereas the CS departments emphasize theory and programming. There are, of course, exceptions to all the above trends. Recently a few EE departments identified computer engineering as one of their major components and call themselves Electrical and Computer Engineering Departments, e.g., University of Michigan, Ann Arbor and University of Wisconsin, Madison. Also, CS programs are sometimes included in Departments of Mathematics, or Statistics or Industrial Engineering.

We have used the terms computer science (CS) and computer engineering (CE) without defining them. Perhaps the distinction between them can best be made by taking a closer look at each. The computer scientist is interested in

the theory and science of computation and programming. Thus, areas such as automata theory, formal theory of languages, complexity theory, numerical analysis and the mathematical foundations of algorithms, and data structures (thus, the science of programming a la Wirth) cover the discipline of computer science. The computer engineer is interested in the specification, design, implementation, and utilization (operation) of data processing systems including both hardware and software. Thus, computer engineering can be defined as that branch of engineering concerned with the organization, design, and utilization of digital processing systems as general purpose or specialized computers or as components of larger systems.[2] Thus the computer engineer (including the software engineer) uses the principles of computer science and/or electrical engineering in specifying, designing, implementing, and utilizing computer systems for specific applications.

CURRICULUM DEVELOPMENT

Three basic milestones can be identified in the curriculum development of the CSE education. They are (1) ACM Curriculum 68, (2) COSINE Committee recommendations, and (3) Computer Society's Model Curriculum Subcommittee (CSMCS) recommendations.

(1) *ACM Curriculum 68*—The ACM's Curriculum Committee on Computer Science (C^3S) published a set of recommendations called the Curriculum 68,[1] in March 1968. This was a comprehensive set of proposals for four-year undergraduate programs and some graduate programs. It also included description of contents of supporting courses in mathematics. In a previous set of recommendations, the committee devoted considerable attention to the justification and description of computer science as a discipline. Curriculum 68 was adapted by several universities as a model for their computer science programs. Its major effort had been to help standardize the undergraduate and graduate programs in many CS departments. The Curriculum 68 provided a clear description of course contents together with pertinent technical references. It also specified a sequence of core or essential courses that should be taught in a four-year undergraduate curriculum. Aiming primarily at programming and mathematically oriented computer science areas, it shied away from any recommendations for engineering oriented computer education.

(2) *COSINE Committee*—In the middle sixties, the COSINE Committee of the National Academy of Engineering studied the computer options in Electrical Engineering Departments. In a series of reports, they discussed various aspects of computer education in electrical engineering, including courses in computer organization,[4] digital subsystems,[3,5] digital systems laboratories,[6] and minicomputers.[8] An important COSINE report known as the Coates Committee's report[2] defined the computer option in electrical engineering which set forth a basis for the development of many future computer engineering programs. Also, the COSINE Committee's report on operating systems[7] provided the first comprehensive course description in that important area. Judging from the number of electrical engineering departments having computer science and engineering options patterned after COSINE Committee reports, it can be said that COSINE has been quite successful. The COSINE Committee's workshops and reports helped to initiate several faculty in EE department into computer engineering and helped make CE a major component of EE.

(3) *Computer Society's Efforts*—The Model Curricula Subcommittee of the Computer Society's Education Committee started efforts in 1974 to develop a four-year curriculum in CSE. "Development of model curricula that mesh computer science and engineering has, over the past decade, been a tar pit and many great and powerful beasts have thrashed violently in it."[10] The Subcommittee divided the CSE program into four subject areas and have provided course definitions and contents in each. The subject areas are digital logic, computer organization and architecture, operating systems and software engineering, and theory of computing. It is evident that these subject areas are quite broad and no single four-year curriculum could treat them adequately. Hence, the Subcommittee has proposed model curricula which are formed with elements considered essential in each of these subject areas. A number of options in the proposed curricula would provide some specialization. Increased specialization is provided at the graduate level.

In a way, the Computer Society's Model Curriculum objectives were different from those of ACM's Curriculum 68, the major difference being that the former recognized the need for both computer science and computer engineering in a single curriculum. In that sense, the Computer Society's Model Curriculum recommendations "define curricula that are interdisciplinary in nature with emphasis placed both on computer engineering and computer science." This was also the first effort to bridge the gap between computer science and computer engineering and hardware and software. To date, a number of reports have been published by the Model Curricula Subcommittee which discuss some critical issues and rationale for their recommendations.[10,11] Another significant contribution of the Computer Society is the report on Computer Architecture Curriculum.[12] In this study several well-known educators, engineers, and scientists have identified the functions and the role of the computer architect and then proposed a broad based curriculum consisting of both computer science and computer engineering subjects to educate future computer architects.

In effect, the recommended curricula stress good basic scientific and engineering education which provide the student the potential to continue education all through the professional career to assimilate and use the advances of computer technology.

DISE committee's work

Digital Systems Education Committee (DISE) was formed in 1974 with the support of National Science Foundation with the object of providing quality educational materials in the general area of digital systems. The purposes of the

project and the goals are [CAIN]: (1) to develop and/or coordinate the development of educational/instructional materials in the digital systems area; (2) to achieve widespread dissemination and use of developed materials; and (3) to encourage, develop and facilitate mutual cooperation and information transfer between the academic and industrial sectors. The ultimate objective of the DISE project was to help the educators to keep the courses and curricula current and in step with the rapid technological and theoretical developments. The committee solicited and supported proposals for developing educational materials such as textbooks, lecture material, videotapes, and self-paced instruction books in various digital system topics. The Committee also provided support for review, evaluation, and testing of these materials. A repository was established under the direction of Prof. C. L. Coates of Purdue University to collect unpublished digital systems educational material and to disseminate information regarding the items in the collection. DISE Committee has closely collaborated with the Computer Society's Model Curriculum Subcommittee using the latter's curriculum recommendations for developing their educational materials. They sponsored workshops on Microprocessors and Education which brought the industry and university engineers together to exchange latest technological information.

CONCLUSION

An extended and more comprehensive evaluation of CSE education will appear in the September issue of the IEEE Proceedings.

ACKNOWLEDGMENT

The author is grateful to Prof. C. L. Coates, Prof. Edwin Jones, Dr. M. Mulder, Prof. D. Rine, Prof. Martha Sloan, Prof. Della Bonnette, and Prof. T. Walker for discussions and suggestions.

A panel session—Accreditation of computer-oriented academic programs

SESSION CHAIRMAN—GERALD E. WAGNER
California State Polytechnic University, Pomona

Panel Members

Thomas H. Athey—California State Polytechnic University
Sonya L. (Sam) Anderson—T.H. Garner Company
Donald B. Medley—Moorpark College
Eugene B. Smith—U.S. Department of Agriculture

PANEL OVERVIEW—Gerald E. Wagner

The term "accreditation" is defined by the Standard College Dictionary as, "The granting of approved status to an academic institution by an accrediting body after an examination of its courses, standards, etc." Traditionally different levels of accreditation have been available. For example, individual degree programs (majors) can be accredited, total programs can be accredited such as is provided by the American Assembly of Collegiate Schools of Business (AACSB), and entire university programs can be accredited.

This panel will limit itself to the topic of accreditation as it applies to a single academic program. The actual name of the computer degree program is insignificant for the purposes of this presentation and all computer-oriented degree programs are included whether they be called "Computer Science," "Business Data Processing," "Information Systems," "Information Science," or something else. The entire subject or accreditation will be reviewed—both pro and con—as it relates to these programs.

Any decision to accredit or not to accredit academic computer degree programs could have a serious impact on many different groups within our society. The positive and negative aspects of accreditation will be discussed as it relates to: (1) students (both Community College and University), (2) degree-granting institutions, and (3) future employers of the graduates of the degree programs.

Many different professional organizations have attempted to define curricular patterns, but as of this date, no attempt has been made to provide a method for evaluating academic programs. These past efforts have not been wasted though and any efforts to develop accreditation "standards" could and should utilize much of knowledge gained through experiences of these other groups. Some of the relevant efforts in this area will be discussed as they relate to the accreditation process.

Further insight may be gained regarding the accreditation process by reviewing the history of other accreditation groups. In particular, the American Assembly of Collegiate Schools of Business and the Engineers Council for Professional Development will be discussed for that purpose.

Although accreditation has its inherent problems, the benefits to be gained appear to outweigh any of the potential problems or disadvantages that may result. The panel members recommend that immediate steps be taken to develop a workable accreditation process. The first step to be taken would be to establish a committee with representatives from business, professional associations and academic institutions. Furthermore, it is recommended that any efforts to develop accreditation standards must recognize the different roles that different types of computer degree programs play in our society. Any standards must be designed to encourage creativity—not stifle it—as long as the "creativity" does not detract from or change the overall objectives of the academic program.

ACCREDITATION OF COMMUNITY COLLEGE DATA PROCESSING PROGRAMS—Don B. Medley

Black's Law Dictionary defines accreditation as "To send with credentials as an envoy." The New Century Dictionary by Appleton-Century-Crofts, Inc. defines accredit as follows:

> To bring into credit; invest with credit or authority; also to send with credentials; also, to give credence to; believe; trust; also, to credit with something ascribed.

My concern is that we in higher education are sending our graduates out with credentials as an envoy and the credentials are being rejected. Considerable effort has been expended by the government and the several professional organizations in the definition of curriculum patterns for programs at all levels of higher education but little has been done to accredit or validate the programs after they are implemented. Probably the most active organization to work on curriculum development and design has been the Association for Computing Machinery (ACM). A curriculum working paper containing recommendations and guidelines

for a community and junior college career program in computer programming was published in the Special Interest Group on Computer Science Education (SIGCSE) bulletin in June, 1977.

The paper addresses the courses required in such a program and the detail content of each course is defined. The instructional resources, equipment and faculty needs are covered but the only comments related to accreditation deal with articulation. While this developmental work and the followup effort defined in the articulation section are extremely important and must be continued and expanded, there is also a pressing need for a formal evaluation program that will accredit the offerings of particular institutions.

An evaluation system for community college occupational program (COPES) has existed in California since 1971. COPES is a system for voluntary evaluation of occupational programs administered through the Chancellor's Office, California Community Colleges in Sacramento, California. Among the top strengths of the COPES evaluation as rated by the COPES teams are:

- Qualifications of instructional staff
- Occupational experience of instructors
- Quality of occupational instruction
- Administration's commitment to occupational education
- Adequacy and availability of instructional materials
- Updating of instructional content and method
- Utilization of instructional facilities and equipment

Another case for accreditation standards is developing with the expansion of the programs offering college credit for "Life Learning and Experience". Perhaps the professional associations could work with the College Entrance Examination Board and have the information systems included in their long-range examination of American education called Future Directions for a Learning Society.

ACCREDITATION: PROBLEMS AND PERSPECTIVE—Eugene B. Smith

Computer Science education has evolved over the last 25 years to a significant element of many academic programs. The level of training varies from introductory material for all students to the research oriented PhD degree. The scope of the material covered and the location of the instruction within the Univeristy vary widely. The level of maturity of this field dealing with computers and their use has reached a point where there should be a concerted effort to initiate some predefined measure of quality control over the instruction being provided. Accreditation is an accepted vehicle for identifying and maintaining a specified level of quality for academic programs.

If one were to contemplate advocating accreditation for computer related educational programs, it is important to understand what the term accreditation implies. This paper will provide a discussion of the functions of accreditation, the types of accreditation, and the accreditation procedure.

Educational institutions in the United States are not controlled by a single Federal ministry. Accrediting bodies include governmental agencies, regional associations, and programmatic associations. Both institutions and program areas within institutions may receive various types of accreditation. Some consideration must be given to the levels of the institution which would be included in any accreditation effort.

A brief discussion of other accreditation groups should provide some insight into the approach which could be taken in implementing this type of effort. References to the history of the American Assembly of Collegiate Schools of Business (AACSB) and The Engineers Council for Professional Development will be provided.

A better understanding of the accreditation process and identification of the players who must participate in such an activity will provide an atmosphere within which potential problem areas can be identified. Considering the state and scope of computer oriented education, now is the time to begin an attempt to develop a workable accreditation process. A reasonable first step would be to establish a qualified task force with the dedication required to initiate an accreditation effort. A coalition of business and academic representatives, with the support of the professional associations should be formed.

ACCREDITATION—A UNIVERSITY PERSPECTIVE—Thomas H. Athey

Universities have a major part to play in the training of individuals who desire to become EDP professionals. The significance of this role will increase in the near future as user organizations progress to more sophisticated and encompassing computer-based information systems. These types of systems will require individuals who have sufficient skills at the entry level to make a meaningful contribution to the organization plus a broad enough perspective to function effectively in society. Universities are uniquely qualified to assume this responsibility.

There are many groups who should be vitally interested in the training process performed by the university. These stakeholders include employers, associated departments within the universities, junior colleges and high schools, and students. These stakeholders need reliable evidence concerning the excellence of curriculum and the resultant competency of the graduates who desire to apply these learned EDP skills.

One of the ways of developing indicators of quality and competency is through the accreditation process. In the past, this has been attempted by several professional organizations within the EDP field. The initial work has been in establishing the resources utilized in the various programs to include measurement of the type of equipment available, the number of faculty, etc. The next stage in development

has been in curriculum building. Establishing the types of courses and patterns that seem to be most appropriate for acquiring particular EDP skills and perspectives. A most ambitious approach has been put forth by the Accreditation Research Committee of AACSB. They are concentrating on a value added method by which they propose to measure competence levels of knowledge, skills, aptitudes, attitudes, and personal characteristics of individuals who complete various programs.

While the major advantage of accreditation is the resulting verification process, there are several other benefits which could accrue from a well designed plan. These would include (1) development of more meaningful and effective articulation agreements between junior colleges and universities, (2) explicit recognition of the highly different orientations required of curriculum aimed at different segments of the EDP professional market, and (3) the development of aptitude tests which are much more inclusive and valid than the present programmer's aptitude tests.

The accreditation process is not without its potential disadvantages. These include (1) a strong tendency to insure uniformity of programs, which could result in stifling innovation, (2) the possibility exists for universities to become too vocationally oriented and forget that their mission is education, and (3) if any type of mass testing is required, not being able to constantly update the testing procedure to reflect the needs of the rapidly changing field.

Overall the case for an accreditation process seems very strong. However, to be successfully implemented the accreditation body must include representatives from each of the major stakeholders in the training process and useful measures of competency must be determined.

Recent progress in Japan

It is hoped that the area entitled "Recent Progress in Japan" will provide the audience with a better understanding of computer technology in Japan. The primary objective is to overview the present status and the future prospects of both semiconductor and computer technologies from viewpoints of recent activities in the field of research and development, and to present some main research efforts on the development of computers and their application systems suitable for Japanese society.

The first session consisting of two papers is devoted to presenting the state of semiconductor technology in Japan. Semiconductor technology is expected to be responsible for the next major evolution, not only in the computer industry but also in the electronics industry in general. The first paper includes a review of the recent advances in electron optical studies relating to electron beam pattern generation with sub-micron resolution using the variable shaped beam technique. The direct-writing electron beam technology capable of sub-micron geometry is considered to be one of the most important steps towards the achievement of advanced VLSI ICs for next-generation computers. The second paper presents research and development activities in both academic laboratories and semiconductor industries in Japan. It also explores new semiconductor devices offering excellent high-speed switching characteristics with low power dissipation, which are expected to be used for realizing future computers.

The second session is intended to overview the development of computers and technical progress in their application systems in three separate papers. The first paper describes, after a short historical background, the technological characteristics of newly developed computer series with emphasis on their architectures and LSI implementations. The research and development projects of both VLSI and PIPS (Pattern Information Processing System), which are organized by computer industries, academic laboratories and the Government are taken up briefly. The second paper discusses recent features and future prospects of remote data processing in Japan from the viewpoints of various aspects of technology, such as development background, computer network architecture or telecommunication. The final paper discusses the technological trends in real-time application systems through describing the design concept of a very reliable operation control system for the high-speed railway system called the "Shinkansen."

The third session consists of three papers concerned with recent outstanding research efforts on the development and application of relatively small computers.

The first paper gives a detailed description of a very high-performance NMOS/SOS microprocessor developed as part of the PIPS project. This microprocessor contains approximately 7,000 gates in a single chip with 80 pins, and executes most microinstructions at the speed of 200 ns. The technology applied to the realization of this microprocessor speaks well of the potential power of Japanese semiconductor technology today. The second paper describes a very interesting application of computers, namely a comprehensive automobile control system giving the driver indications of the best routes to take, as well as other information such as specific traffic regulations. Moreover, it contributes to economical use of gasoline and reduction of air pollution.

The rapid progress of LSI technology and minicomputers has great potential to build very reliable computing systems using distributed processor systems concept. The final paper describes how distributed computers can be effectively applied to advanced process industries, where control systems, that are more reliable than the ones in use now, are needed. This paper discusses the requirements, design considerations, advantages and possibilities of these systems from the viewpoints of both hardware and software developments.

Electron beam lithography for advanced LSI fabrication

by EIICHI GOTO

INTRODUCTION

The current technology used in IC (Integrated Circuit) and LSI (Large Scale Integration) fabrication is based on optical lithography or the art of photocopying. The light wave length sets an ultimate and absolute limit on the resolution of the optical method at about one micron ($\mu m = 10^{-6}$ meter) and the current LSI technology has almost reached this limit.

In microscopy, a drastic improvement of resolution was achieved in the 1930's by switching from glass (light) optics to electron optics. The similar is taking place in lithography for LSI fabrication. X-ray lithography and electron beam lithography are the two promising methods for improving the resolution by at least one order of magnitude over optical lithography. The characteristic features of these three lithographic methods are summarized in Table I.

In Table I, "Mask in Contact" means that a mask, with a master pattern inscribed on it, is placed in close proximity to the target (silicon wafer covered with photo-resist) so as to selectively expose the target to the incident beam. The finite and rather short life of the masks in contact is the major disadvantage of this scheme.

In Table I, "Mask Projection" means that an image forming projection system (actually a lens) is placed between the mask and the target so that the mask does not have to be in contact with the target. Since there is no material suitable for making an X-ray projection lens, this scheme is not applicable to X-ray.

In Table I, "Direct Pattern Generation" means a feature in which the incident beam is maneuvered so as to generate the pattern directly on the target without using a mask. While this feature can be implemented by suitably deflecting an electron beam at high speed without any fundamental difficulties, this is not the case for light and X-rays. Note that the sub-micron pattern generation feature is also needed for making the masks themselves. Therefore, "electron beam pattern generation" is the key and the very heart of advanced LSI technology which requires sub-optical or sub-micron resolutions.

Moreover, because of flexibility and many other practical reasons, electron beam pattern generation is considered advantageous for making masks to be used with optical lithography in many cases.

The development of practical electron beam pattern generation schemes is reviewed in a later section. The recent developments in electron optics, i.e., the theoretical foundation of the image-forming processes of electron beams, are reviewed and their implications to the practical systems are discussed. Fly's eye optics which may find some use in the future is also discussed.

ELECTRON BEAM PATTERN GENERATION SCHEMES

Figure 1 shows three practical electron beam pattern generation schemes, and their developments are summarized in Table II.

In Figure 1, "Spot Scanning" means that an electron beam, with a small circular cross-section (spot), typically of 0.1 micron in diameter, is deflected electrically (by applying magnetic deflection field or electrostatic deflection field or both) and the pattern is generated by scanning the beam across the area to be exposed to the beam. In other words, the pattern is generated similarly to the pictures on a television screen, except for much increased resolution. So far as scanning and the resolution are concerned, this scheme is similar to SEM (Scanning Electron Microscope). Actually, SEM's with slight modifications were used in the early models of pattern-generating machines. For example, the first Japanese pattern-generating machine JBX-2A was developed concurrently with the first SEM, JSM-1. Using this spot scanning machine (JBX-2A), Tarui and his collaborators successfully made MOS transistors purely with electron

TABLE I.—A Comparison of Lithographic Methods

	"Mask in Contact"	"Mask Projection"	"Direct Pattern Generation"	Ultimate Resolution
Optical	0	0	x	$\gtrsim$ 1 μm
X-Ray	0	x	x	$\lesssim$0.1 μm
Electron Beam	0	0	0	$\lesssim$0.1 μm

0—Practicable. x—Impracticable.

beam pattern generation without using any masks at all in 1968 [L1].

EBES2 and VL-1 (entries 3 and 4, Table II) are also "spot scanning" machines. In EBES2 the electron beam is deflected electrically only in one direction (deflection width 0.128~0.256 mm) and the target is scanned mechanically in the other direction so as to scan and generate two dimensional patterns. In VL-1 the electron beam is deflected two dimensionally within a square scanning area of 5 mm by 5 mm.

Referring to Figure 1, "Fixed Shaped Beam" means that the cross-section of the electron beam at the target has a fixed shape, typically a square of 2.5 μm by 2.5 μm. This is achieved by projecting the image of a mask with a square hole on to the target. The pattern is generated by scanning and/or patching the area to be exposed to the beam. EL-1 is a "fixed shaped beam" machine.

In Figure 1, "Variable Shaped Beam" means that the shape of the cross-section of the beam at the target is variable, typically a rectangle x by y μm with x and y being varied from 0.1 to 25 μm. This is achieved, for example, by using two masks each having a square hole. The image of the first mask is projected on the second mask and the image of the second mask is further projected on the target. The combined action of the two masks are varied by the beam-shaping deflector placed between the two masks, and the shaped beam is directed to a selected position on the target by means of beam-positioning deflector placed between the second mask and the target. The "variable shaped beam" concept was first reported at the May 1977 EIPBT (Electron, Ion and Photon Beam Technology) Symposium by four independent groups (entries 6, 7, 8, and 9, Table II).

Figure 2 is a photograph of one of the first test patterns generated by JBX-6A, the variable shaped beam machine of the Japanese group. Entry 10 in Table II shows the result of the design and feasibility studies made by the authors' group on the variable shaped beam scheme.

Before making comparison and evaluation of the various pattern generation schemes we shall review the recent advances in electron optics.

ADVANCES IN ELECTRON OPTICS

The studies on the image-forming processes of electron beams are called electron optics. Similar to glass (light) optics, the deviations in the actual image from the ideal image are called geometrical aberrations.

The term "geometrical" means that the wave nature of the beam is being neglected. Since the wave nature or quantum mechanical effects can be neglected in the schemes shown in Table II, we shall drop the term "geometrical" hereinafter for simplicity. The aberration theory of the pure (deflection-less) image-forming process of electron beam is well established and we can learn the results from definitive text books on the subject, such as those authored by Glaser [E1] and El-Kareh [E2].

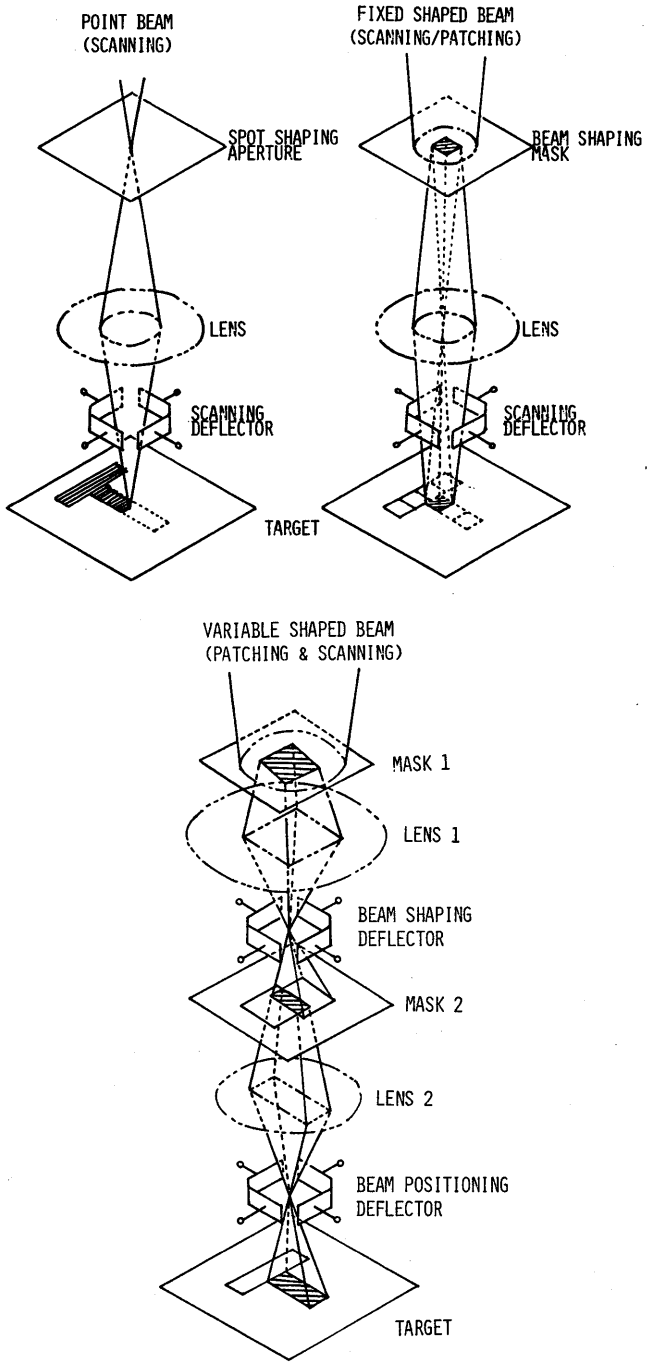

Figure 1—Electron beam pattern generation schemes

TABLE II.—Electron Beam Pattern Generators

0	Model	Beam Shape (μm)	Resolution (μm)	Total Beam Curr. (A)	Electrical Scan Width or Area	Year Reported	Developed at/by	Reference

However, when electrical deflection of the beam enters, the theories developed up to the 1960's are all incomplete in that the focusing field and the deflection field are spacially separated. A unified treatment of spacially superimposed focusing and deflecting fields are needed for the full development of the aberration theory and this has been accomplished only very recently.

Electron optics is a rather specialized art full of jargon of lengthy mathematical formulas and odd terminologies for non-specialists. The authors would try their best to review the advance without entering the jargon. Nevertheless, we shall need the definitions of, at least, some quantities for the sake of clarity.

Figure 3 shows the definitions of three (optical) parameters α, β and γ. We assume that there is a final electron lens (the objective lens) which projects the beam on the target. The shape of the beam on the target is called the image. The distance (specifically called the working distance in pattern-generating machines) from the objective lens to the target is denoted by L.

The parameter $\alpha=F/2=a/L$, with a being the aperture radius of the lens, is the half aperture angle at the image. The brightness of an optical lens (say of a camera) is usually measured by using an index F called the F-number. Hence, $\alpha=F/2$ means that α is the index representing the brightness of the electron lens.

The parameter $\beta=b/L$, with b being the size of the image, is an index representing the size of the electronic image relative to the (working) distance L.

The parameter $\gamma=c/L$, with c being the amount (or the length) of deflection on the target, is an index representing the amount of deflection relative to L.

The ratio $\Delta V/V$, with V being the acceleration voltage of the electron, represents the relative spread in electron energy, which may be caused by thermal effects on the cathode, variations in the accelerating voltage itself as well as by the Boersch effect to be discussed later.

The aberration theory has to do with expressing the quantity $\delta w=\delta(x+iy)$, the deviation of the actual beam point

incident on the target from the ideal point, as a function of α, β, γ and $\Delta V/V$, where $x+iy$ is the two dimensional cartesian coordinate in the target plane in complex form. Namely, we have a function f such that $\delta w=f(\alpha,\beta,\gamma,\Delta V/V)$.

This function is usually expanded into a Taylor series, and each term in the series is given a specific name. For example, the terms including the energy spread index ($\Delta V/V$) are called chromatic aberrations.

The recent advances in the aberration theory and results in the design of electron optical systems with reduced aberrations are summarized in Table III.

First, note that the deflection-less ($\gamma=0$) pure image-forming case has to do with the special case $\delta w=f(\alpha,\beta,0,\Delta V/V)$, and that for "spot scanning" the point image ($\beta=0$) function $f(\alpha,0,\gamma,\Delta V/V)$ would be sufficient but the full function $f(\alpha,\beta,\gamma,\Delta V/V)$ would be needed for "fixed- and variable-shaped" beam schemes.

Ohiwa, Goto and Ono (#1 in Table III) introduced a MOL (Moving Objective Lens) concept and showed that there exists ($\exists f$) a system for point image ($\beta=0$) free of all deflection-induced aberrations, i.e., $f(\alpha,0,\gamma,0)=g(\alpha)$. Chromatic aberrations, however, were not included (assuming $\Delta V/V=0$).

Munro (#3) derived the formula for point image case ($\beta=0$) with chromatic aberrations.

Goto and Soma (#6) derived the formula for the finite image case ($\beta\neq 0$) and also theoretically proved the existence of systems free of all deflection-induced aberrations by making use of the MOL concept.

Soma (#8) derived the most general formula valid for any combination of magnetic and electro-static fields and for electrons running at relativistic speeds. The formula is some 80 pages long and the computerized formula manipulation system Reduce 2 [E12] was utilized for the deriviation. It is extremely difficult to handle such a long formula without such manipulation systems.

The other entries in Table III with "min" (for minimization) gave practical results in reducing various aberrations (there are some 20 aberrations.)

We want to emphasize that, in all the aberration reduction calculations made by the authors' group (entries 1, 6, 7 and 9 in Table II), we also required the beam to land vertically on the target. As a result of these studies, all aberrations except for two have been found to be either eliminable or negligibly small in practice. The two are the spherical aberration δw_s and the axial chromatic aberration δw_a, which have the following forms:

$$\delta w_s=S\alpha^3, \quad \delta w_a=A\alpha\Delta V/V$$

where S and A are the aberration constants. Note that these aberrations exist even in the deflection-less point image case ($\beta=\gamma=0$), i.e., $f(\alpha,0,0,\Delta V/V)=S\alpha^3+A\alpha(\Delta V/V)$. In spite of a great number of efforts trying to eliminate the spherical aberration, no practical scheme has been found yet. [E3] These two aberrations are explained pictorially in Figure 4. The spherical aberration means that electrons having larger aperture angle α are bent stronger by the lens, and the axial chromatic aberration means that slower electrons ($\Delta V/V<0$) are bent stronger by the lens.

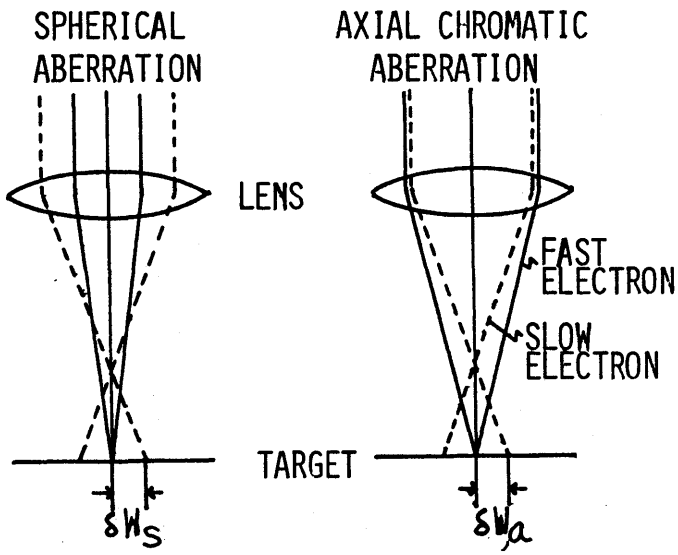

Figure 4—Spherical and axial chromatic aberration

LIMITS ON CURRENT DENSITY AND EXPOSURE SPEED

Besides geometrical aberrations there is another factor, not having its counterpart in light optics, which causes

broadening in the shape of electron beams. That is the electron-electron interaction. When the intensity of an electron beam is increased beyond a certain limit the electrons would start to repel each other and collide with others thereby broadening the shape of the beam. The theory of such broadening is not in a fully satisfactory form [B2] at present.

Among others the Boersch effect, named after the first observer of the effect, [B1], is a controversial issue. Some experimentalists have even questioned the very existence of the effect itself. [B5, B6] Boersch and some others [B6] observed broadening in electron energy ($\Delta V/V$) which is much larger than the thermal fluctuations to be expected from the cathode temperature, when electrons are passed through a spacial region of high electron density. Boersch effect would imply an increase of chromatic aberrations. In addition to the Boersch effect, the space charge causes the displacement of electron trajectories. By regarding the electron beam as a continuous and charged fluid, the displacement caused by the average (averaged over all electron trajectories) space charge effect can be easily derived, yielding the following to be called the space charge broadening formula:

$$\delta w_{sc} = KIL/(V v \alpha), \text{ (in CGS units)},$$

where α is the half aperture angle, V is the accelerating voltage and L is the path length of the electron as defined in the previous section. Further, I is the total beam current (*not the current per unit area*), v is the electron speed ($v = \sqrt{2eV/m}$), and K is a number of the order of unity, which does not depend critically upon the image size β nor on other detailed structures of the system. Thus, we may well use $K=1$ as the rule of thumb.

The experiments performed on JBX-6A (Table II, #6) indicate that axial chromatic aberration and chromatic aberration due to the Boersch effect could hardly affect the projected 0.1 micron resolution and that the observed broadening of the image agrees reasonably well with the space charge aberration δw_{sc}. Thus, the spherical aberration δw_s and the space charge aberration δw_{sc} are concluded to be the major limitations imposed on the resolution and on the beam current.

The space charge aberration $\delta w_{sc} = KIL/(V v \alpha)$ would be reduced by increasing α, the brightness of the objective lens, but this would increase the spherical aberration $\delta w_s = S\alpha^3$. Hence, there is an optimum value of α as a result of compromise. The lithographic process requires the acceleration voltage V to be around 20 K volt. Using the design figures of $L = S = 10$ cm, we arrived at the conclusion that "more than 1 micro ampere beam current would be feasible at 0.1 micro meter resolution" as indicated in Table II, #10.

The following are the implications of 1 μA beam current.

1. The lithographic sensitivity of the advanced electron resist material is better than 10^{-6} coulomb/cm^2. Hence, exposure speed of 1 cm^2/sec would be achieved (20 sec exposure time for 2 inch wafer).
2. If "spot scanning" with 1 μA beam current in a 0.1 μm spot were used, scanning speed of 10^{10} spots/sec (10 Giga-Hz) would be needed, which would be extremely difficult to engineer. For this reason alone, one would have to use "shaped beam" schemes in order to increase the scanning speed.
3. Moreover, 1 μA in a 0.1 μm spot implies 10^4 A/cm^2 in current density. A very bright cathode (e.g., field emission type) would be needed to realize such high current densities, but this would reduce the engineering freedom in the cathode design. The current density would be greatly reduced in "shaped beam" schemes.
4. From these considerations just given, "shaped beam" schemes are believed to be quite advantageous and even a necessity for attaining high exposure speed. On the other hand, "spot scanning" may be advantageous for lower speed devices because of its structural simplicity.

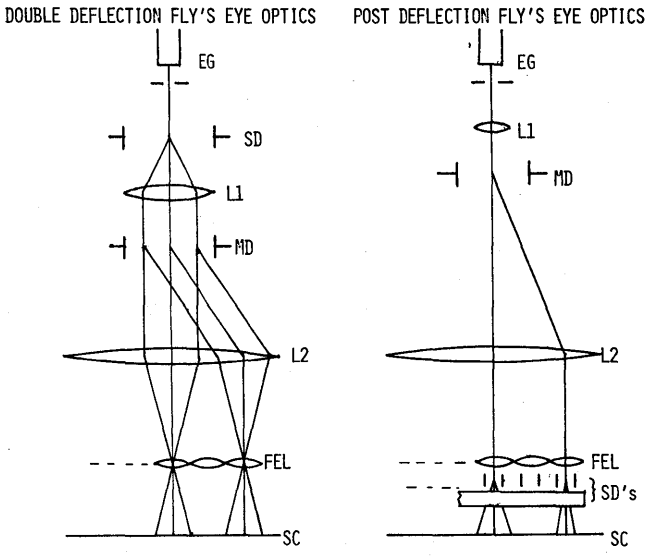

Figure 5—Fly's eye optical schemes

FLY'S EYE OPTICS FOR PURE ELECTRICAL LARGE AREA SCANNING

In all the electron beam pattern generation schemes described earlier (cf. Table II), the electrically scanned areas (typically 5×5 mm^2) are too small to cover the entire target area of silicon wafers, typically two to five inches in diameter. Hence, the target is placed on a mechanically scannable stage so as to back up the electrical scanning. The widening of the electrically scanned area is difficult because it would imply an increase in the working distance L resulting in an adverse effect on the space charge aberration $\delta w_{sc} = KIL/(V v \alpha)$.

Fly's eye optics may provide a method for scanning a large area purely electrically. Figure 5 shows two fly's eye schemes. The "post deflection" type was invented by Newberry [F1] and the "double deflection" type, by one of the present authors. [EG] [F2, F3, F6]. In Figure 5, FEL (Fly's Eye Lens) is illustrated by a matrix of lenses. In both types, the electron beam is selectively passed through a specific

lens in the FEL by the action of the main deflector MD. The beam is further deflected by sub-deflector(s) SD(s), so as to scan a small area. The difference between the two schemes consists in that while a number of small sub-deflectors are placed after the FEL in the "post deflection" scheme, a single sub-deflector placed before the FEL is sufficient in the "double deflection" scheme. Lenses L1 and L2 are inserted in the "double deflection" scheme for the explanatory purpose but they may be removed.

The "post deflection" scheme and its modifications are used in electron beam memory schemes, with sub-micron memory cells. [F4, F5, F7]. The "double deflection" scheme is used in very high precision cathode ray tubes. [F2, F3, F6].

CONCLUSION

Electron beam pattern generators with 0.1 micron resolution running at a speed greater than 1 cm^2/sec are believed to be technologically feasible, based on electron optical studies. The "variable shaped beam" scheme will be used in faster machines and the "spot scanning" scheme, in slower machines.

The impacts of such pattern generators on LSI fabrication are rather difficult to foresee precisely because of the conglomerate nature of the LSI technology. We, as specialists in electron optics, firmly believe that the electron beam can never be the bottleneck in the development of advanced LSI's with sub-micron and sub-optical patterns.

We would like to acknowledge Messrs. S. Miyauchi, K. Tanaka and T. Someya of JEOL for stimulating discussions and for providing us with the photograph of the test pattern (Figure 2).

Semiconductor technology in Japan

by TAKUO SUGANO
The University of Tokyo
Tokyo, Japan

INTRODUCTION

The present status of semiconductor technology in Japan will be reviewed with special emphasis on research and development of semiconductor devices and of large scale integrated circuits for computers. First of all, major programs of R&D of semiconductor devices and large scale integrated circuits will be briefly described and then important achievement, especially on semiconductor devices for high speed digital application and on large scale integrated circuits for logic and memory use, will be discussed.

MAJOR RESEARCH PROGRAMS

Research and development of semiconductor devices and large scale integrated circuits are active in industry, governmental and semi-governmental laboratories and universities.

The Electrical Communication Laboratories, Nippon Telegraph and Telephone Public Corporation (NT&T) and the Electrotechnical Laboratory, Agency of Industrial Science and Technology, are significantly contributing to R&D of LSI through their own work and also through their projects, although their activity is not limited to LSI technology. NT&T is stimulating R&D in industry through their technical innovation such as electronic telephone exchange, data communication and picture transmission. The Electrotechnical Laboratory, too, is promoting R&D in industry through governmental projects such as pattern recognition.

In March 1976, VLSI (Very Large Scale Integration) Technology Research Association was established by the seven corporations in Japanese computer industry, such as Computer Development Laboratories, Inc., Fujitsu Limited, Hitachi, Ltd., Mitsubishi Electric Corporation, NEC-Toshiba Information Systems Inc., Nippon Electric Co. Ltd., and Tokyo Shibaura Electric Co. Ltd.

This is based on the four year national project for developing VLSI technology in cooperation with the Electrotechnical Laboratory and NTT. R&D is carried out at three laboratories: Cooperative Laboratories, responsible for fundamental technologies and Computer Development Laboratories, Inc. and Laboratories of NEC-Toshiba Information Systems Inc. both responsible for application technologies.

The total budget for R&D is approximately 70,000 million Yen (Approx. $290 million) and R&D subjects are covering (1) microfabrication technology, (2) crystal technology, (3) design technology, (4) process technology, (5) test and evaluation technology, and (6) device technology.

The Science and Technology Agency, which is sponsoring the big national projects such as space science and technology and atomic energy, is exploring the possibility of developing various subjects. The Agency picked up the subject "III-V Semiconductor for Functional Devices" and financed the Electrotechnical Laboratory and others for investigation and research on Gunn effect digital devices for computers.

The Ministry of Education, Research and Culture is granting financial aid for special research programs besides financing university for research done by individual staff or small group of staffs.

One of the programs is "Surface Electronics," new surface and thin film technologies of compound semiconductors, and includes R&D of technology for insulator, mainly oxide film formation on the surface of GaAs wafers and of its application to surface passivation of GaAs devices and to fabrication of GaAs MOSFETs and integrated circuits. This was a three year project and terminated in March 1978.

SILICON DEVICES

Many technological advances have been made to improve high frequency characteristics of bipolar transistors and MOSFETs. Smart self-alignment technique was successfully applied to MOSFETs as DSA (Diffusion-Self-Aligned) and to bipolar transistors as SET (Stepped Electrode Transistor) to avoid critical mask alignment. Various types of DSA MOSFETs have been announced as a high speed, sub-micron channel device with high drain avalanche breakdown voltage and without punch-through effect. Cut-off frequency of about seven GHz was reported even in the first experimental device by the Electrotechnical Laboratory.[1]

In order to raise the maximum oscillation frequency of bipolar transistors, very small inter-electrode gap between the base electrode and the emitter was realized by a self-alignment technique as shown in Figure 1. The Electrical Communication Laboratories called this transistor as SET and reported that the gap less than 0.4 μm was achieved and the cut off frequency of $|S_{21}{}^{e}|^2$ has reached to 8.4 GHz, although precise mask alignment whose tolerance was smaller than 0.3 μm was not used.[2]

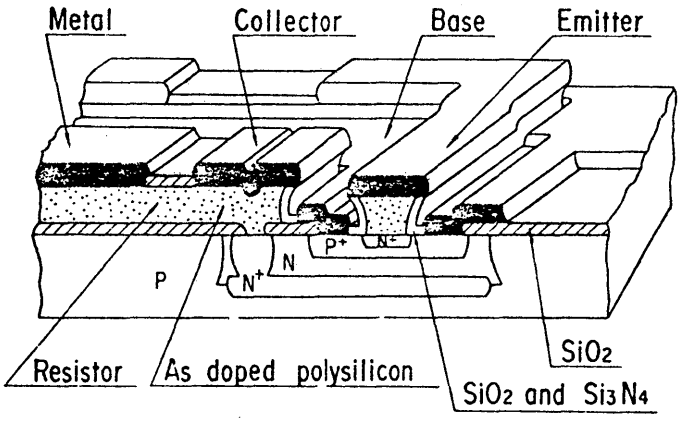

Figure 1—Structure of E^2IC

SIT (Static Induction Transistor) was proposed and developed in Tohoku University. This has a very short channel with high resistivity as illustrated in Figure 2 and triode-like current-voltage characteristics. The delay-time-power product is small and less than 0.01 pJ.[3] This device is useful also as a high output power transistor at microwave frequencies and Mitsubishi announced 20wSIT at 1GHz.[4]

GaAs DEVICES

Gunn effect functional devices with Schottky control gates, developed in the University of Tokyo and other cooperating organizations, are expected to have very small delay time-power product[5] such as 0.001 pJ for $Ga_{0.82}In_{0.18}Sb$.

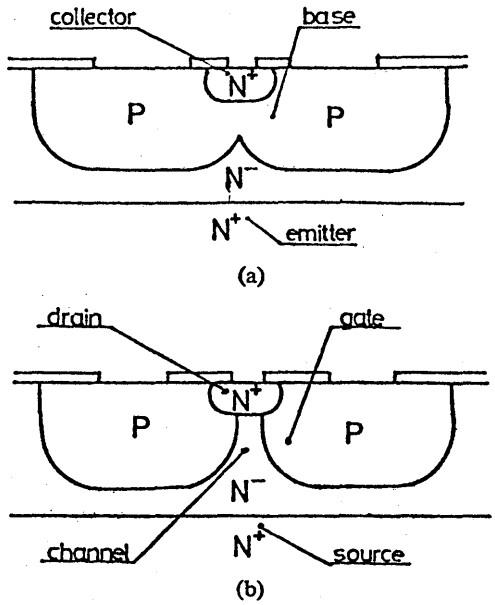

Figure 2—The structures of new transistor types made by lateral p-diffusion.
(a) bipolar transistor
(b) static induction transistor

This motivated the extensive study of material processing technology on III-V semiconductors in Japan.

The special research program "Surface Electronics" stimulated the research of technology of oxide film formation on the surface of GaAs wafers in universities. A group at Hokkaido University worked on anodic oxidation in the mixture of tartaric acid, glycol and water[6] and another group at the University of Tokyo worked on anodic oxidation in oxygen plasma.[7] In addition to R&D in universities, Matsushita developed the technique of thermal oxidation of GaAs in reduced ambient pressure[8] and Fujitu reported GaAs MOSFETs with the maximum oscillation frequency of 13 GHz using plasma oxidation technique.[9]

HIGH SPEED LOGIC

Logic integrated circuits with higher speed with more density of integration have been achieved by new circuit configuration and devices with better performance capability, supported by novel process technology.

The Electrical Communication Laboratories developed the new technologies, called N±IPOS(N^+ Insulation by Oxidized Porous Silicon) and E^2IC (Elevated Electrode Integrated Circuit) process to minimize the isolation area and isolation capacitance and to make the size of bipolar transistors smaller. Both N±IPOS and E^2IC are self-aligning technologies and the former is associated with isolation layer formation and base diffusion and the latter is effective in electrode formation.

Non-threshold logic proposed from the Electrical Communication Laboratories is a unique circuit configuration where bipolar transistors are operating in the active region only and never go to the saturation region. Therefore NTL IC fabricated by E^2IC technology showed the very short delay time per gate of 85 psec and the very small delay time-power product of 0.075 pJ.[10] In 8 Bit ALU with 180 gates integrated in a chip of 1.6×1.0 mm^2 the delay time was 260 psec per gate.[11]

Using the configuration similar to I^2L, SIT logic IC showed the power consumption of 7 μw per gate and delay time of 30 nsec per gate and the smallest delay time-power product of 2 fJ.[12]

Improvement of I^2L using dielectric isolation or vertical pnp injector has been done by the Electrical Communication Laboratories and Mitsubishi. The former reported the delay time of six nsec and the delay time-power product of 0.3 pJ for three collectors configuration[13] and the latter announced the delay time power product of 0.07 pJ.[14]

A new logic circuit configuration, Wired OR Wired AND Logic (W^2L) was announced from OKI. Figure 3(a) illustrates an inverter of W^2L. Both A and B are the outputs due to an input, but the directions of the output current flow are opposite to each other as shown by the arrows. The output current of A terminal exists only when the logical output status is 'H' and of B only when the logical output status is "L." Figure 3(b) shows a circuit configuration corresponding to Figure 3(a). The performance of W^2L as shown in Table I is just intermediate between TTL and I^2L.[15]

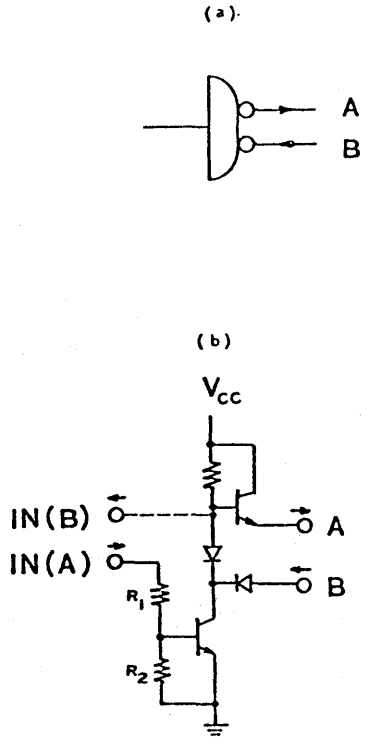

Figure 3—Basic inverter of W^2L

Four bits ALU composed by n channel enhancement type DSA MOSFETs with n channel depletion type MOSFETs as load showed 2.9 nsec as the delay time per gate and 0.71 mW as the power consumption per gate which was reported by NEC and the Electrotechnical Laboratory.[16]

Recently Mitsubishi announced DSA masterslice LSI for 920 gates random logic, whose performance is listed in Table II.[17]

Punch through mode operation of a submicron gate MOSFET is useful because of its inherent high speed performance and low output impedance. Fujitsu proposed to use this mode of operation for high speed logic. An experimental 13 stage ring oscillator consisting of E/D inverters and buffer circuit by 1 μm gate MOSFET (effective gate length of 0.5 μm) with 350 Å gate oxide film showed 90 ps switching delay and an E/E inverter indicated the delay time-power product of 2 fJ.[18]

TABLE I

	T^2L	W^2L	I^2L
Delay Time ns/gate	3-30	3-30	10-100
Power Consumption mW/gate	2-20	1-10	0.01-1
Threshold Voltage V	1.4	0.7-1.4	0.7
Power Supply V	5	1.6-5	0.8-5
Load Drive	good	good	poor
Mask	6	6	4
Transistor Mode	normal	normal	inverse
Active Area Ratio /gate	1	0.4	0.1
/ALU	1	0.3	0.2

TABLE II—Feature of the DSA MOS Masterslice Chip

Number of Circuits	800 internal gate cells 116 output gate cells	
Power Supplies	V_{cc} 5V single power supply	
Propagation Delay Time	basic cell (minimum interconnection)	1.0 ns at 3.6 mW
	basic cell (average interconnection of ALU)	3.0 ns at 3.6 mW
Output buffer	TTL compatible t_r 7 ns at 1 TTL load t_f 5 ns at 1 TTL load	
Total power dissipation	internal gate cells	2.5 W
	output buffer circuits	0.5 W
Chip size	7.68×7.88 mm²	
Number of pins	maximum 120 pins	

Toshiba paid much effort for developing SOS devices and reported 1300 gates LSI by n channel Si gate, E/D configuration. This LSI RFO (Register File O) is composed of 250 bits static RAM and peripheral circuits. This chip size is 4.14×4.47 mm² and the delay time per gate is 0.70 nsec and the access time is 65 nsec, the power consumption is 450 mW and the delay time-power product per gate is 0.21 pJ.[19] R&D of GaAs ICs were reported, too.

Normally Off-Type GaAs MESFETs were used for high speed logic by Fujitsu. An experimental 13 stage ring oscillator showed the delay time of 280 psec and the delay time-power product of 74 fJ.[20]

Significant progress of Gunn effect functional devices has been made by the Electrotechnical Laboratory and Fujitsu. Fujitsu announced two bits shift register which could be operated at the clock rate of 1.6 GHz.[21] Recently 20 ps/gate Gunn-effect high speed carry finding device for 8 bit binary adder was released by the Electrotechnical Laboratory.[22]

MEMORY IC

Significant reduction of power consumption in bipolar RAM was achieved. Fully static 4 K bipolar TTL RAM whose typical access time is 25 nsec and power consumption is as low as 350 mW has been developed by Hitachi. To reduce power consumption, stand-by current of a cell is decreased to 4 μA and it is increased by sinking current through lower word line at the instant when the cell is going to be selected. The fabrication process includes oxide isolation with double layer metallization and transistors with the emitter of 3 μm×3 μm in size have low parasitic capacitances (C_{TS}=0.13 pF, C_{TC}=0.041 pF and C_{TE}=0.034 pF).

The chip size is 3.4 mm×6.3 mm.[23] Similar 4 K static bipolar TTL RAM was announced by NEC. The access time is 40 nsec and the power consumption is 500 mW. The size of a memory cell is 38 μm×60 μm and of a chip is 3.24 mm×5.3 mm. Novel polycrystalline silicon self-aligned

(PSA) technique in combination with non-epi technology (diffused collector) and LOCOS process was used.[24]

The Electrical Communication Laboratories released a 64 K bit MOS RAM whose access time is 200 nsec and power dissipation is 150 mW. MOSFETs whose effective channel length is 2 μm, gate oxide thickness is 500 Å, junction depth is 0.25 μm and threshold voltage is 0.8 V at 1 V drain voltage are used. The technologies: As doped polysilicon gate, selective oxidation, Mo metallization, all ion-implantation, flowed phospho-silicate glass and fine pattern technology, 2 μm pattern width, are incorporated. The cell size is 14 μm×15 μm and the chip size is 6.1 mm×5.8 mm.[25]

Clocked CMOS 4 K static RAM, measuring 4.7 mm square, has been developed by Toshiba. Conventional Si gate technology and fine patterning technology of 5 μm were used and by narrowing the width of the boundary region, the cell area of 47.0 μm×68.0 μm was achieved. The access time is 200 nsec, and the operational power dissipation is 50 mW at the cycle time of 1 μsec and the stand-by power dissipation is 0.5 μW.[26] Recently Toshiba reported new multiplexed electrode per bit structure for a 64-K bit charge-coupled-device memory, where a merging serial register is combined with an ME/B array to make a practical and flexible CCD array. The memory operates typically at 5 M bits/sec data rate, while a 512-bit test array is operated in less than 140 nsec transfer execution time.[27]

Non-volatile semiconductory memory has been developed, too, as an erasable read only memory (EROM), an electrically alterable read only memory (EAROM), and a non-volatile random access memory (NVRAM). Two types of non-volatile semiconductor memory, which are a metal-insulator-oxide-silicon (MIOS) structure and a floating gate structure, were pursued.[28] As MIOS devices MAOS,[29] MTa_2O_5-Al_2O_3 OS[30] and MOSOS[31] were studied. As floating gate devices FAMOS is the first one, but it has disadvantages such that the controllability of stored charge amount in writing operation is not sufficient and the electron injection ratio into the floating gate is rather small. These result in longer programming time. However these disadvantages have been removed by introducing avalanche injection with stacked gate structure (SAMOS),[32] which was developed by Toshiba.

Recently Toshiba announced 2 K bit electrically alterable avalanche-injection type ROM with stacked-gate structure. The writing time is 20 μsec for a single transistor and is less than 5 sec for a fully decoded 2048-bit memory. Erasure of the memory is accomplished either by ultra-violet light irradiation onto the floating gate or by electric field emission of electrons from the floating gate to the control gate.[33]

The combination of hot electron injection and direct tunneling injection in p-channel MNOS memory transistor was used to make a 1024 bit RAM, whose chip size is 3.60×3.61 mm^2, and read access time is 600 nsec and write cycle time is 10 μsec-100 μsec by Toshiba.[34]

Recently a single 5 V supply 16 K EPROM (Erasable Programmable Read Only Memory) using DSA technique and self-aligned gate technology was announced by NEC. The access time is 300 nsec, the power consumption is 450 mW and the chip size is 3.6 mm×4.98 mm.[35]

CONCLUDING REMARKS

It should be notified that:

(1) self-alignment technique is successfully used to fabricate devices such as DSA and SET, and
(2) much efforts are paid to develop new devices like SIT and Gunn effect digital devices.

Of course steady improvement of conventional integrated circuits including devices used in them is going on and this is backed up with new process, technology and new circuit configuration.

ACKNOWLEDGMENT

The author would like to thank Cooperative Laboratories of VLSI Technology Research Association, the Electrical Communication Laboratories, Fujitsu, Hitachi, Mitsubishi, Nippon Electric, OKI, and Tokyo Shibaura Electric for permitting him to include their published and/or unpublished data in this manuscript. Otherwise this review would not have been possible.

The development of computers in Japan

by OSAMU ISHII
Electrotechnical Laboratory
Tokyo, Japan

INTRODUCTION

Japan's research and development of computers began in the 1940's. However, Japanese production of commercial computers started a decade after the U.S. production did. Since then the computer industry has developed into the most rapidly growing industry in Japan. Thirty-nine thousand computers were installed as of the end of 1976. This is second in the world after the United States.

It is difficult to cover all the computer industry and its R&D activities. The aim of this paper is to give a brief review of Japanese computer technology, with a short historical background, and a description of present status and some ongoing developments.

DEVELOPMENT OF JAPANESE DIGITAL COMPUTERS

The research on computers in Japan began at universities and national laboratories. Japan's first digital computer, ETL Mark-1, a small scale experimental relay computer, was completed at the Electrotechnical Laboratory of the Japanese Government, in 1952.[1] Then the relay computers, FACOM 100[2] and ETL Mark-2[1] were constructed in 1954 and 1955 respectively. These machines were used for Japan's first computing services.

The first stored program computer in Japan, called Fujic, which employed vacuum tubes and a mercury delay-line storage, was completed in 1956.[3] The research and development of transistor computers started almost at the same time and ETL Mark-3, a small experimental computer was also completed in 1956.[4] ETL Mark-4,[5] which followed Mark-3, was constructed in the next year, and the technologies developed were transferred to many types of commercial computers.

In the same period, the parametron,[6] a logical element using the phenomenon called the parametric oscillation, was invented, and parametron computers PC-1 (1958),[7] and M-1 (1957)[8] were constructed at the University of Tokyo and the Electrical Communication Laboratory (ECL) of Nippon Telegraph and Telephone Public Corporation (NTT). Several types of commercial computers later employed the technologies developed for these pilot computers.

Japanese companies began to manufacture and market computers around this time. In the 1960's computers began to be introduced into various fields, but at the time Japan was said to be ten years behind the U.S. in technology and industrial management. Faced with this situation, the Japanese Government and computer industry realized that an extraordinary effort was required to close the gap. At that time the "National Research and Development Program" was established in 1966, and the "Super High-Performance Computer Development Project"[9] was carried out by the Agency of Industrial Science and Technology of the Ministry of International Trade and Industry (MITI). The project was completed in 1971, and the technologies developed by the project were applied to several new commercial computer series in Japan.

In the later half of the 1960's, the era of third generation computers, domestic computer manufacturers announced their commercial series of computers. They were: FACOM 230 Series (Fujitsu), HITAC 8000 Series (Hitachi), NEAC 2200 Series (Nippon Electric, NEC), TOSBAC Series (Toshiba), MELCOM Series (Mitsubishi) and OKITAC Series (Oki).

In 1968, NTT started the development of DIPS-1 (Dendenkosha Information Processing System-1),[10] which is a large scale computer designed for a nation-wide data communication service. DIPS-1 started offering the computing service in December 1973.

Following DIPS-1, NTT developed in co-operation with the domestic mainframe manufacturers the DIPS-11 series which included three models.

In 1972, under the promotion of the Japanese Government, the six domestic computer manufacturers were reorganized into three groups, and each group started the development of a new computer series. These series were called "M Series" (Fujitsu-Hitachi group), "ACOS Series" (NEC-Toshiba group) and "COSMO Series" (Mitsubishi-Oki group). The completion of all models of these series from large scale computers to small computers had been announced by the spring of 1977.

COMPUTER INDUSTRY IN JAPAN

The commercial production of electronic computers in Japan was started in the late 1950's by electronics and telecommunications equipment manufacturers, as opposed

to business equipment manufacturers in the United States. Another point of difference between U.S. companies and Japanese companies is that the latter started with the production of solid-state computers skipping over vacuum tube systems. At that time, however, the computer industry was very new to the Japanese, not only from the point of view of technology but also from that of rental systems. The Japanese Government recognized the importance of this field of industry, and the Japan Electronic Computer Company (JECC) was established with the support of MITI by domestic computer manufacturers in 1962 for the purpose of establishing a rental system in Japan. Through the 1960's, the Japanese computer industry has progressed remarkably, especially in the later half of the decade, and application of computers has penetrated many sectors of Japanese society. Figure 1 shows the trend of computer production after 1965 and the trends of peripherals, terminals and small business computers in Japan. The growth of the production of terminals reflects the rapid growth of on-line systems in various fields of computer applications, such as banking, seat reservations and inventory control systems.

Table I shows the composite ratio of applications of on-line systems in Japan.[11]

Besides domestic computer manufacturers, there are many foreign manufacturers in the Japanese computer market. For instance, IBM and NCR have established their fully owned subsidiaries, and other companies are carrying out technical and sales activities in joint-ventures with Japanese firms. Others have sales offices in Japan.

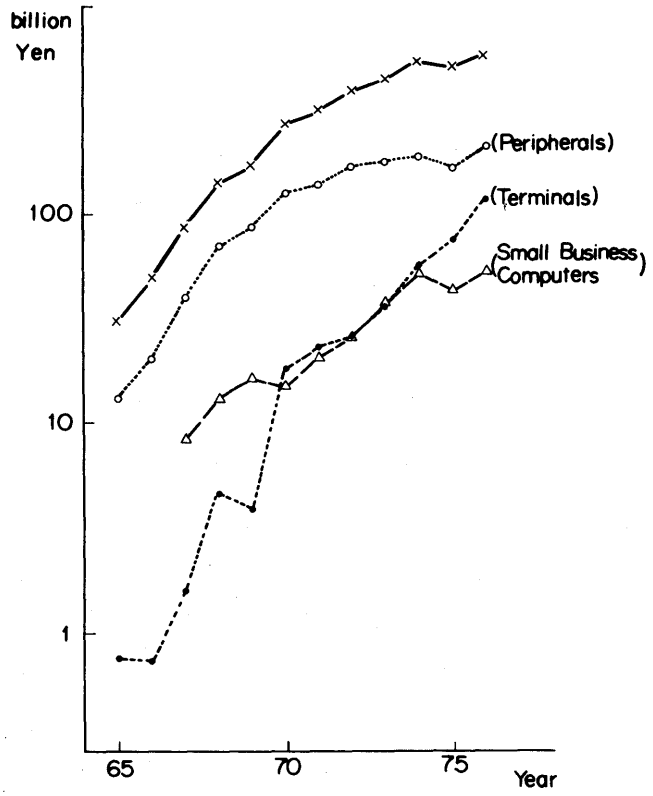

Figure 1—Production of computer systems in Japan (Source: MITI)

TABLE I.—Applications of On-Line Systems

Fields	Composition (%)
Finance, Securities, Insurance	21.3
Manufacturing, Sales, Stocks	43.8
Computing Service	8.1
Pollution Monitoring	7.3
Transportation, Traffic Control	5.3
Others	14.2
Total	100.0

The share of domestic and foreign products in the Japanese market are shown in Table II, as of the end of December 1976. In terms of total system value, domestic production accounts for 56.8 percent, and imports for 43.2 percent. But for large scale systems, imports exceed domestic production.

The market for small and very small computers is growing and they are penetrating the large computer market rapidly because of their cost performance. "Office computers" or "Office systems" (small business computers) are becoming feasible for small enterprises, and sales in 1977 are expected to reach 100 billion yen.

Microcomputer applications are expected to increase markedly, not only for computers, but also for various types of peripheral controls and equipment controllers. Sales are expected to be 20 billion yen for the 1977 fiscal year.

Japan has prudently liberalized capital transaction and trade regulations for the data processing industry. Although surrounded by controversy regulations for hardware were liberalized up to 100 percent in December 1975 and for software in April 1976.

DEVELOPMENT OF 3.5 GENERATION COMPUTERS

The three groups of the six domestic computer manufacturers started to develop three new 3.5 generation computer series under MITI's support in 1972. Since 1974, each group announced new computer models of their series one after another and all three completed their series by the spring of 1977.

The series are shown in Table III, with rough correspondence of the system scale between IBM System/370. Originally the cost/performance of these series surpassed that of the IBM System/370. In 1977, however, IBM announced the 303X processors, and cut the prices of the System/370, also the value of the yen increased, so the situation has changed.

Technological trends adopted in the new series computers are:

(1) Development of LSI and packaging technology
(2) Stress on IBM compatibility

TABLE II.—General-Purpose Computer Installations in Japan as of the end of December 1976 (Source: MITI)

System Scale*	Domestic Systems		Imported Systems		Total	
	No. of Sets	Value**	No. of Sets	Value**	No. of Sets	Value**
Large	1,247	703,634	932	761,885	2,179	1,465,519
Medium	4,617	456,967	1,465	183,938	6,082	640,904
Small	8,235	156,803	2,788	57,782	11,023	214,585
Very Small	10,985	68,461	8,658	52,485	19,643	120,946
Total	25,084	1,385,864	13,843	1,056,090	38,927	2,441,953

* System scale is classified by purchase price as follows:

Large : More than 250 million yen
Medium : 40 - 250 million yen
Small : 10 - 40 million yen
Very small : Less than 10 million yen

** Value; million yen, the conversion rates between Japanese Yen and U.S. Dollar are approximately 290:1 for 1976

(3) Virtual storage and multi-processing
(4) Considerations for data communication and data base oriented systems

Table IV summarizes the characteristics of several representative new series computers (large scale models).

Domestic mainframe manufacturers are also producing many kinds of peripherals including magnetic disk units similar to IBM's.

Many operating systems were developed. The operating systems for each series and model group are shown in Table V. The development of OS aimed at the realization of system functions and performance, which would equal or better IBM's MVS SVS, OS/VS1 or DOS/VS. The most important consideration in developing OS was compatibility with the operating systems which were being supported by computer manufacturers.

NTT's DIPS-1 was developed during the era of third generation computers. DIPS-11, which is a 3.5 generation version of the DIPS-1, consists of Model 10, Model 20 and Model 30. Model 30, the largest system of the series, surpasses the performance of the IBM System/370 Model 168. Table VI shows a summary of DIPS characteristics. These models have full compatibility with each other on software and peripheral equipment.

Another trend in data processing is distributed processing, or computer networks. In 1974, IBM announced SNA (System Network Architecture), and some extensions were introduced in 1976. After the introduction of SNA, most mainframe manufacturers announced their versions of network architecture. Japanese manufacturers for example announced, ANSA (Advanced Network System Architecture, Toshiba), DINA (Distributed Information Processing Network Architecture, NEC), MNA (Multishare Network Architecture, Mitsubishi), MSNA (M Series Network Architecture, Fujitsu-Hitachi), FNA (Fujitsu Network Architecture, Fujitsu), HNA (Hitachi Network Architecture, Hitachi) and DONA (Decentralized Open Network Architecture, Oki). NTT is now promoting DDX (Digital Data Exchange) and has also announced its own network architecture, DCNA (Data Communication Network Architecture). These network architectures are not yet well es-

tablished. However, they will play an important role in future computer systems in Japan.

RECENT TECHNOLOGIES AND PROJECTS

System architecture

An important goal of the development of the new computer series is realization of high OS efficiency for transaction processing and high level language oriented environments. Existing computer systems need a lot of supervisor processing for multi-processing control, which causes an increase in system overhead. The new process oriented architecture and firmware implementation for multi-programming control reduces system overhead, and increases system throughputs. Also, by adoption of the high-level language oriented architecture, instruction steps for execution of high level language statements were substantially reduced. Table VII shows the relative improvement of OS efficiency for the ACOS series.[12]

TABLE V.—Operating Systems Listed by Series and Group

M Series			ACOS Series		COSMO Series

Virtual storage

The concept of virtual storage became common after the IBM System/370 adopted it. The M, ACOS and COSMO series employ the similar virtual storage technology. The details of the control such as page or segment sizes are different in each series. In some of the new series machines, channel address translation mechanisms are implemented by hardware. This was made possible by the progress in semiconductor technology.

Optional processors

The array processors such as the CDC STAR 100 or the CRAY-I are provided in the new series for a high-speed arithmetic processing option. These processors are designed for ease of use, for example, Hitachi's "IAP" allows standard FORTRAN programming.

LSI and package assembling

Semiconductor LSI's and LSI assembling techniques are the most important parts of modern computer hardware technology.

For instance, the floor space, weight and power consumption of the main frame of DIPS-11 (1975-76)[13] were reduced one fourth to one third, one third to two thirds, and a half to two thirds respectively from those of its predecessor, DIPS-1 (1971). These improvements were mainly realized by the progress in LSI technology and assembly techniques.

Typical LSI specifications used in the new series computers are shown in Table VIII. As an example, the logic LSI chip for the ACOS series,[14] is shown in Figure 2. In this case, the assembling has three distinct levels:

(1) Semiconductor LSI chip: LCML (LSI oriented low energy CML), max. 200 gates per chip, 7 pico joule per gate.

TABLE VIII.—Typical Specifications of LSI Used in M and ACOS Series

Item		M Series	ACOS Series
Logic	Chip size	4 x 4mm	3.2 x 3.2mm
	Gates/chip	100	Max. 200
	Delay time/gate	0.7ns	0.7ns
	Power dissipation/gate	35mW	10mW
Memory	Bits/chip	4,096	4,096
	Access time	100ns	Max. 200ns
	Cycle time	220ns	Max. 400ns
	Power dissipation/bit	0.12mW	0.11mW

(2) LSI package: 80mm × 80mm ceramic package, max. 110 LSI chips (max. 3,500 gates) per package, 240 connector pins. Forced air cooling.
(3) High density printed board: 530mm × 390mm, 15 conductor layers printed board, 12 LSI packages (max. 40,000 gates) per board.

Figure 3 is a photograph showing the LSI chips on the package.

Kanji input and output

The Japanese language is usually written in a mixture of "Kanji" (ideographic) and "Kana" (phonetic) characters. There are now only 48 phonetic characters, but several thousand ideographic characters are used in Japan (2,000-3,000 characters are popular, sometimes up to 10,000 characters are needed). Because the Japanese language is not

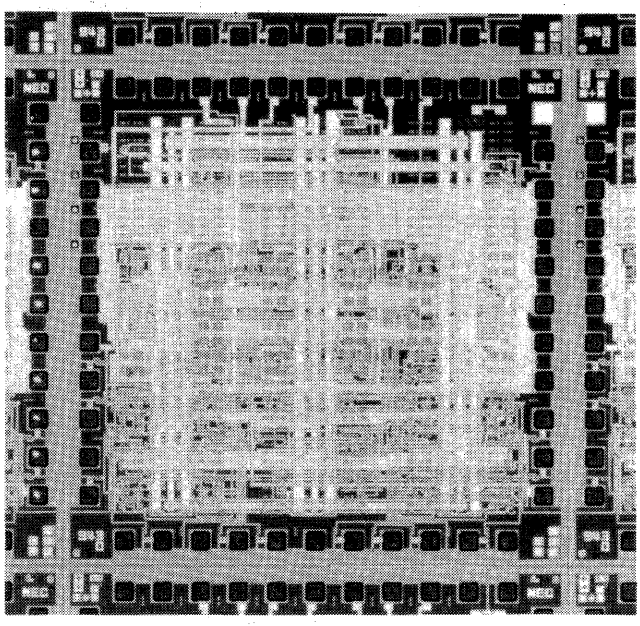

Figure 2—Logic LSI chip

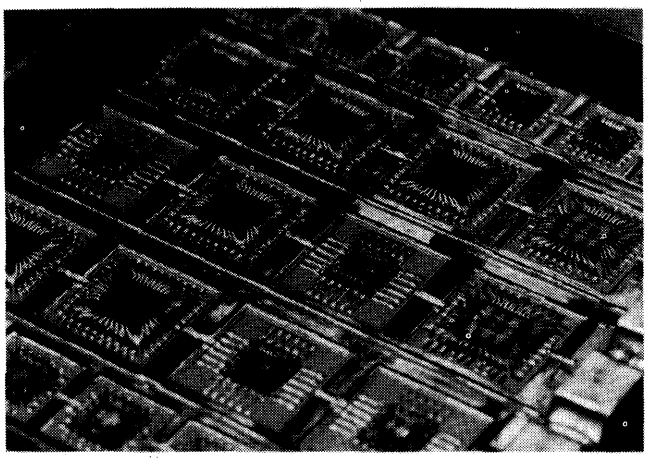

Figure 3—Logic LSI chips on the package

adaptable to a purely phonetic writing system "Kanji" are a most important medium for information exchange. However, computer systems today are not powerful enough to handle "Kanji." The main reason is lack of suitable input and output devices.

For output devices, expensive character generators are needed because of the huge character sets and complicated form of each character. Figure 4 shows an example of Kanji printer output[15] which includes "Kanji," "Kana" and some alpha-numeric characters represented by 24×24 dot matrix. Many types of memories have been used for Kanji font memories. However, the progress in LSI technology is reducing memory costs, so that one major problem, "Kanji" output, is expected to be solved in the near future.

"Kanji" input is a more difficult problem than output because of its man-machine interactions. A conventional "Kanji" typewriter has a great many character keys and several shift keys because of its large character sets. Accordingly, it is very difficult for even a skilled operator to use a "Kanji" typewriter.

Table IX is a comparison of typical characteristics of the English alphabet and "Kanji" I/O devices. The input speed of the "Kanji" device is about one fifth that of the alphabet in characters per minute. However, one "Kanji" character sometimes corresponds to one word so that the input speed of total information would be better than one fifth.

There are many types of "Kanji" selection mechanisms

２４×２４ドットマトリックス

３．７ｍｍ×３．７ｍｍ

漢字２０字／秒

Figure 4—An example of Kanji printer output

for the input device. Table X summarizes trade off between input speed and training necessary for various "Kanji" input devices and systems.

"Kanji" OCRs are being researched, in addition to OCRs for "Kana" and alpha-numeric characters now commercially in operation.

The VLSI project

Through the development of the 3.5 generation computers, it became clear that semiconductor technology, especially ultra-high density integration techniques, will play a key role in the future computer industry. In view of this situation, domestic computer manufacturers are emphasizing the "Very Large Scale Integration" (VLSI) project under MITI's support and guidance. The VLSI technology research association was started by a joint effort of five domestic mainframe manufacturers, NTT, and the government's ETL which provided technical guidance. The goal of this project is to develop the basic LSI and LSI production technologies for fourth generation computers. Production and process techniques for very precise (sub-micron) patterns using electron-beam, x-ray and conventional photolithography are being developed. From 1976 to 1979, a total of 70 billion yen is expected to be invested in this project.

The development program of pattern information processing systems

In today's "computerized society," computer utilization is becoming more and more varied, and increasingly higher efficiency and intelligence are expected. To cope with such requirements, it is desirable that future information systems advance into the area of pattern information processing.

The Japanese Government started a research and devel-

TABLE IX.—Comparison of Alphabet and Kanji I/O

	Character Set (C)	Dot Matrix (D)	Memory Capacity (C) x (D)	Code	Input Speed	Price ($) (Typewriter)
Alphabet (A)	26	5 x 7	910	1 Byte	250 ch./min. (50 words/min.)	100

opment program on "Pattern Information Processing Systems (PIPS)" in July 1971.

The research activities are:

(1) Development of new materials and devices which may be applicable to pattern information processing.
(2) Studies of subsystems for such visual and aural patterns as characters, speech, pictures and three dimensional objects, as well as for understanding natural language.
(3) Development of information systems having such new capabilities as parallel processing, associative information retrieval, and inference, or learning.

The activities in these research areas are closely related to each other. The final goal of the project is to construct a prototype system referred to as PIPS, which will be able to integrate the accomplishments attained in each area.

The pilot models for character recognition, picture and three dimensional object recognition, and word voice recognition, were demonstrated in July 1977.

Besides these pattern recognition subsystems, a high-performance LSI microprocessor,[16] multi-microprocessor systems, high-level language oriented machines, a magnetic bubble data base machine, and several other systems are under development.

CONCLUSION

Twenty years have passed since the commercial production of computers started in Japan. During this period the speed of technical development has been extremely rapid, and the applications of computers has increased greatly. It has affected almost every sector of society. The computer industry has become one of the most important industries in Japan. Now, there are new challenges facing the industry. In the next decade information processing systems which meet a wide variety of social needs must be developed. In these circumstances, technology which improves the cost/performance of computers will as always be sought after. But special applications related to traditional Japanese culture, mainly concerned with the language, will increase their role in Japanese society.

ACKNOWLEDGMENTS

The author appreciates the support in the preparation of this paper by the Japan Electronic Industry Development Association. Many organizations have supplied information, in particular Fujitsu, Hitachi, Nippon Electric, Mitsubishi Electric, Oki Electric, Toshiba and Nippon Telegraph and Telephone Public Corporation. The author is also appreciative of the advice of Professor H. Aiso of Keio University. Also, his thanks go to Mr. M. Meserve for his kind assistance in checking this manuscript.

Remote data processing in Japan

by KANJIRO KOSHI and KIMIO IBUKI
Nippon Telegraph and Telephone Public Corporation
Tokyo, Japan

INTRODUCTION

This paper introduces the development process, some recent features and the perspectives of remote data processing in Japan. The development process shows that remote data processing in Japan has maintained a steady progress in number of systems and in its application.

Recent features pertain to remote data processing in Japan, concerning recent application patterns. Also, a forecast is made of how the remote data processing in Japan will grow from the viewpoints of the boundary expansion as well as increases in technological capability.

REMOTE DATA PROCESSING CHANGES AND PRESENT SITUATION

A much more significant role will be played by remote data processing, in order both to cope with modern innovations and to meet requirements of sophisticated and complex business activities and management. Because remote data processing can process and transmit information. A long-term forecast has been announced wherein remote data processing will grow over 20 percent each year in the future.

Computer usage in our country began in 1955 when the Nomura Security Co., Ltd. and Tokyo Stock Exchange introduced UNIVAC-120. The first remote data processing system was MARS, used by Japan National Railways, and JALCOM, used by Japan Air Lines. Both were seat reservation systems. Their operation started in 1964. There were 40,000 general purpose computers installed as of March 1977; 3,000 computers are used for remote data processing, showing a steady growth year by year.

Remote data processing development background

The background of computer usage development and remote data processing in Japan is outlined from social and economic, technological and legislative standpoints.

Social and economic

As the result of technological innovation, Japan has attained decent growth during the 1960's and early 1970's.

Steel and petrochemical enterprises, electric power industries etc. rationalized both productivity improvement and managerial efficiency by introducing new plants and technology. The purpose was the extension of business scale and profit.

This economic growth may be partly due to the existence of abundant, cheaper and high quality labor force. The increase in demand for labor force, caused by the economic development, brought about not only full employment but also both a shortage of manpower and wage hikes. As a consequence, enterprises were obliged to make efforts toward saving manpower. Hence, remote data processing became recognized as a basic and indispensable tool, because it has sophisticated data transmission and processing functions.

Technological background

Generally speaking, computer manufacturing enterprises as a newcomer should have totalized and highly advanced technological ability. Almost all computer manufacturers were at the same time communication equipment manufacturers.

In the 1960's, NTT applied great efforts to provide nationwide direct-dialing telephone network through researching various technologies, such as electronic switching and multiplexing radio or carrier transmission by coaxial cables. Resulting from this research, NTT made various technological contributions and aids to communication equipment manufacturers. Furthermore, NTT vigorously promoted the DIPS development project during the latter half of the 1960's and early 1970's, with the cooperation of principal Japanese computer manufacturers. DIPS uses very large scale 3.5 generation computers for NTT's remote data processing use. Through this cooperation, NTT played a leading technological role and furnished significant impacts in pertinent technologies and their advance. The Japanese government has also supported Japan's computer industries since the early period, through various technological developments and research by government related laboratories on hardware and software. It was early recognized that computer industries will play a key role in changing the Japanese industrial structure into a knowledge intensive format.

Legislative background

Public telecommunication services providers vary according to countries. Japanese law dictates that these services should be provided only by NTT and KDD.

There may also be various ways to operate remote data processing services, combined computers and telecommunications. In Japan, they are regarded as one of major telecommunication services and considered to be operated in principle in a competitive market. Furthermore, it was considered desirable, for the progress of remote data processing technologies in Japan, that common carriers be permitted to operate those services. Thus, these common carriers were able to join that market under certain restrictions. In 1971, the Public Telecommunications Law, mainly for telephone and telegraph, was amended to legalize the provision of remote data processing. This amendment enabled not only common use of leased lines by a group of companies or the operation of remote data processing by private companies, but also their operation by NTT and KDD. It significantly contributed to the development of remote data processing in Japan.

Since then, remote data processing systems are provided in three ways. One is implementation by users. Second is implementation and vending by NTT or KDD. Last is implementation and vending by private companies. Each contributes to the development of remote data processing in cooperation, making the most of their individual characteristics.

Remote data processing changes and present situation

Computer usage in Japan

Table I shows the change in the number of general purpose computers and that of computers for remote data processing use. It can be seen that, during the past decade, each number has increased 11.4 times and 14 times, respectively. The general purpose computers growth rate has been 32 percent each year and that of computer for remote data processing use has been annually 46 percent during the same period. So, the remote data processing growth rate is larger than that of general purpose computers. This means steady progress in remote data processing, as is also shown in increasing ratio of on-line computers. This trend is very prominent, especially during these past few years.

Change in number of remote data processing systems

Table II shows the change in the number of remote data processing systems. As shown by the table, the number of systems now is 25 times larger than in 1969. The average growth rate is nearly 50 percent annually.

Remote data processing application areas

Remote data processing application areas are shown in Table III. The table shows that the proportion has hardly changed. About 65 percent of all remote data processing systems are occupied by finance, insurance, securities systems and production, inventory control or sales management systems. Therefore, remote data processing may be summarized as mainly used to process massive business administration created data in order to increase business efficiency or rationalize manpower. Furthermore, it will be clear that new type systems are growing because pollution control systems have increased about seven times and traffic control systems have increased four times in number.

SOME RECENT REMOTE DATA PROCESSING USAGE FEATURES

Upgrading initial systems

In Japan, banking organizations have been the major users of remote data processing since early years. Banking type systems still occupy a larger proportion of all the systems. The initial purpose of these systems was simply to improve business efficiency. However, they have been revised and

converted into second or third generation for totalizing or extension of application areas. Thus, banking type systems are playing a vital role in our economical activities. A nationwide banking system was installed in 1973. This system is a message switching system connected to 7,600 offices of 87 banks. It handles communications pertaining to and settlements of inter-bank domestic exchange transactions. As represented by this example, such systems that cover independent companies and form computer networks tend to increase.

Catching up on computerization efforts

Minor enterprises in Japan are now on their way to computerization. Larger enterprises mostly completed computerization in the early period and have replaced their former systems by on-line systems. In recent years, small business computers and remote information systems have become popular among minor class companies as suitable tools for their business scale. There have also appeared systems that are shared among companies engaged in the same business field.

Such efficient and totalized utilization will become such that small scale business computers, of the stand alone type possessed by minor companies, will be linked to a large scale computer system. Thus, remote information services will play a complementary role as data processing devices for minor class enterprises.

Increase in systems close to our life

The improvement of social and national welfare is being required more and more as Japanese people deem the quality of their lives more important than economical affluence. Therefore, they have begun to pay an attention to systems which satisfy those requirements. NTT has already implemented Emergency Medical Information System, Environment-Pollution Information System, En-route Radar Data Processing System and Foodstuff-Market Information System. Because each pattern is new and different from the others, it is true that there are many problems to be solved in the field of technologies, hardware and software and system operation.

Remote data processing perspectives

Remote data processing perspectives can be viewed from three viewpoints. They are the extension of boundaries, numerical increase and technological development.

Enterprise class systems

Computerization in enterprises and industries has continued growing by nearly 30 percent each year during the past decade. Even now it keeps growing steadily. Remote data processing usage is expected to increase with increasing demand for inter-enterprise type of systems besides the increase of intra-enterprise type of systems. Enterprises tend to implement remote data processing systems that can handle settling accounts, message exchange or business calculation among business related enterprises, a certain group of enterprises or those in the same business.

On the other hand it will be probable that cheaper POS terminals will become more popular among shops or supermarkets. In this case, such systems as are combined with POS terminals will appear. This kind of system will have great impact on society.

With the increase in demand for inter-enterprise systems,

it will be more and more necessary to implement the public data network as a common tool. Utilization of shared type database will also be more frequent among enterprises in the same field or by a certain group of enterprises.

Systems related to social welfare and national life

There are many fields left to be computerized and many problems to be solved. Examples of underdeveloped fields are pollution control, environment protection, medical treatment, education, human and commodities transportation control, disaster countermeasures, commerce and improvement of local life standard. NTT has already researched and implemented such systems as Automated Meteorological Data Acquisition System, Environment-Pollution Information System, Emergency Medical Information System and En-route Radar Data Processing System. Although each of them is obtaining good results, their portion is still very small. Therefore, this class of remote data processing usage today can be said to still be in its infancy. However, considering that many remote data processing systems related to this class are being energetically discussed now, intensive demand will appear before long. (cf. Table IV)

Many systems of this class would take a certain time to become popular with the public. The reason is that the cost and resulting benefits of a system of this class don't balance now or that the present demand is not strong enough. It is generally conceived that governmental subsidization or patronage would be an incentive to the demands of this kind.

Strong similarity exists among individual systems used by local government, in education or in medical treatment. If the cost of system development is reduced far enough and the cost and resulting benefits balance by the standardized implementation or sharing software, this would be good stimulation for the realization of this class of systems.

On the other hand, a system of this class has the aspect that massive data is stored and that it often handles information service or information retrieval services. These characteristics would signify that database oriented systems increase in number. From the standpoint that the systems of this class tend to be used publicly, the security or integrity of data has especially to be assessed carefully.

Personal usage class systems

There are two examples of this class in operation in Japan. One is the system for calculation by pushbutton telephone, called DIALS. The other is the seat reservation system for the "bullet" train using the pushbutton telephone. This service is provided by Japan National Railways. Based on the

TABLE IV.—Examples of Systems Now Being Discussed

Local Society	○		○	○ ○	○	Home Video Information Municipal Hotel Reservation

number of systems of this class implemented, the present situation is still in its infancy.

To popularize remote data processing for personal use, service providers need to stimulate its demand as a first step. Popularization of this class mostly depends upon whether such service can be provided that is attractive and easy to access at a cheap price.

It is very likely that home computers or on-line terminals will become as popular as telephones or electronic calculaters with the rapid price reduction for microcomputers or minicomputers. In this situation, the second step is expected to be demands for various services appearing from the users. In this stage, remote data processing may be said to be completely popular enough. In the near future, automated telemetering service, reservation service and information service are considered sure to appear. Automated telemetering service is now being put to the test in the suburbs of Tokyo.

Basic technologies

Computer network

As remote data processing service extends its boundaries and increases in number, steady progress in computer network technologies is expected that will enable sharing hardware, software and database. In case of centralized computer systems, the expansion of its size does not necessarily bring economical or functional scale merits. This is considered to be the principal reason why a distributed system has appeared. Besides this, three other reasons can be pointed out. One is that the plan for digital switched data network has appeared from the network technology side. The second one is that the network architecture has been proposed from the computer technology side. The last one is that pertinent device technology has rapidly advanced.

In Japan, NTT plans to implement both a circuit switched network and a packet switched network in early 1979 as a public data network for computer connection. For network architecture, NTT also plans "Data Communication Network Architecture (DCNA)." It defines the interface conditions and protocols among the elements of remote data processing systems. The main aims are the improvement of fiexibility in systems, network transparency, decentralized processing and linkage of independent computer systems. With DCNA, it will be easier to connect computer systems made by different manufacturers.

Remote information services

There are several dozens of companies in Japan that offer remote information services. Usage and technology are expected to change as follows.

(a) The present usage may be summarized as the sharing of computer power at low cost. From now on, the usage level will be more sophisticated, utilizing the highly developed functions of remote information services or applications such as forecast, simulation and so on.
(b) It will be more popular to share and utilize high-quality databases or efficient applications that some other users have developed.
(c) With the rapid popularization of microcomputers and small scale business computers, users will tend to utilize both small scale business computers and remote information services, depending on each merit. They will use small scale ones for simple business data processing or patterned data processing. They will use remote information services mainly for sophisticated and large scale data processing capability.

Database

Although the present utilization of databases is not so popular in Japan, utilization will be prompted more hereafter. The following are expected for database utilization and related technologies.

(a) Enterprise will introduce database systems for business use, because the uniformity of information will be recognized as more important to make business activities more efficient.
(b) Governmental systems often store massive amounts of data. Various merits would be derived from the DBMS adoption. A steady increase is expected on systems in numbers that adopt DBMS if cost-benefit is sufficiently improved, with the technological advance of mass storage devices.
(c) Large scale systems often store bulk information and have nationwide spread. In this case, distributed database will often be preferable when considering avoiding software complexity, reliability improvement, peak traffic smoothing and reduction in communication cost. For this reason, distributed type of database will be popular, especially among large scale governmental systems.
(d) Some remote information service offerers will appear trying to offer specified kinds of databases and applications.

EPILOG

Computer technology was born in the U.S. and assisted greatly in mankind's dream to send people to the moon. This technology was transplanted to Japanese soil carefully nurtured, sprouted and rooted. It also withstood the hardship of the winter caused by the oil crisis and is now growing steadily. Japan has elevated the standard of remote data processing technologies, combined with telecommunication technologies, through persistent efforts and adding various original ideas. Some remote data processing systems may even be said to be unprecedented and to have no similar example in other countries. Remote data processing is expected to have great impacts on society, economy and way of life.

Train operation control system for high-speed railway

by YOSHIRO HAYASHI and SHIGEO YOKOTA
Japanese National Railways
Tokyo, Japan

and

TAIZO NAUCHI
Hitachi, Ltd. Head Office
Tokyo, Japan

INTRODUCTION

It was in 1964 that the Shinkansen made its debut between Tokyo and Shin Osaka. It was extended westward to Okayama in March 1972 and then on to Hakata in March 1975. It is now a more than 1,000-km long traffic artery of Japan and is functioning smoothly.

Constructed as a safety-performance high-speed means of passenger transport en masse in great comfort, the Shinkansen has proven its worthiness, playing a vital role in the economic and social growth of the nation. To have it play its part, the latest technical achievements are introduced to produce its rolling stock, track, electric facilities, etc. and control the operation of these aided by computer. It may be said that the Shinkansen is a typical modern railway operating under a total system.

In this paper, the conditions needed of the train operation control system for a high-speed mass-transport railway and how to meet these conditions will be explained.

DEVELOPMENT OF TRAIN OPERATION CONTROL SYSTEM

The Shinkansen calls for a train operation control system, vastly and basically different from that for conventional railways. One of the conditions attributable to the difference is the incomparable high speed. Here the conventional way of the driver operating his train by keeping his eyes on the wayside signal indications would never work. For this reason we employed the cab signal system together with, what is called, ATC (Automatic Train Control). To meet another condition of mass transport, there is CTC (Centralized Traffic Control) at work, though this is not entirely new. However, when it comes to a high-speed mass transport, like the Shinkansen, CTC has been proved to be an effective means of smooth dispatching and transportation. With the apparatus for these systems and the conventional interlocking device, the Tokaido Shinkansen was opened in 1964.

As the number of trains increased after 10 years, the CTC alone could not help the dispatches owing to a flood of information coming into the control center; therefore, CTC had to be backed up with computer. That is to have the computer do as much as possible to control train operation, collect data, classify these and do the transmission and to have the dispatchers devoting themselves to the job of making judgments by using the computer at will. To meet this demand, COMTRAC (Computer-aided Traffic Control System) was introduced.

OUTSTANDING FEATURES OF TRAIN OPERATION CONTROL SYSTEM

In order to operate high-speed trains in large numbers, safely, precisely and efficiently, the basic requirement for train operation control is to have all the elements of the system work together smoothly under prescribed plans (train diagram and working schedule).

With the trains that run on given rails, unlike any other modes of transport, it is clear that high efficiency can be obtained when they are operated under a meticulously planned diagram, instead of in a haphazard way. Even when confusion takes place for some reason, it is possible for all the elements of the control system to get down to work as a whole with the single purpose of "restoring the prescribed plan." One of the outstanding features of train operation is that it works as all planned out.

When train operation is disrupted seriously by a train accident or a natural disaster, it also is possible under the control system to command all its elements to partially change the plan.

Unlike other industries in general, train operation is a commodity that cannot be kept in stock. It has to be provided to suit the demand of the passengers. Overall revision of train diagram once in two to three years and quarterly minor revisions, therefore, are taken in as a matter of course. The train operation system with these features is shown in Figure 1, divided into three functions of Planning, Doing & Seeing.

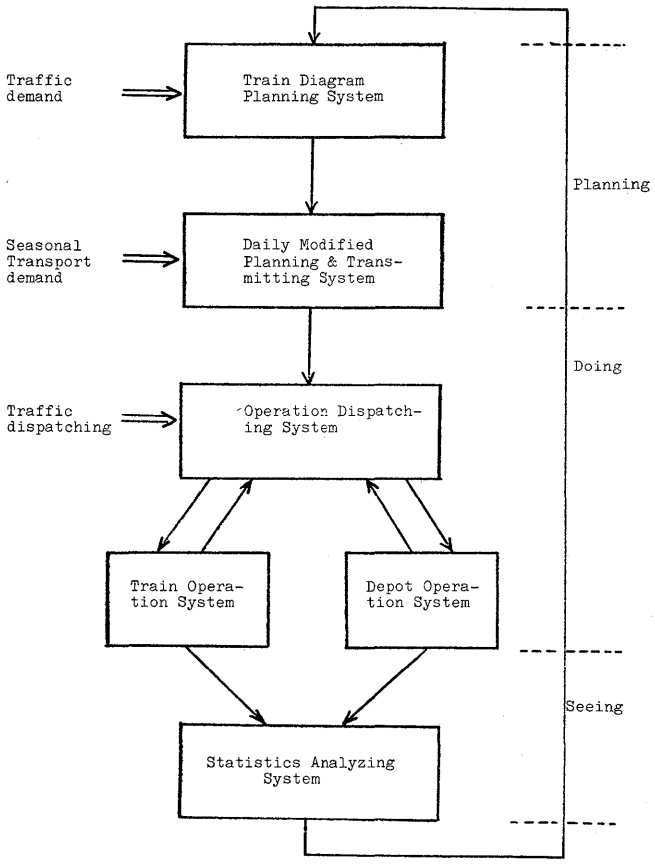

Figure 1—Schematic drawing of train operation control system

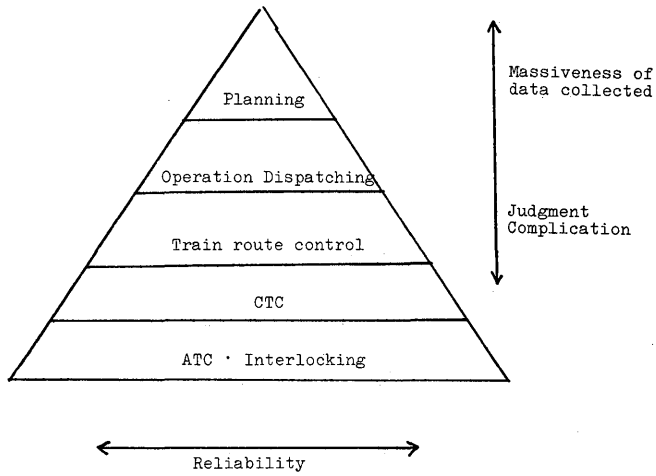

Figure 2—Reliability characteristics in COMTRAC

COMTRAC

Basic concept of reliability design

Various functions shown in Figure 1, closely link themselves together to do the functions. When the reliability, data quality, massiveness of data handled and response time are arranged, we have Figure 2 (COMTRAC Reliability Characteristics). The whole Operation Control System is seen here in a stairway structure, the lower the step, the higher in reliability and the more real time-like. The higher the step, on the contrary, the higher in data accumulation and in judgment complication. Another point to be noted is that the Operation Control System is so made up that once the upper-step function fails out, a lower step fall-back part of the function has failed out.

With this adapted, the stairway structure is taken in the COMTRAC System. As higher reliability and response are demanded of lower functions and as higher-step functions demand more data accumulation and judgment complication, the functions of the system are divided into two groups according to the evaluation criteria. That is, into one group of those functions that strongly demand reliability and responsiveness to be accommodated in the route control system and the other group of functions demanding all sorts of data and others higher-level judgments in the operation adjustment system. As upper level functions call for more and more of those data that the computer is incapable of handling and more and more of human judgment, a man-machine system is needed, leaving the lower-level functions calling for less human intervention to be performed by an automatic system.

COMTRAC functions

A new train traffic control system with computer control is schematically shown in Figure 3. Among many functions necessary for the traffic control, COMTRAC is so designed

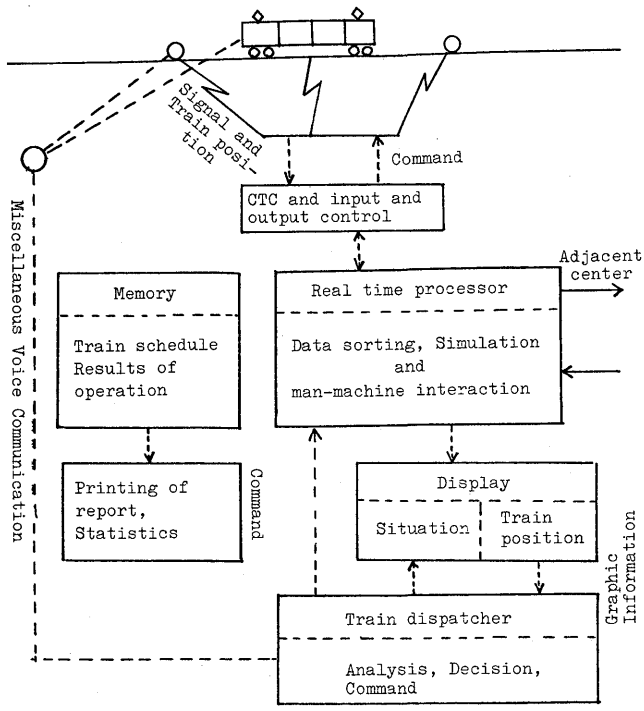

Figure 3—Schematic diagram of COMTRAC system

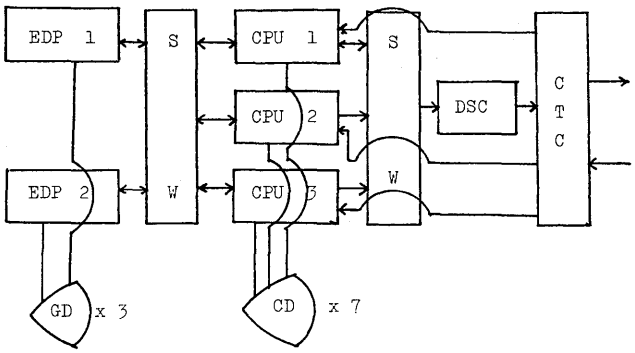

Figure 4—Computer configuration of COMTRAC phase-2

that it can perform the following functions consisted of five subsystems.

1. Planning Subsystem that compiles the plan to implement train and rolling stock turnarounds in accord with the basic and extraordinary plans for train operation.
2. Dispatching Subsystem that monitors whether trains are being operated normally according to the train operation diagram prepared for the day by the Planning Subsystem. On detecting a diagram confusion, the computer automatically renders judgment, if the case is a simple one. If the confusion is serious, due to a train accident, for instance, the train diagram for four to five hours is predicated by simulation and the system prepares a train diagram thereafter and indicates it on GD (Graphic Display). Diagram modifications as decided through the computer are automatically transmitted from time to time to places concerned.
3. Route Control Subsystem that traces each train as diagrammed by the Planning and the Dispatching Subsystems and automatically sets its route. It also monitors the signals in all the stations.
4. The Subsystem to provide data for station announcements. Automation of route control enables the system to detect train positions and train delays, and the information is made use of in making station announcements. The train-to-leave signs on the platforms are automatically controlled, too.
5. Statistics Analyzing Subsystem that prepares all sorts of reports on trains operated and compiles reference materials for administration.

TABLE I.—Types of Passenger Train on Increase (Stopping Station Pattern)

At the time of opening between Tokyo & Shin-Osaka	Between Shin Osaka down to Okayama	Between Okayama down to Hakata
2 types	5 types	9 types

TABLE II.—Route-Setting Automation Checking Growth in the Number of Dispatchers

	Before	Ph-1 when extended to Okayama	Ph-2 when extended to Hakata
A: Train dispatchers	43	52	51
B: Electric railcar train dispatchers	14	15	28
C: Section length (km)	520	680	1060
$\frac{A+B}{C}$	0.110	0.099	0.084

Concept of system composition

In producing a computerized system for the functions explained earlier, the degree of reliability and the response time demanded of each function should be clarified and the unique characteristic of each function need be taken fully into consideration.

The route control system that is directly concerned with train operation is completely a process-control system, setting train routes by the data gathered in the Center by CTC and in accord with the train diagram. It being the last output part of COMTRAC, the highest reliability is demanded of it and the data handled here also must be high in reliability.

The Dispatching System detects diagram confusion by tracing each train with the data provided by the Route Control System and then it really starts displaying its function. As the automatic judgment portion of it is considered to be similar to the monitoring function in the case of train operation, we thought it be better performed under the Route Control System and set one minute as the target for the response time for the diagram simulation function. As for the data transmission function, we thought it hardly matters if acknowledgment of its receipt is made of a change in the plan within several minutes at the worst after the change is decided upon.

The Dispatching System is to be made up as man-machine system as stated before, with man-machine interface centering around GD (Graphic Display) for complicated judgment simulation and around CD (Character Display) for simple item simulation. It is made up as a multicomputer system with two divisions, one a highly reliable system, centering around route control and the other a data processing system centering around train operation adjustment with man-machine equipment included and the fall-back idea partly taken in, as is shown in Figure 4.

TABLE III.—Number of Trains and Lever-Handling Frequencies

	Before	Ph-1 when extended to Okayama	Ph-2 when extended to Hakata
No.of trains a day	170	231	275
Lever-handling frequency a day	4,200	7,000	10,500

TABLE IV.—Availability

	Apr. '76	May	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.	Jan. '77	Feb.	Mar.	Average
System Availability	100	100	100	99.93	100	100	100	100	100	100	100	100	99.99
Dual Availability	99.89	100	100	99.85	99.96	99.84	100	100	99.90	99.69	99.97	99.92	99.92
No.of system down cases	0	0	0	1	0	0	0	0	0	0	0	0	

(Remark: The one case of system-down was due to software bug)

With this make-up, the Route Control System is as reliable as CTC with the target of 99.99 percent set for the working efficiency, and the Train Dispatching System, also with the target of 99.9 percent, downtime within 10 minutes.

To attain these targets, a 2-out-of-3 computer system was developed for the Route Control System, and a DSC (Dual System Controller) for the Train Operation Control.

As the Train Dispatching System handles a great number of data for many hours, two large-sized computers are introduced for duplex operation.

EFFECTS OF SYSTEM INTRODUCTION & WORKING COEFFICIENCY

In carrying on high-speed mass transport the best way to secure efficiency, safety and preciseness is to perform all the jobs concerned under single command, based on the diagram prepared by the Train Diagram Planning System.

Thus, when a computer system takes care of diagram planning with infallible data, the following effects can be expected:

(1) Infallible train control is possible (Prevention of route missetting)—Prevention of such accidents as train collision to preserve safety is ensured by ATC and interlocking device on the spot. However, missetting of routes for high-speed mass transporting trains gives rise to train diagram confusion; hence missetting is regarded as a serious accident in train operation administration. Although there are no detailed records of route missetting before COMTRAC was introduced, such cases appear to have taken place several times a month. For the large number of various types of trains operating the Shinkansen today, with the stopping station pattern as it is, it surely would be impossible to set routes by human hand without COMTRAC at work, even if the number of dispatchers were increased. After the introduction of COMTRAC, there were three cases of route missetting—two cases, programming misses, and one, an input miss by dispatcher due to man-machine trouble.

(2) Control of trains diversifying in type to meet the demand is possible—Users' demands on the Shinkansen, the main traffic artery in Japan and long in operating section, change from season to season and diverse types of train are operated to meet their demands. Introduction of COMTRAC has thus brought forth a complicated transport form of operating diverse types of train to meet the users' demands. In Table I, the diversification of train types is shown.

(3) The growing number of dispatchers checked by automation of route setting—The number of dispatchers before and after COMTRAC is shown in Table II. Under Ph-1 System, data transmission and rolling stock turnaround control were not performed but the system had the effect of checking the growing number of dispatchers. The systematization also had a notable effect in changing the dispatchers' work from lever handling for route setting to their primary job (train operation adjustment, for instance). With the introduction of Ph-2 System, data transmission and rolling stock turnaround control were performed and the effect of checking the growing number of dispatchers has grown all the more.

(4) It is possible to cope with the demand for high-speed mass transport—The growth of the number of trains and the route setting frequencies are shown in Table III. The route setting by lever operation before COMTRAC averaged once in every one to two minutes. At the time of opening the Shin Osaka-Okayama Section it grew to once in every 30 sec to one minute and then to once in every 10 sec to 20 sec when the Okayama-Hakata Section was opened. It is impossible for man to handle the lever for route setting at such a frequency. The System is presently working nicely with the target reliability value attained. There has been only one case of system-down during the year from April 1976 to March 1977 and this was due to software logic bug. (Refer to Table III.)

FUTURE OF COMTRAC

JNR has two other Shinkansen lines, Tohoku and Joetsu, scheduled for opening within several years and is planning to form a nationwide Shinkansen network. COMTRAC will then be indispensable, as more and more diverse types of high-speed mass transporting trains have to be operated within the network. To be ready for it, COMTRAC will have to expand its scope of control, improve its functions to the infallible extent and grow not only into a train operation control system but also into a traffic control system, as well as to have it linked to MARS (Seat reservation system), Rolling Stock Control System and Management Information System, so that it can provide service more commensurate with the transport demands.

Development of a high-performance universal computing element—PULCE*

by HAJIME IIZUKA and YUTAKA HAYASHI
Electrotechnical Laboratory
Tokyo, Japan

and

KEIKICHI TAMARU and HISASHI HARA
Tokyo Shibaura Electric Co.
Kawasaki, Japan

INTRODUCTION

Since the first introduction of the microprocessor, various kinds of microprocessors have been developed. There have been remarkable achievements both in the level of integration and processing speed. However, most microprocessors developed to date are oriented to device control applications or low class minicomputer replacement. It is true that some bit-sliced microprocessors can operate at very high speeds, but they are neither one-chip, nor do they have much functional capability.

On the other hand, with the current state of the art in semiconductor technology, it seems possible to integrate considerable amounts of computing power in a chip and at the same time to achieve high speed operation comparable to existing discrete processors.

The Electrotechnical Laboratory and Tokyo Shibaura Electric Co. (Toshiba) R&D center are engaged in a research effort in this area and have developed a new high-performance universal computing element—PULCE. This paper describes its architectural design, [1,2] as well as the semiconductor technology develped for its implementation.

BASIC DESIGN

Initial target of semiconductor technology

At the beginning of the project, future trends of semiconductor technology were thoroughly investigated by evaluating pioneering experimental results[3] and the annual rate of improvement in the performance of MOS-LSI's.

The targets for 1977-1978 chip production were fixed in 1972 by the Electrotechnical Laboratory. On the basis of extrapolated chip size, line width in photoengraving technology and annual rate of increase of integration of MOS-LSI's, the number of gates per chip was estimated as more than 5000 but less than 10,000. Assuming an air cooled package, total power consumed in one package should be at most 1 Watt or a little more. Thus power dissipation per gate is limited to less than 0.2mW/gate for integration level of 5000 gates/chip, leaving some room for additional power dissipation in output buffers. An ED-MOS gate in which a depletion type MOS transistor is used as a load was selected as a unit cell for high speed, low supply voltage (5V or less) and high integration density.

Based on preliminary experiments, delay-power product of a MOS gate with fan out of 3 was manipulated to be less than 0.4pJ for a LSI with a line width of 4μm or less. A 4μm line width was assumed in 1972 to be one of the advanced MOS-LSI production standards of 1977. Thus the value of propagation delay time t_{pd} per gate with small interconnection stray capacitance and fan out of 3 was set to be less than 2ns. In a μpu LSI, the loading capacitance of each gate depends on logic design and pattern layout, particularly on wiring length, so t_{pd} of a gate cannot be predetermined. The target value of t_{pd} with fan out of 3 is one of the essential parameters to estimate device design and semiconductor process technology. Overall speed of a μpu LSI largely depends also on its architecture and interconnections.

Basic architectural design

From a standpoint of architectural design, the 5000 gates integration level was one of the two biggest restricting factors, because it was not considered large enough for our design aims of integrating a high-performance microprocessor in one chip.

Another big problem was the number of pins. If we employed a commonly used package with less than 50 pins, we could not achieve a processing capability which would match the internal speed, because interface pins must be

* This work was done as part of the PIPS (Pattern Information Processing System) Project, an ongoing research program funded by the Japanese Government.

used in a time-multiplexed fashion. Furthermore, instruction word-length is shortened and detailed control may be impossible. Therefore, it was decided to adopt a flat package with 80 pins. The development of a high-performance interface to satisfy this condition, as well as the choice of functions to put in PULCE, were the most important design problems.

In view of the technological level of semiconductor and computer systems, and the requirements imposed by the desired applications, we adopted the following considerations as the basis of the architectural design.

Exclusion of sequence control

As LSI μpu technology is based on mass production, its architecture must be general-purpose. Usually, processor functions (instructions) are divided into the following three categories, in which the relationships with general purpose requirements are different.

(1) F type (Functional)—Arithmetic and logical processing functions.
(2) P type (Procedural)—Sequence control functions.
(3) E type (External)—External control functions.

Requirements of the F type instructions do not differ in any applications as far as the microinstruction level is concerned. Accordingly, it is relatively easy to extract functions with wide generality for this type. However, each system entails a different requirement for the P type, especially with respect to interrupt processing, and hence P type standardization is difficult. Furthermore, because of the large number of interface lines and constraints on the amount of hardware, usually only simple functions, which may be unsatisfactory for the purpose of PULCE, can be integrated in an LSI chip. Finally, the E type has special features for each application. But, as these are external functions, only general-purpose considerations and interface expansibility need be dealt with for this type.

In view of the above considerations, and because of constraints on the level of integration and number of pins, we decided not to include a sequence control portion in the LSI chip. Instead we concentrated F type functions. Only the general-purpose requirements and flexibility of interfaces for external implementation of suitable P and E functions are considered.

16-bit basic word length

The length of data processed at one time is very important for this type of μpu. One method is to achieve expansibility by slicing a word into 4 or 8 bits, but there are items, like status information, which cannot always be handled well by the bit slicing, and even 8 bits may be too short for the integration level. Therefore, we have adopted 16 bits as basic word length and 32 bits for interface, and provided PULCE with some architectural features in relation to the simplification of double length data processing.

Emulation oriented

Here emulation means not only interpretation of machine instructions of existing computers, but also includes emulations of new system architectures or intermediate languages directed to high level languages. This is one of the important features of new processors. For this purpose, mask registers and a few mode bits which are effective for extracting fields in a word are provided. Operating in conjunction with a multi-bit shifter, the mask registers serve not only for partial field processing as in (macro)instruction decoding, but also for the usual processing.

Stack function

Pushdown stacks are now employed in various applications and their effectiveness is widely recognized. Therefore, a special hardware support which always keeps the upper portion of a stack in internal registers is provided to increase its processing speed.

Flexible control of hardware details by microprogram

Generally speaking, as the level of a functional module becomes higher, it becomes more difficult to implement or modify a lower level function. In other words, modularity decreases flexibility. This is called "loss of transparency" due to modularization.[4] In the case of such high level modules as PULCE, where general-purpose requirements are important, the loss of transparency must be kept as small as possible. For this purpose microprogram control by unusually long (32 bits) instructions has been adopted for flexible control of hardware details.

Regular structure

It is expected that this kind of μpu will be programmed by general users who are not always hardware specialists. This situation is different from the static microprogramming cases. Therefore, the organization of the instruction repertoire and internal structure should be as regular and as easily understood as possible.

ARCHITECTURE

PULCE is organized in a 3-bus structure around the ALU and a shifter as shown in the block diagram of Figure 1.

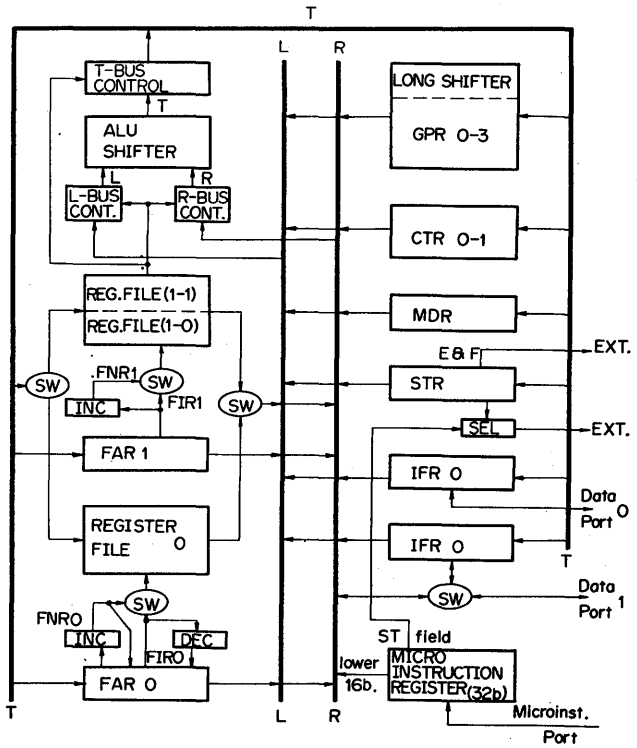

Figure 1—PULCE block diagram (GPR: General purpose register, CTR: Counter, MDR: Mode register, STR: Status register, IFR: Interface register, FAR: File address register, FIR: File indirect register, FNR: File next register, INC: Incrementer, DEC: Decrementer, SEL: Bit selector, SW: Switch)

Functional units

Main registers

The 16 registers listed in Table I are always directly accessible and most of them are assigned dedicated functions as clearly shown by their names. However, FIR's, FNR's and IFR's are provided with some special features described below.

Each FIR is a word in a register file pointed to by FARO-1, so no specific hardware exists for FIR's. Each FNR is a word in a register file whose address is the content of corresponding FAR plus one. Using both FIR and FNR, two continuous words in a register file can be processed without changing the FAR content. This feature is convenient for emulation of system architecture with word lengths of 32 or 64 bits. On the other hand, when SM bit in MDR is set, FNR0 is used for a stack function and its behavior differs from that described above (see *Stack operation*).

IFR's are registers for communications with external hardware attached to PULCE and their input/output connections are made to interface ports via bidirectional buffers. The input/output through these ports are controlled externally instead of by internal microinstructions. Furthermore, IFR0 can be externally set/reset in a bitwise manner, and as a result, this register can be used as an external status register. In addition, if desired, a port of IFR1 can be directly connected to R-bus in PULCE by externally activating a special control terminal. This feature enables a user to either look at data on the R bus or put data on the R bus from interface ports.

TABLE I.—Main Registers

Mnemonic	Name	Length(bits)	Number	hardware*3
GPR	General Purpose	16	4	○
FAR	File Address	4	2	○
MDR	MoDe	16(4)*1	1	○
STR*2	StaTus	16	1	○
FIR	File Indirect	16	2	×
IFR	InterFace	16	2	○
FNR	File Next	16	2	×
CTR	CounTer	16	2	○

Register files

Two register files (RF0 and RF1) of 16 words are provided. RF0 is a general purpose register set, but it could be used for storage of the upper portion of the stack when MDR's SM bit is set (see *stack operation*). The second register file RF1 is divided into two 8 words subfiles, RF1-0 and RF1-1. Seven words in RF1-1 can be used as mask registers.

Arithmetic and Logic unit

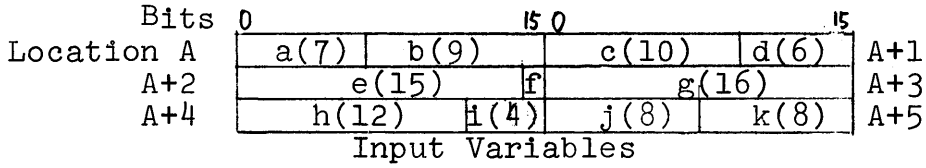
ALU consists of a binary parallel adder, 1-digit decimal adder/subtracter and logic circuits for AND, IOR, XOR, NOR and some special logic functions.

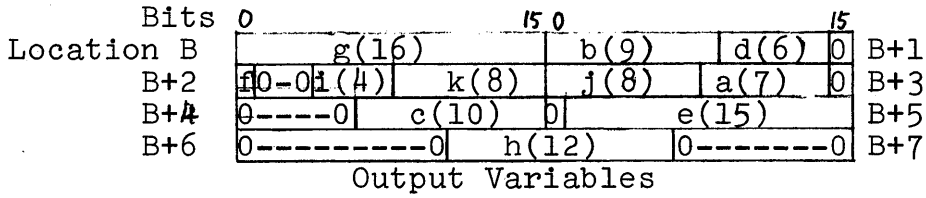
Masking

If designated by the MKfield of a microinstruction, data on L and R buses are ANDed with designated mask registers in RF1-1 before being loaded to ALU. ALU output may also be ANDed with a mask register before being put on the T bus. This feature facilitates effective extraction and processing of a partial field in a register. A trial coding of Church's field processing problems[5] as shown in Figure 2 proved the effectiveness of this feature.

Shifters

PULCE is provided with two types of shifters, a single word length multibit type and a one bit multiword (up to 4 words) shifter. The former can shift a single word 1-15 bits in one machine cycle. Cooperating with mask registers, it





Problem 1: Coding Results

memory access	38	12
execution	136	28
mask set	0	6

(b) Problem 2

Figure 2—Coding results of partial field reformatting

efficiently extracts partial field in a word. General purpose registers GPR0-3 are equipped with a one bit long shifter, and contents of the selected one to four GPR's can be shifted as a one long word. It is effective for multiplication and division.

Stack operation

Since constraints on volume of hardware rule out the use of an independent stack, provision is made for a special hardware support (called Ring Stack) which keeps an upper portion of the stack in register file 0. Thus, when the MDR's SM bit is set, RF0 is accessed by FNR0 in the following manner.

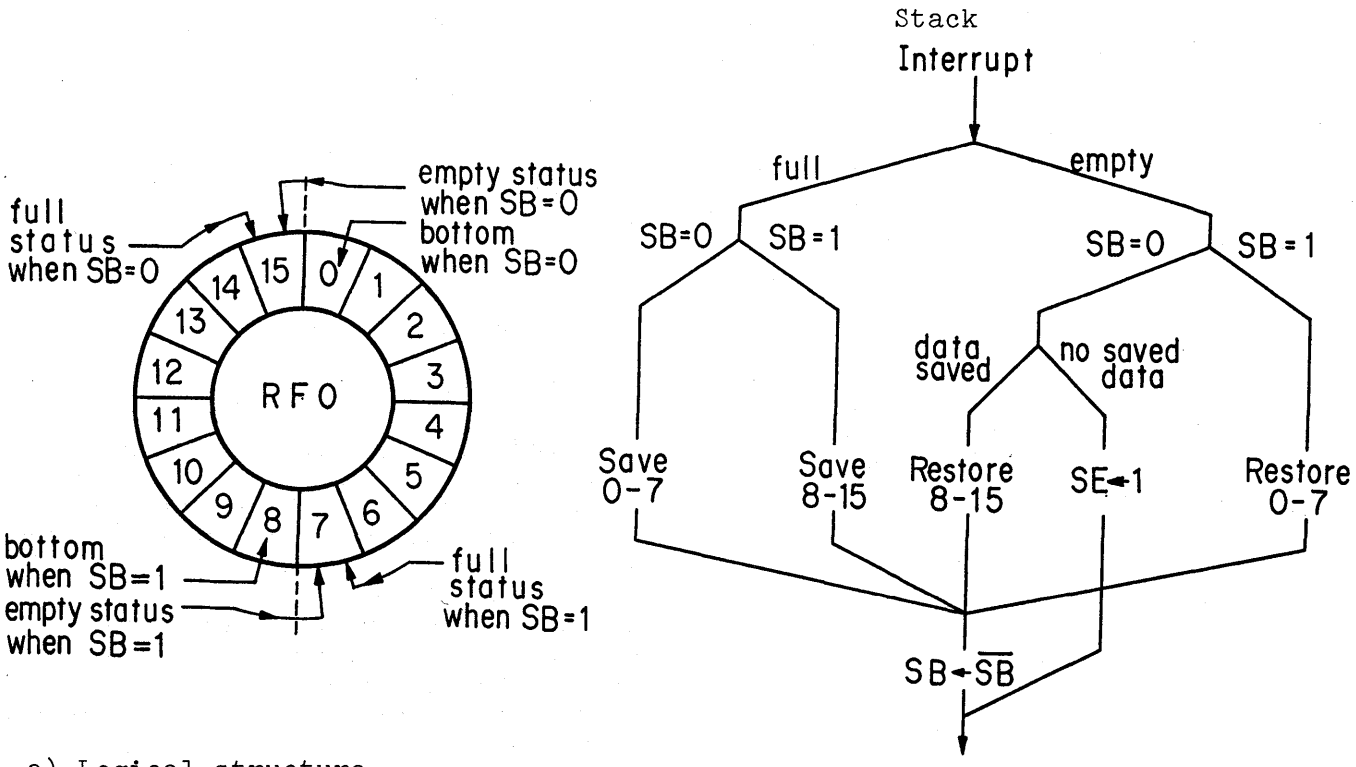
(1) When FNR0 is assigned in the T field of an instruction, FAR0 is incremented at the beginning of its execution. Then at the end of its execution MDR's SE bit is reset, and if FAR0 equals 15 (when MDR's SB is reset) or FAR0 equals 7 (when SB is set) at this time, STR's F bit which indicates "stack full" is set.
(2) When FNR0 is assigned in the R field, FARO is decremented at the end of execution, provided that SE is reset at the beginning. Furthermore, if FAR0 equals 15 (when MDR's SB is rest)/7 (when SB is set), STR's E bit which indicates "stack empty" is also set. However, if SE is set at the beginning, E bit is set and this instruction is ignored.

As is easily seen, (1) and (2) of the above operation correspond to "push" and "pop" operations of the stack. SE is a bit which is set by a microprogram when the stack is completely empty, and by using this bit, stack underflow is detected. SB is used to alternate the set conditions of STR's E and F bits between the middle and the bottom of RF0, essentially making it a ring of registers (see Figure 3a). Accordingly, by saving 8 words in RF0 in external memory when F is set and restoring these 8 words to RF0 when E is set, an upper portion of the stack can always be kept in RF0 (see Figure 3b).

Simulation of Ring Stack has been done and the results are shown in Figure 4. The probability of data transfer to and from external memory is substantially reduced by the Ring Stack, when the number of continuous push/pop operations is less than the hardware stack size (16).

Microinstructions

The microinstruction repertoire is designed not only for ease of application but also for controllability of the μpu. There are six formats shown in Figure 5.



a) Logical structure.

b) Interrupt processing flow.

Figure 3—Ring stack mechanism

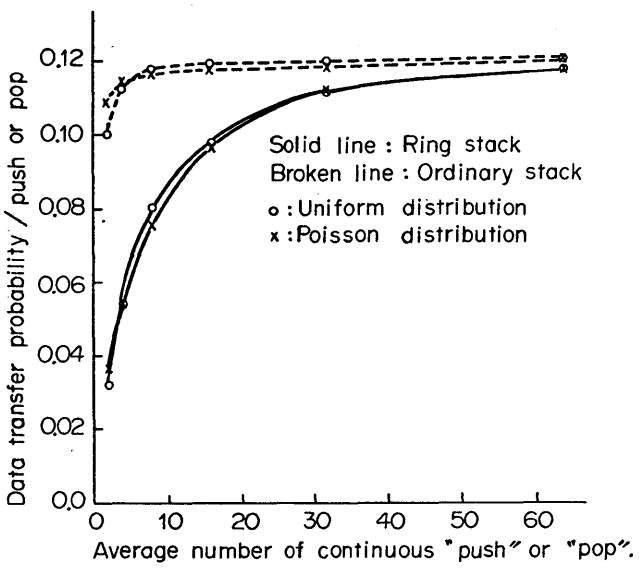


Figure 4—Performance evaluation of the ring stack

RR type instructions

This type is used for operations between registers or a register and 5-bit literal.

Operation code (RR)—RR designates any one of 16 operations consisting of 4 logical operations, 6 binary addition/subtraction, 4 decimal addition/subtraction and two special operations for multiplication and division.

Status assignment (STB, STC)—STB assigns a bit in STR and the next instruction may be ineffective depending on its value. STC bit complements skip condition.

Status save (SS)—SS bit indicates whether status information after execution is saved in STR or not. This control enables the programmer to retain past status information in STR.

Bus control (TC, LC, RC)—TC controls loading of data on the T bus into an assigned register, and RC designates whether the R field is a literal or register number, while LC indicates whether the assigned register content or "0" is put on the L bus.

Counter control (CT)—CT is a field to indicate that one or both of two counters are decremented. It is mainly used for loop control.

RE type instructions

These instructions are for operations between a register and a 16-bit literal. The lower 16 bits (E) of the instruction are interpreted as a literal and put on the R bus. In addition to normal arithmetic and logical operations, RE type is provided with a special operation called pattern match which puts on the T bus an AND of 16 bits information decoded from the lower 4 bits of L input and a literal (E). This is useful for classifying codes, detecting signs in decimal operations, etc.

RH type instructions

These are operations between a register and an 8-bit literal. As this type can take advantage of the masking feature, it is useful for processing of 8-bit data.

SH type instructions

Instructions of this type shift the content of a register assigned in the T field by the amount (maximum of 15 bits) indicated by the R input in one machine cycle. In addition to normal shift modes, there is one special logical shift in which GPR0 is implied as a source register. This is often useful for processing of partial fields in a register, because the original content of the register is not changed by the instruction execution.

LS type instruction

This is a long shift instruction of GPR0-3. Assigning a repeat mode in the MM field, only this instruction can be repeated until the designated counter becomes zero or the skip condition is fulfilled.

NP type instructions

Instructions whose upper 3 bits equal "111" do not have any effect internally. In other words, NP type is designed individually for each system to control sequence and external operations.

SEMICONDUCTOR TECHNOLOGY

n MOS/SOS technology

To actually produce PULCE from the design we have described, devices, that are of high integration density, of low power consumption, of high speed and of small stray capacity had to be developed. Considering the state of the art in semiconductor technology, *n*-channel E/D MOS circuits on sapphire substrate (*n* MOS/SOS technology) seemed to be the most suitable device for this LSI. Especially small stray capacitance associated with n^+ diffusion layer wiring and thin film wiring on an insulating sapphire substrate is suitable for a μpu in which long parallel bus lines meander on the substrate.

Most of the studies of silicon on sapphire technology have been concentrated on CMOS/SOS.[6] There has not been any attempt to fabricate high density *n*-channel MOS logic circuits utilizing SOS technology, but an *n*-channel E/D gate is considered to be superior to a CMOS gate because of its

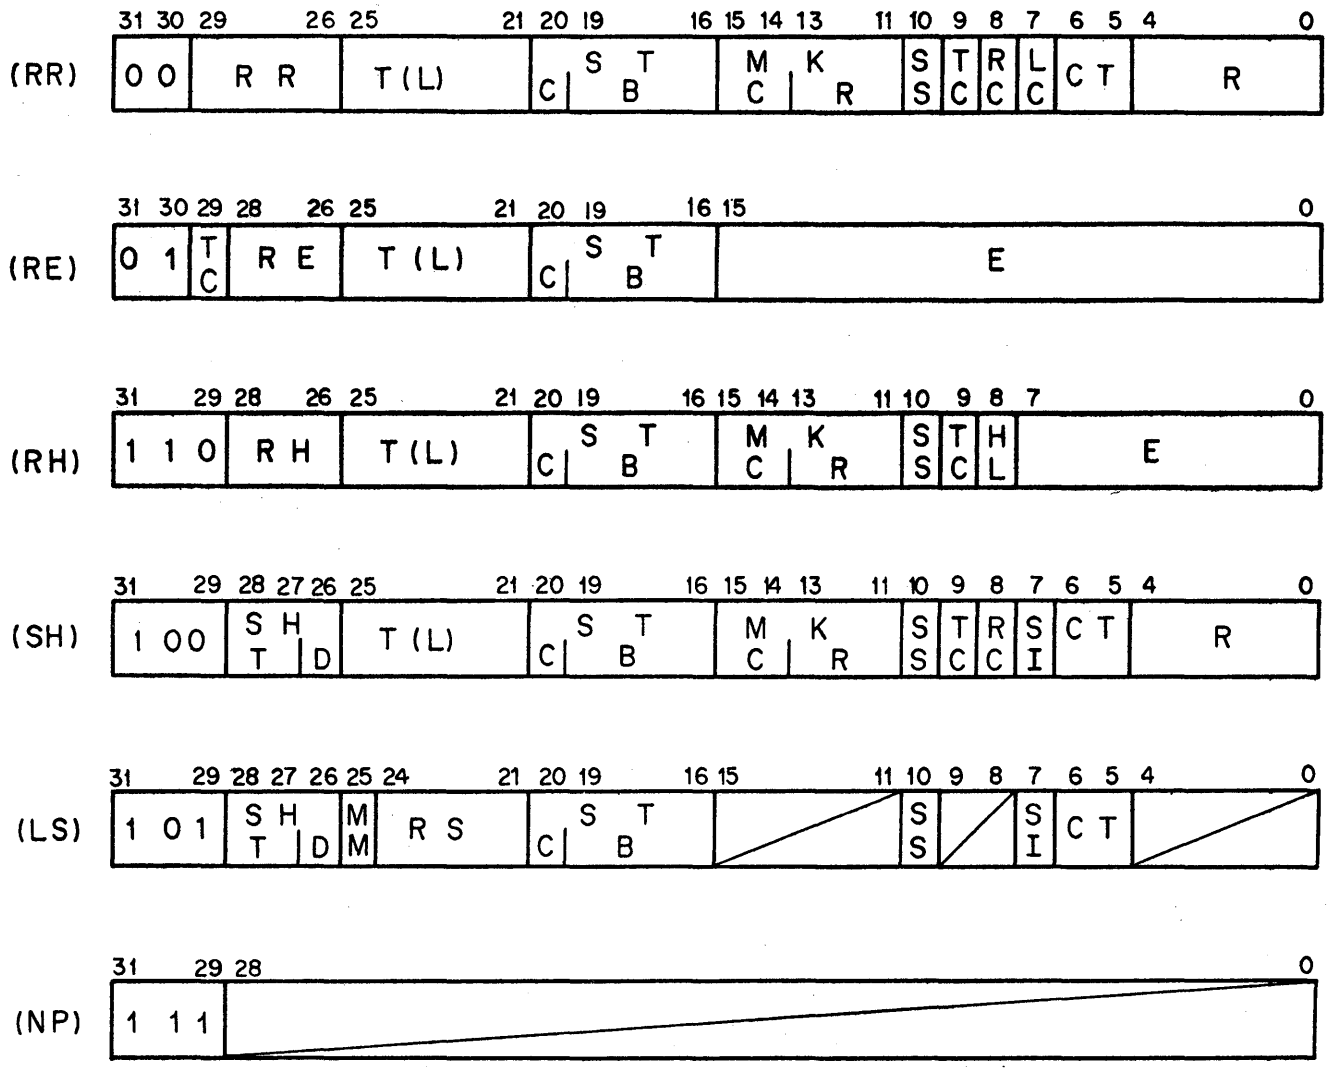

Figure 5—Microinstruction formats (RR: Op. code, T(L): T&L bus, ST: Status, MK: Mask control, SS: Status save, TC: T bus control, RC: R bus control, LC: L bus control, CT: Counter control, R: R bus, RE: Op. code, E: Emit, RH: Op. code, HL: High-low control, SHT: Shift type, SHD: Shift direction, SI: Shift-in control, MM: Multimode, RS: Register select)

high packing density and design simplicity. So, before the final fabrication of the PULCE LSI, three years of R&D were spent developing the high density *n*-channel MOS/SOS process. The method of polishing the sapphire substrate, the hetero-epitaxial thin silicon film growth condition for reduced defect density, the research on origins of drain leakage current and the stabilizing of fine line photoengraving conditions on SOS wafers were included in the R&D project.

Preliminary experiments

Before actual fabrication of the PULCE LSI, functional blocks such as register and arithmetic logical unit RALU and register file RF0 were developed as experimental devices on SOS. The RALU which contains about 2400 gates consists of 16 words by 16 bits local storage, 16 bits adder, two working registers and control circuits. The chip size is 5.00×4.72mm using 6 μm design rule.[7] The typical propagation delay time through 11 NOR gates in carry circuits is 70ns, one third of that on bulk silicon. Register file RF0 consists of 16 words by 16 bits register file, 4 bits file address register FAR0, input buffer circuits and three (T,R,L) busses. This register file performs complex functions such as writing data on the T bus and reading out data on the R and L bus simultaneously. The design rule used is the same 4μm rule as that of the final design. The chip size is 4.41×4.74mm and 1,300 gates are included. The access time is about 30ns or less as shown in Figure 6 and is within 20ns of the design target of 50ns.

The PULCE LSI is fabricated by 4μm design rule and coplanar process. Figure 7 shows the relation of average propagation delay time t_{pd} and power dissipation P_d of the *n* MOS/SOS gate. The parameters of the figure are the ratio of the channel width to the channel length of load transistor of the inverter (4μm:4μm and 4μm:3μm), and the thickness

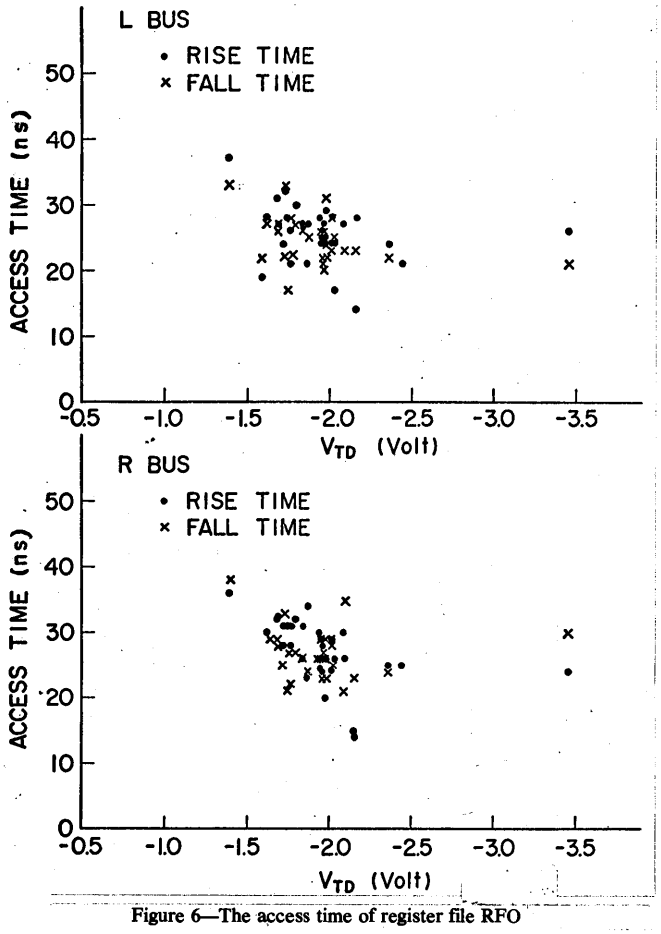

Figure 6—The access time of register file RFO

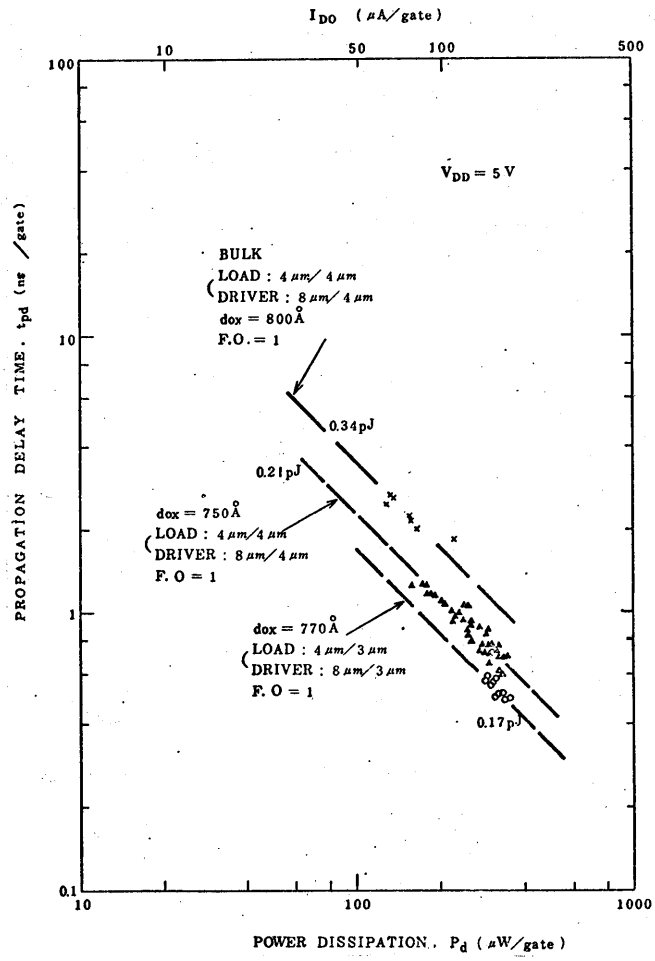

Figure 7—The relation of average propagation delay time vs. power dissipation for n MOS/SOS gates

of gate oxide, 750Å and 770Å respectively. This figure shows the difference of the $t_{pd} \cdot P_d$ product on SOS (0.21pJ) and on bulk silicon (0.34pJ) in the same design pattern. It is clear that SOS is faster than bulk silicon by a factor of 1.6 at the same power dissipation.

Fabrication of the PULCE LSI

For the fabrication of PULCE LSI new technology such as the coplanar process on SOS which improves low gate breakdown voltage and prevents extra drain current in ordinary SOS structure,[8] and circuits with four types of transistors as shown in Table II which reduce power dissipation were used. The gate used E/D circuits, the threshold voltage of which is 0.8±0.2V (V_{TE}) for E type transistors and −2.0±0.3V (V_{TD}) for D type transistors. In addition to these transistors, two other threshold voltage transistors were used. The first one was the load transistor of a memory cell which was fabricated by boron and phosphor ion implantation. The threshold voltage V_{TED} is −0.5V. Power dissipation of memory cells in the register file was reduced by a factor of ten compared to all the same D type transistors. The another threshold voltage transistor was the intrinsic transistor (I type transistor). The pushpull driver using a D type load transistor to drive the large capacitance of bus lines requires power consumption at low output voltage level. Using an E type load transistor causes the voltage to drop to the level of the threshold voltage. To solve this problem, an I type load transistor for which no ion implantation technique was used was incorporated in the pushpull line driver. It has a threshold voltage V_{TI} equal to −0.5~+0.3V. Power dissipation was reduced by a factor of ten and by using a large size load transistor the circuit speed was kept at the same level.

TABLE II.—Four Types of Transistors

Type	Ion implantation		Typical V_T
	Boron	Phosphorous	
E	○	×	0.8V
D	×	○	-2.0V
I	○	×	-0.2V
E-D	×	○	-0.5V

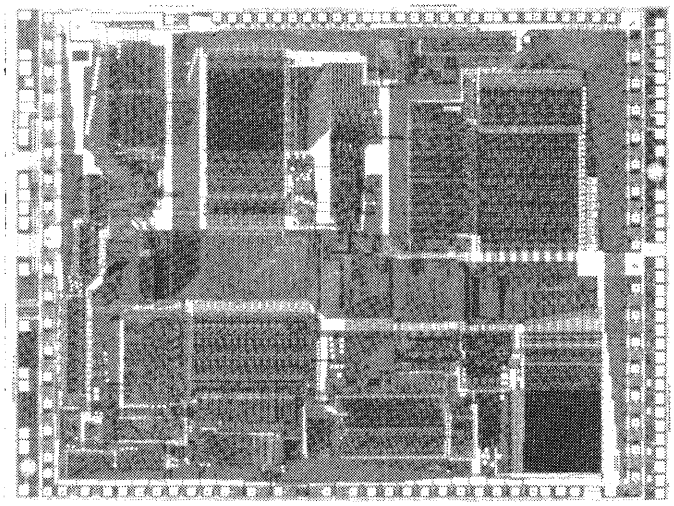

Figure 8—Photomicrograph on the PULCE LSI

Figure 8 shows the photomicrograph of a PULCE LSI. The chip size is 8.85×6.66mm. There are 7,000 logic gates and 20,000 transistors. The processor has a 200ns microinstruction cycle time using a single phase clock. The delay through the look ahead carry path of 10 gates for a 16 bits arithmetic operation is 35ns and the binary addition time including decoder delay ranges from 80ns to 115ns. Multibit shifter delay is 30ns. The chip uses a single 5V power supply and dissipates 1.5W at its full rated speed. Figure 9 is a photograph of the 80 pins package which has five aluminum cooling fins. The heat resistance is 10° C/W at 1m/sec air flow.

TABLE III.—Summary of the Performance of PULCE

Device type	n MOS/SOS
Chip size	8.85 × 6.66mm
Gates in a chip	7000
Transistors in a chip	20000
Package	80-pin flat package with cooling fins.
Power supply	5V
Machine cycle	200ns
Power dissipation	1.5W
Operating temperature	0°C-50°C
Data width	16bits
Microinstruction	32bits supplied from outside
Registers	44
(General purpose)	29
(Mask)	7
(Dedicated)	(16bits) 6
	(4bits) 2
Shifter	0-15bits
(Single word)	1bit
(2,3,4 words)	
Decimal operation	add/sub (1 digit)
Stack	Hardware support
Multiply/divide	No hardware as such, but special hardware available to support these instruction

CONCLUSION

We have described the architecture of a new high-performance microprocessor PULCE and the semiconductor technology developed for its implementation. The first functionally complete LSI PULCE was constructed in the fall of 1977 and is now being evaluated. The performance of LSI PULCE is summarized in Table III.

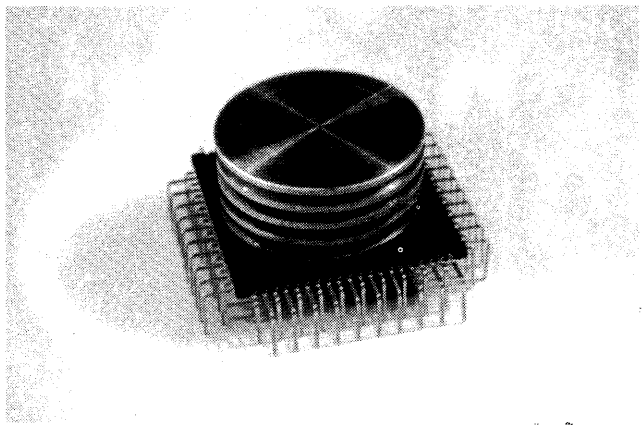

Figure 9—Photograph of 80 pins package

Before the actual implementation of LSI PULCE, we built several experimental machines with PULCE architecture by using TTL SSI's and MSI's, and they have been successfully used to construct processor modules of experimental modular multiprocessor systems.[2,9]

Now we are planning to use LSI PULCE in many research areas, including a data base machine, a LISP machine, a character recognition system and a polyprocessor system. Among these the first application will be a high-performance personal computer, which will be completed by the first quarter of 1978.

ACKNOWLEDGMENT

Many people, indeed too many to mention in this short space, have given the authors support and advice during this project. We wish to express our sincere appreciation to everyone and especially to Messrs. T. Furuya (ETL), H. Tango (Toshiba), T. Sato (Toshiba), and all those associated with this research. The authors also wish to acknowledge the support and encouragement provided by Drs. H. Nisino (ETL), O. Ishii (ETL), K. Kurokawa (ETL), Y. Tarui (ETL; now at the Cooperative Lab., VLSI Technology Research Association) and T. Tarui (Toshiba).

CACS—Urban traffic control system featuring computer control

by TORU MIKAMI
Nippon Electric Co., Ltd.,
Kawasaki City, Japan

INTRODUCTION

In Japan, the number of automobiles has exceeded thirty million and the number of driver's license holders reached thirty-five million (approximately thirty-five percent of the total population) at the end of 1976. Automobile traffic in many cities has been increasing rapidly year by year. Automobiles and trucks, at present in Japan, perform the most important part of a means for transporting passengers and goods. In fact, for seven years, the amount of transportation by automobiles exceeded that by railways in Japan.

Increased use of automobiles in cities, on the other hand, has caused many serious problems: traffic congestion, traffic accidents, air pollution from exhaust gas etc. For example, more than thirty persons are killed by automobile accidents every day. These problems impose great losses and strains on city dwellers. The city traffic problem has become one of the most important social problems in Japan.

To solve this traffic problem, many means and systems have been considered and applied to the cities. Area traffic signal control systems have been installed in the major cities of Japan. Many big cities have also been equipped with air pollution surveillance systems. Enforcing traffic regulations, extending safety facilities, developing new city transportation systems and many other means have been tried.

It cannot be said, however, that the situation has changed for the better. Both time involved and area covered by traffic congestion in the city are still increasing. As a result even with an increase in the number of vehicles, the transporting capacity of automobiles in the city is decreasing.

In order to solve the city traffic problem, it is basically necessary, in addition to the above, to consider a means for increasing efficient utility of the road network in a city. For this purpose, Comprehensive Automobile Control System (CACS) project, which is introduced in this paper, was established and is continuing. The purpose of the CACS project is to develop an effective means and system for controlling the city automobile traffic comprehensively and efficiently. Technically, this project aims to develop a total information processing system for the automobile traffic by combining car electronic device, car-ground communication, computer control and network technologies. This system will be used in coordination with the existing traffic control system mentioned above.

The CACS project is financed by the Agency of Industrial Science and Technology, Ministry of International Trade and Industry. The project started in 1973 and is planned to continue six years. More than twenty million dollars have been invested up to now. Organizations involved in this project are the Research Association for Comprehensive Automobile Control Technology, Toyota Motor Co., Ltd., Nippon Denso Co., Ltd., Sumitomo Electric Industries, Ltd., Nippon Electric Co., Ltd., Hitachi, Ltd. and others.

SYSTEM OBJECTIVES AND FUNCTIONS

In the CACS project, for analysis of city automobile traffic problems, the following four system objectives have been adopted:

1. Relieve vehicle traffic congestion.
2. Reduce exhaust pollution that accompanies traffic congestion
3. Prevent automobile accidents
4. Increase public and social applicability of automobile use.

In order to achieve these objectives, the following four functions have been set up as technology development target functions:

1. Provide optimal route guidance to moving vehicles while preventing congestion and resultant exhaust pollution during the traffic congestion period
2. Provide travel priority to emergency and public service vehicles
3. Provide drivers with driving information pertinent to safe driving
4. Provide drivers with other advance information on, for example, the state of traffic emergency in a specific area.

In the actual CACS project development phase, these

target functions are realized through the development of five subsystems shown below:

1. Route guidance subsystem—A system which guides drivers to their destinations via optimal routes according to traffic conditions by displaying guidance information visually inside vehicles.
2. Route display board subsystem—A system which gives drivers the information on road congestion status and recommends routes by outside visual displays.
3. Driving information subsystem—A system which brings to drivers attention information on traffic regulations and driving warnings by inside indications.
4. Traffic incident information subsystem—A system which transmits accident information and the like to drivers for the area through which they are driving by car radios enforced to receive concerned signals.
5. Public service vehicle priority subsystem—A system which allows public service vehicles, such as ambulances, fire engines and repair trucks pass through with priority. This system is to operate in conjunction with signal control systems.

These five subsystems constitute Comprehensive Automobile Control System. Figure 1 shows a conceptual configuration of the CAC system. Figure 1 also shows potential relationships in the future between CAC system and representative external systems, such as area traffic signal control system, expressway surveillance system and others. Traffic administration and road administration also have important relations to the CAC system operation.

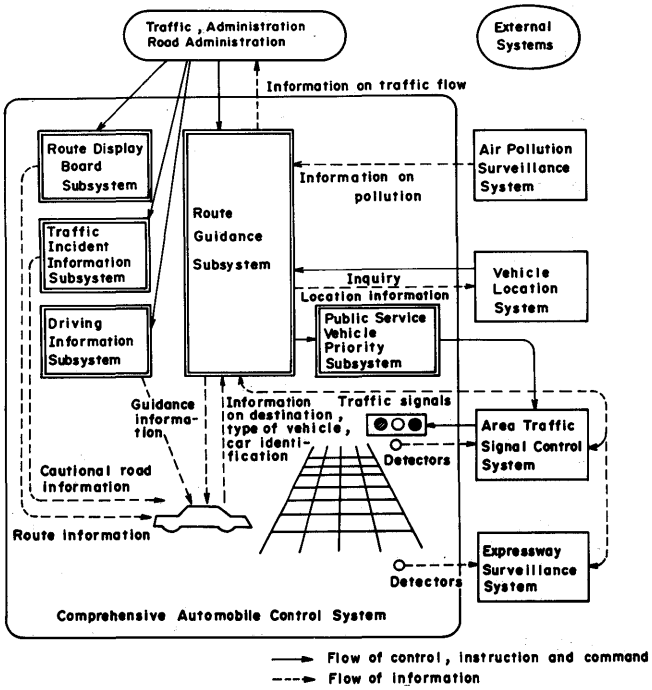

Figure 1—Comprehensive automobile control system concept

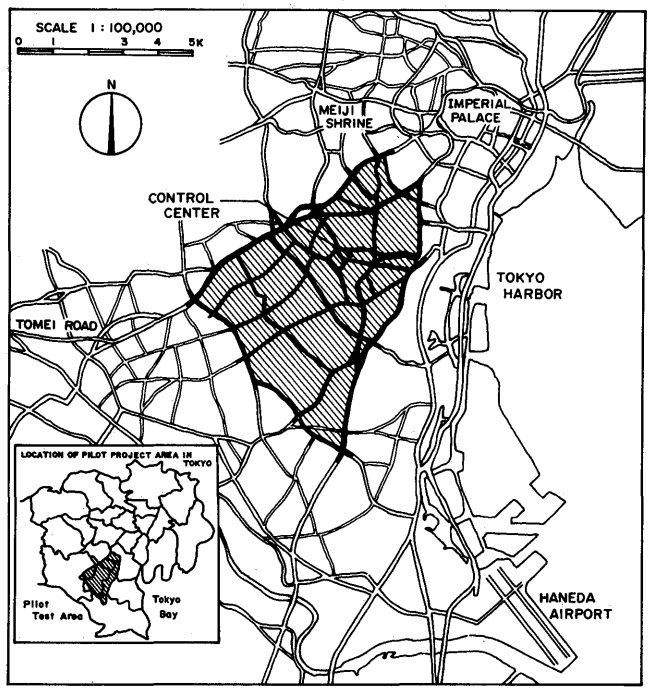

Figure 2—Pilot test area

PILOT SYSTEM TEST

A pilot system test was conducted in the CACS project for a year beginning in October of 1977. Purposes of this pilot system test are to:

1. Evaluate the effectiveness of developed technologies in city streets
2. Collect traffic data for future system design
3. Evaluate social acceptability of this system.

The pilot test area is a 28-square kilometer area in the southwestern section of Tokyo (see Figure 2). This pilot area contains a road network representative of the road network of the entire city; 89 main intersections in this area (including 15 expressway ramps) have been chosen as guidance intersections for route guidance. Three hundred thirty test vehicles, which are equipped with full sets of vehicle units, and 1,000 data collecting vehicles, which are equipped with transmitting parts of vehicle units only, are planned to be used in the pilot test.

PILOT SYSTEM FEATURES

The pilot system is composed of the following five subsystems:

- Route guidance subsystem (RGS)
- Driving information subsystem (DIS)
- Traffic incident information subsystem (TIS)
- Route display board subsystem (RDB)
- Public service vehicle priority subsystem (PVP)

Figure 8 shows the system configuration which realizes functions of these five subsystems.

Main features of the pilot system configuration are as follow:

1. The route guidance subsystem forms the central part of the pilot system. The realtime data on traffic conditions are collected by the route guidance subsystem and are used by other subsystems. The guidance indication is fed to test vehicles only in the pilot area but any point in 23 wards of Tokyo can be designated as the destination.
2. The driving information subsystem mostly shares the same equipment with the route guidance subsystem.
3. The traffic incident information subsystem and route display board subsystem also utilize the equipment, especially computers, of the route guidance subsystem.
4. For the public service vehicle priority subsystem, only the function of identifying public service vehicles and their locations is realized.

ROUTE GUIDANCE SUBSYSTEM

Destination code

A driver who wants route guidance subsystem service determines a destination code number corresponding to his desired destination by looking at the guidance road network map of the pilot system. The destination code is represented by a seven digit number. The first two digits represent a region whose area is approximately equal to that of prefecture (2,000km^2~14,000km^2). A section (whose area is, as in the case of Tokyo, about 30km^2) in the region is represented by the first four digits. Each section is divided into less than seven zones (the fifth digit) and the zone includes less than sixty-three points (destinations) (the last two digits). Each point (destination) corresponds to individual sides of the road between intersections.

Vehicle unit and roadside unit

Each test vehicle is equipped with a vehicle unit. The vehicle unit consists of a destination encoder, display unit, vehicle loop antenna and control unit (see Figure 3). The driver, at the start of his trip, sets the recognized destination code number on the destination encoder. The driver can also select the use of an expressway by pushing an expressway option button. When the vehicle passes over a road loop antenna buried near a roadside unit before entering a major intersection, the destination code number and expressway option information are transmitted to the roadside unit through the vehicle antenna, along with other information, such as vehicle unit number and vehicle class code. A roadside unit is installed near each one of major intersections in the pilot test area. The roadside unit consists of a roadside control unit and a set of road loop antennas laid under the road in each arm of the intersection. Each roadside unit is connected to a computer center with a communication line (see Figures 3 and 5).

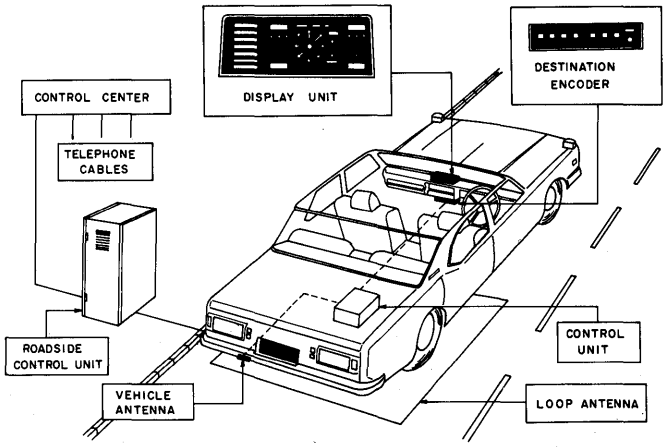

Figure 3—Vehicle unit and roadside unit

Guidance indication

The information from the vehicle unit is fed into the roadside control unit with the information identifying the road from which the vehicle is entering into the intersection. Using the destination code number, expressway option information, vehicle class code and entering link number as key words, the roadside control unit searches a guide table stored in the unit and keys guidance information corresponding to the request. The guidance information is sent back to the vehicle unit through antennas and is indicated on the display unit attached to the dashboard. The indicated information includes the following (see Figure 4):

a. Intersection shape (intersection indicator emblem in Figure 4)
b. Turning direction (indicated with one of seven arrows; the case in Figure 4 indicates a turn to the right)
c. Lane selection before entering intersection
d. Lane selection after passing intersection
e. Slope (UP: uphill, DOWN: downhill)
f. Entrance to expressway
g. Exit from expressway
h. Emergency guidance (detouring instruction)
i. Destination arrival (indicated by flashing arrow).

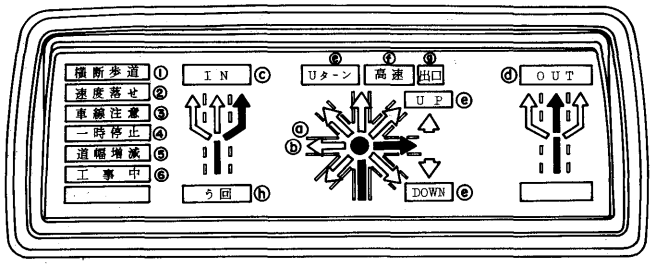

Figure 4—Display unit

Driving in accordance with the guidance indication of this subsystem from the start point to the destination enables the driver to reach the destination in the minimum amount of time even though he is unfamiliar with the place. This guidance indication is automatically updated every fifteen minutes according to changes in present and predicted future traffic conditions.

System configuration

Figure 5 illustrates the route guidance subsystem configuration. One hundred and three roadside units installed at major intersections in the pilot test area are connected to a communication control computer in a control center with 1200 bps speed data communication lines. Six computers are installed in the control center: a communication control computer, central computer, operation control computer, traffic network controller and two route search computers. A traffic network simulater performs a substitute for the route search computers. One hundred and eighty two conventional traffic flow detectors are connected to the system in order to measure the vehicle flow rate and road occupancy.

System operation cycle

General guidance information fed to drivers is automatically updated every fifteen minutes. Every processing required for its renewal, such as traffic data processing, traveling time estimation (arc costs), optimal route computation, guide table formation and so on is consequently carried out in fifteen minute cycles. Some other processings, for example diagnoses of roadside unit efficiency, are also executed every fifteen minutes. The data on traffic flow and road occupancy are collected from detectors at five minute intervals. The information from vehicle units is gathered at one minute intervals. Lengths of these cycles can be changed by commands from an operating console.

The basic operation of this subsystem consists of a sequence of the following three cycle operations. The data on traffic flow, density and running test vehicles are collected in the first fifteen minute cycle. Upon these data, the optimal paths are computed and the guide tables are made in the second fifteen minute cycle. In the third cycle, the guidance for the vehicle is performed according to these guide tables. Therefore, the vehicles are eventually guided on the basis of data for two cycles before.

Information flow and processing

Figure 6 shows an outline of the information flow and processing in this subsystem. The communication control

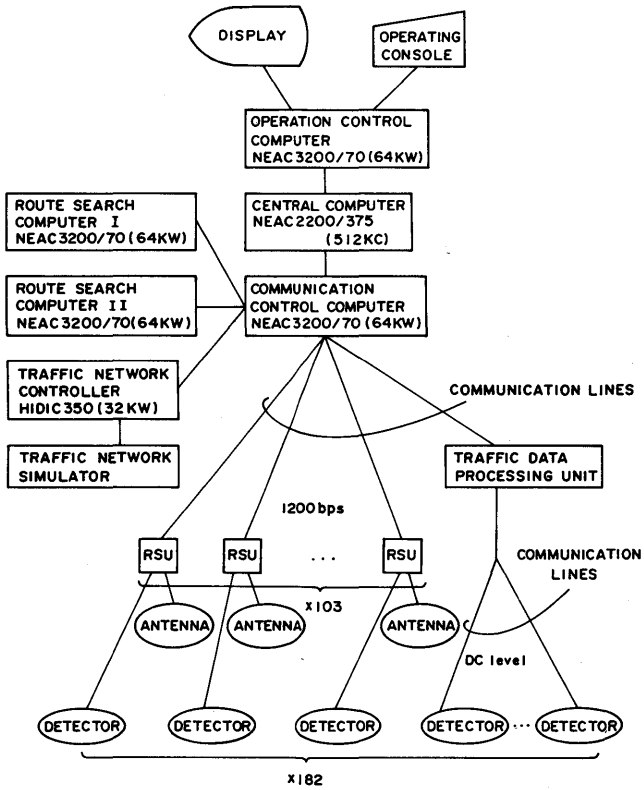

Figure 5—Route guidance subsystem configuration

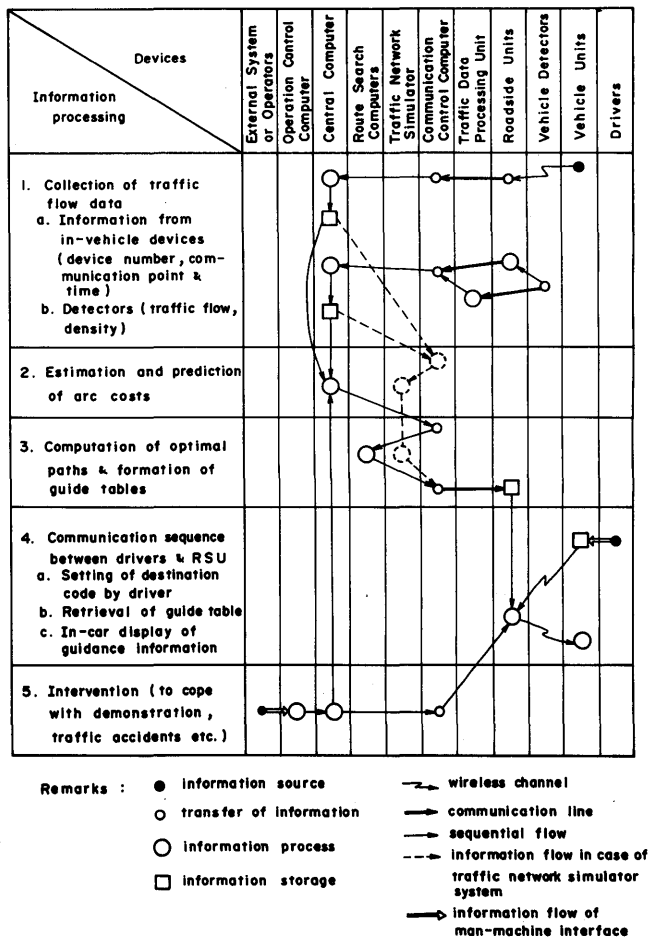

Figure 6—Information flow and processing in route guidance subsystem

computer collects data on points and times of communications between roadside units and equipped vehicles from roadside units and sends the data to the central computer. The data on traffic flow rates and traffic densities, detected by the detectors, are also collected from the roadside units and a traffic data processing unit and sent to the central computer.

In the central computer, an arc cost for each segment of the road network is estimated and predicted on these collected data. Here, the "arc cost" represents the length of time required to traverse the distance from one communication point to the next communication point beyond the intersection. These arc cost data are sent to the route search computers or to the traffic network simulator.

The route search computers compute optimal paths using the arc cost data, pertinent area traffic regulation data and other network data. The computation of optimal route search is performed at each intersection. Time-minimal paths from each intersection (origin) to every point (destination) in the network are computed. For computation economy, the route search network is specially deformed. The network structure is expressed most precisely near the starting point (origin) and its expression becomes less precise as the field goes away from the starting point.

Computation results are condensed into a guide table from every guidance intersection. The guide table is expressed in a combination of list and table structures. The maximum size of the table is less than two kilowords (one word is sixteen bits). The guide table thus formed is transmitted to each roadside unit through the 1200 bps speed data communication line. The use of the guide table at the roadside unit was previously mentioned.

OTHER SUBSYSTEMS

Driving information subsystem

The driving information subsystem gives the driver information helpful to safe driving by inside display and audible signal. When a vehicle equipped with the vehicle unit passes by a buried loop antenna connected to a roadside unit, pertinent area traffic regulations and other information on the road the vehicle is traversing is transmitted to the vehicle unit and any pertinent warning information is shown on the display unit. The warning information is expressed in one of the following messages (see Figure 4):

1. Pedestrian crossing (① in Figure 4)
2. Go slow
3. Change in lane condition
4. Stop
5. Change in width of road
6. Road under construction.

The information on the posted speed transmitted from the roadside unit is stored in the vehicle unit, which checks the vehicle's cruising speed. When the vehicle speed exceeds posted speed limit, an audible warning signal is emitted.

The contents of this driving information, stored in the roadside unit, is updated by the master information in the central file at every system cycle. The contents can also be changed by intervention command from the control room.

Traffic incident information subsystem

The traffic incident information subsystem informs a driver about information on emergencies which affect traffic flow by means of area-limited broadcasting. The broadcast information includes the news on traffic accidents, fire, sudden traffic jam and the like. It also contains advice for the driver such as recommended route, foreseen trip time etc.

In an emergency, the above information, a part of which is made up of arc cost data from the route guidance subsystem, is immediately transmitted from the control center to pertinent TIS roadside units. Each TIS roadside unit broadcasts the information to vehicles through the leaky coaxial cable antennas (LCX). When a vehicle having a car radio equipped with TIS radio adapter enters into LCX range, the vehicle receives the announcements. These announcements interrupt regular radio broadcasts and are received even though the radio is switched off.

Route display board subsystem

The route display board subsystem furnishes data concerning traffic conditions to all drivers of vehicles which are

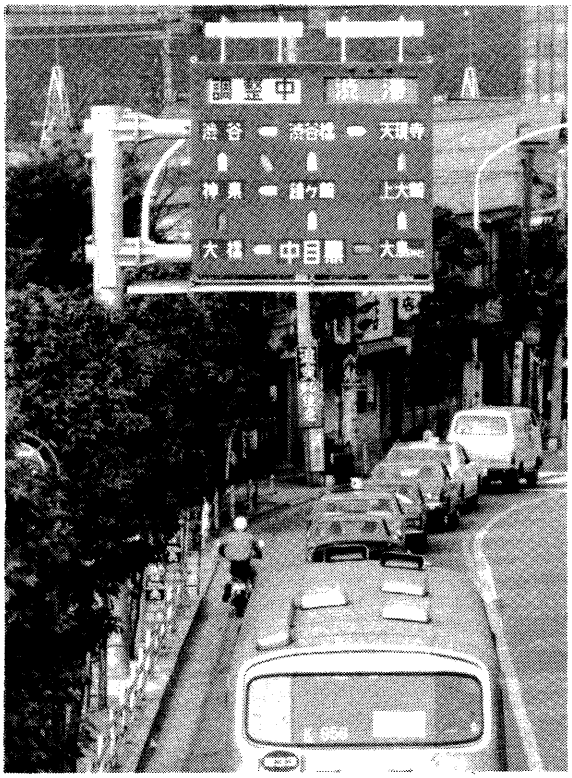

Figure 7—Route display board

not equipped with vehicle units. The information includes data on traffic congestion, accidents and/or recommended routes. This data is indicated on route display boards installed along the road. The names of a number of neighboring intersections and arrows connecting them are illustrated on the board (see Figure 7). The traffic conditions on the route between two intersections connected by an arrow are indicated by the colors of the arrow:

1. Red: heavy congestion
2. Yellow: slight congestion
3. White: no information
4. Green: recommended route to a major intersection

The congestion information and recommended routes result from arc cost data calculated in the route guidance subsystem. They are sent from the central computer system to the route display boards through off-line operator handling.

Public service vehicle priority subsystem

The function of this subsystem is not realized in the present pilot system. Only the capabilities of detecting and tracking the equipped public service vehicles on the central wall type display are checked.

CONTROL ROOM

Figure 8 is a sketch showing total CACS pilot system configuration. A control center is located nearly at the center of the pilot test area. One large-scale computer (NEAC 2200/375), five minicomputers (four NEAC 3200/70 and a HIDIC 350), one special-purpose computer and four specific use processors are installed in the control center.

A control room is included in the control center in order to control and manage operation of the overall system and to supervise pilot test execution. The major devices installed in the control room are a supervisory operating console, four subsystem operating consoles and a wall display (see Figure 9). The wall display includes a central screen display (2.0m×1.5m) with a projector in the rear, color character CRT display, lamp panel and a few indicators.

With the aid of these devices, the following operations are performed in the control room:

1. Initial system set up
2. Starting and stopping the overall operation or partial function of the system
3. System function intervention after an accident, in an emergency situation etc.
4. Recording system operating data
5. Roadside unit status diagnosis
6. Changing system parameters, configuration etc.

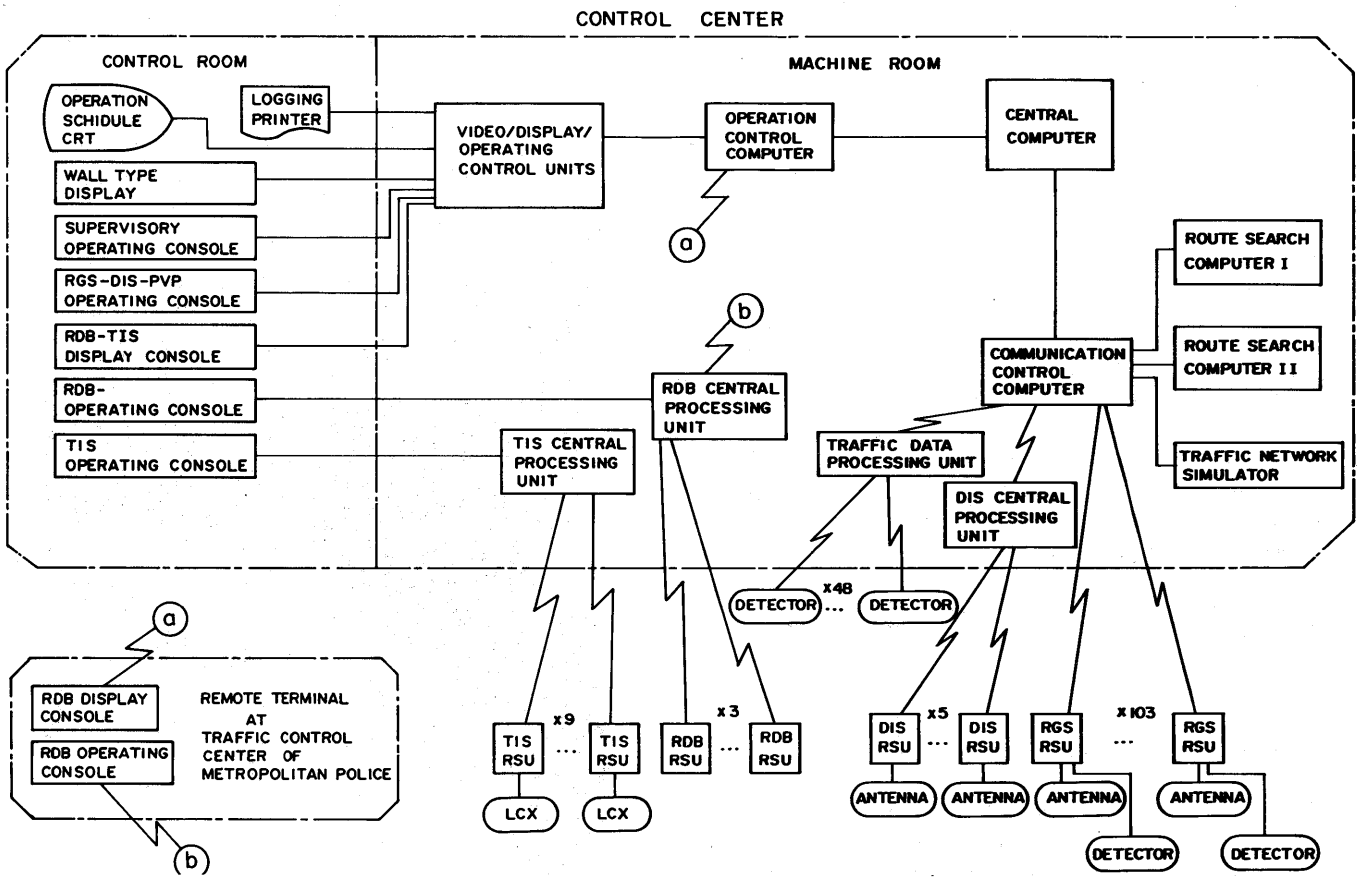

Figure 8—Pilot system configuration

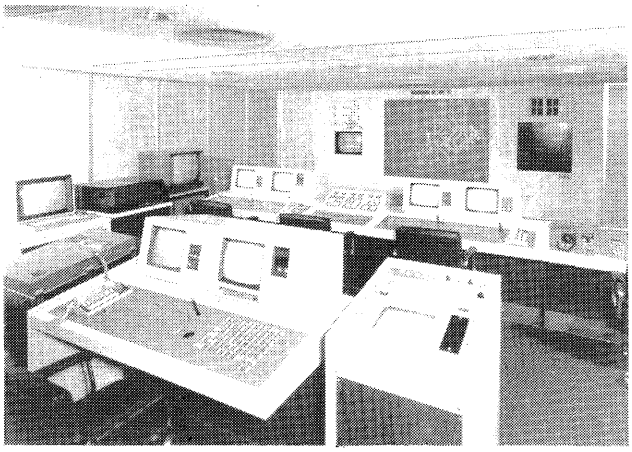

Figure 9—Control room

7. Monitoring traffic conditions
8. Monitoring system and device status

The congestion degree on each road in the pilot test area, public service vehicle location, optimal route and like data are indicated by colors on the map projected on the central screen of the wall display. Information pertinent to tracking a designated vehicle can also be illustrated there. Roadside unit and detectors status data are indicated on the character CRT display. In addition, the computer system's status, test conditions, data and time are shown on the wall display. Most of these figures can also be seen on the color graphic display mounted on the operating console.

CONCLUSION

The Comprehensive Automobile Control System has been described. Essentially, the description has concentrated on its pilot system.

It is expected that the CAC System will produce many beneficial effects on individual drivers and society to:

1. Lighten the driving effort of a driver who is unfamiliar with an area by guiding him on the optimal route to his destination
2. Reduce the time required for traveling from the start point to a specific destination
3. Relieve local traffic congestion in a city
4. Decrease traffic accidents due to careless driving
5. Eliminate the gasoline waste caused by engine idling in traffic congestion
6. Reduce air pollution due to exhaust gas.

A distributed processing system and its application to industrial control

by Y. MATSUMOTO, O. SASAKI and T. SUMI
Toshiba Electric Co.
Tokyo, Japan

INTRODUCTION

Industrial computer systems are characterized with some of their native features major items of which are:

1. Large amounts of information come from physical equipment, not from human objects.
2. The systems must control physical equipment having no human-like intelligence.
3. Quick response or parallel response is a great concern in most cases.
4. Reliability of computer systems and safety consideration to operators and equipment in case of computer malfunction are vital elements.

More than 20 years have passed since the first installation of computers in process industries. Several steam power plants and some of steel industries were the volunteers in Japan. Table I summarizes the features characterizing the progress of the process control system.

There were some significant milestones during the progress of which the remarkables were the appearances of minicomputers, micro-computers and data high-way.

Technical innovations made after each of these milestones have pushed designers toward the preference for distributed configuration of both system architecture and software.

The attempt to actualize various types of dual, duplex, hierarchical systems using multiple numbers of computers connected through channel controllers or memory bus adapters was motivated by the advent of mini-computers beginning in 1970.

Data high-way is brought into real world as the most useful communication tool to connect computers in medium distance apart. It had the reason of its birth in the process designers' demands that more reliable coupling means without losing economical properties than the one they had in using communication lines were desired. CAMAC data way and IEC bus are also used in subsystems to connect instruments and some kinds of actuating devices.

Micro-computers have been welcomed by process designers in quick rise. The word "distributed control system" used to characterize micro-computer-controlled digital control systems has become popular since 1975. This system has micro-computers in their hearts instead of conventional logic elements.

The functional requirements to the computer systems before 1975 were entirely purposed to control physical objects such as valves and motors. However, since 1976 increasing amounts of jobs to handle those kinds of information concerned with management control and production control have come within the scope of process control system. Fortunately the computers called mega-mini or some others which have main memories sizing more than 256 KB have been brought into market. These have been accepted as the suitable intervening computers between conventional physical control systems and the management information system. In this paper, these kinds of computers are called information control computers.

The latest design on the distributed computer system covering the scope of information control through to physical control and some typical applications to some real industries are described in this paper.

SYSTEM CONFIGURATION

Figure 1 shows fundamental configuration of the distributed processing. Computers (CPU), remote scanners (PI/O) and devices are connected to a data high-way through remote stations. The data high-way adopted here (TOSHIBA TOSWAY 1500 or 6300) is loop type. This type of the data high-way has the following characteristics:

1. Dual lines are applied to have good fault-tolerancy against line failures.
2. M:N communications are available.
3. Twisted paired cable or telephone line may be used. PCM type communication is adopted.
4. Protocol is based on ISO-HDLC. Messages are transparent.
5. Cyclic error checks are made.
6. Speed is 6.3 Mbps for high speed type (TOSWAY 6300) and 1.544 Mbps for low speed type (TOSWAY 1500).
7. Maximum numbers of remote stations are 32 for a loop. Maximum numbers of devices for a station are 16.
8. Maximum length permissive between adjoining remote stations is 4 Km. Maximum total length is 100 Km.

NOTES; SCC(SUPERVISORY CONTROL), DDC(DIRECT DIGITAL CONTROL), PC(PROCESS COMPUTER), BC(BUSINESS COMPUTER)

Computers are connected with data high-way through DMA adapter and controllers. The heart of each remote station is made of micro-processor with 16 bits configuration.

Micro-processors are also used in the remote scanners to make them flexible to requirements variety and intelligence. Another noteworthy application of micro-processors is the one to micro-controllers. The purposes that micro-controllers have are PID (proportional-integral-differential), direct digital control and sequential control of equipment such as motors, valves and actuators. These are used to control positions, speeds and sequential timings. A 16 bit microprocessor (TOSHIBA 40L) is adopted to the micro-controller.

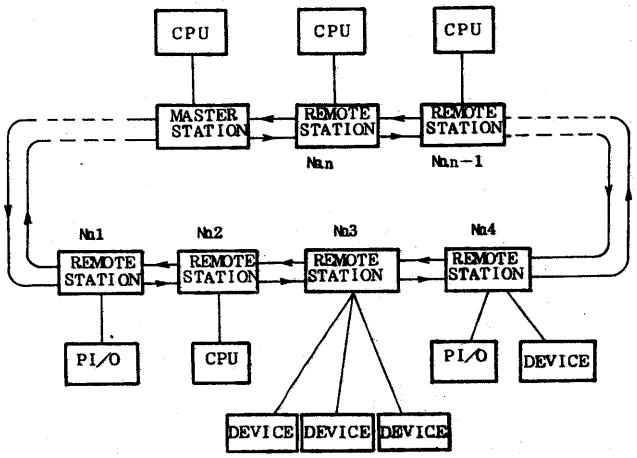

Figure 1—Fundamental system configuration

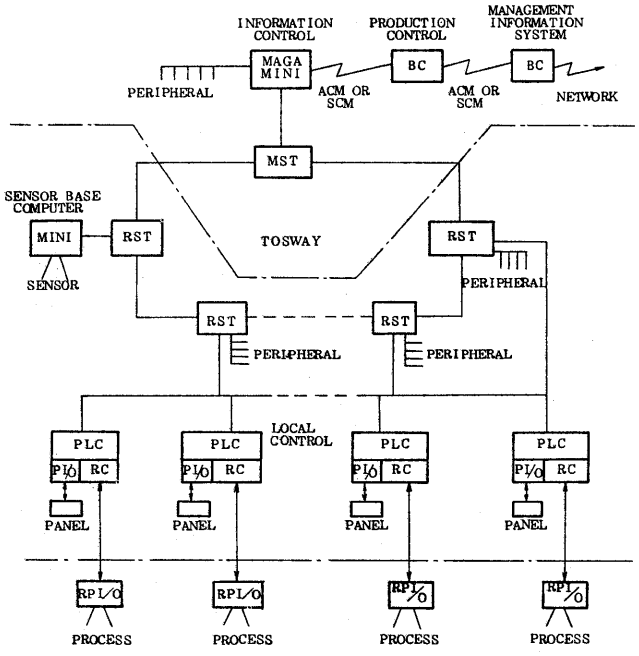
Figure 2 shows an extended system in which we have one master station (MST) and four remote stations (RST). A mega-mini computer with functions to control management information is connected to the master controller. This information control computer is connected also to business computers (BC) of upper level through communication lines. Four micro-controllers, with the functions of PLC (programmable logic control), RC (remote process I/O control) and PI/O (process input and output), are connected to remote stations. Remote process input and output (RPI/O) devices or remote scanners are controlled by micro-controllers.

The information control computer or mega-mini (TOSHIBA series A70) is a 32 bit computer with 1 Mbytes (addressable max. size is 16 Mbytes) main memory. This computer not only provides advantages that will be obtainable by minicomputer architecture, but also provides capability to process large numbers of data with high precision. This is really suitable to exist in the medium level between



PLC ;PROGRAMMABLE LOGIC CONTROLLER
RC ;REMOTE PI/O CONTROLLER
RPI/O;REMOTE SCANNER

Figure 2—An example of distributed computer system

process control system and production control or management control system.

SOFTWARE

An individual operating system resides in each component computer of a distributed system and each operating system works independently. Application programs to be applied to all the component computers are described with a unique high-level language designed for process control. The language (TPL) is a subset of PL/I plus process control functions.

Specific features are:

- Addition of case statement
- Labeled variable and multiple entrance and eliminated from PL/I, while functions effective for raising the reliability of software, such as argument check, are introduced
- Labeled constants are also accepted for the calculation type data
- Protection for the protected variables is given by declaration
- Debugging at the source program level, such as the tracing of program flow and variables, is facilitated by debugging statements
- Re-entrant function
- Process input/output subroutines
- Task control function.

Although we have several kinds of computers in the distributed system, programmers are freed from learning many kinds of languages.

TPL statements also support the functions necessary to succeed:

- Data transfer between main memories of two computers apart
- "Send" and "receive" data between tasks each of which resides on a different computer
- Data transfer to and from any input and output devices through data high-way.

PERFORMANCE TEST

The software life-cycle for our process control systems are composed of minor elementary cycles including requirements definition, design, implementation, test and maintenance cycle. There are milestones in the cycle of which two are the ones treated in this section.

One of the milestones is intended to validate some selected values of the performance before deciding system architecture and software configuration.

In the other milestone, during test cycle, whole values of performance are measured and tested.

The response time of each task exceeded the required limit is liable to cause damage to the plant equipment and decrease the product quality. In order to avoid these cases occuring both in normal operation and abnormal states, designing optimal arrangement of hardwares and softwares are requisite. The first milestone is intended to validate response time of designed system and to find optimal system structures. Predicting response time by calculation is very difficult. So, digital simulation using SIMSCRIPT is adopted as an automated analysis tool, in this milestone.[1]

Description is made here about an automated analysis tool for rolling mill computer control systems.

Process modelling

The modelling for simulation is shown in Figure 3. A, B, and C, are entities which simulate outside objects commu-

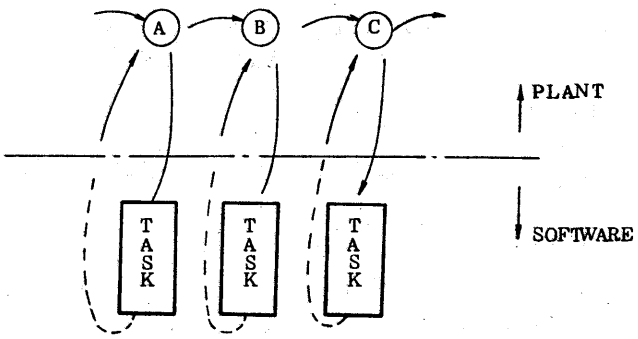


Figure 3—Process model

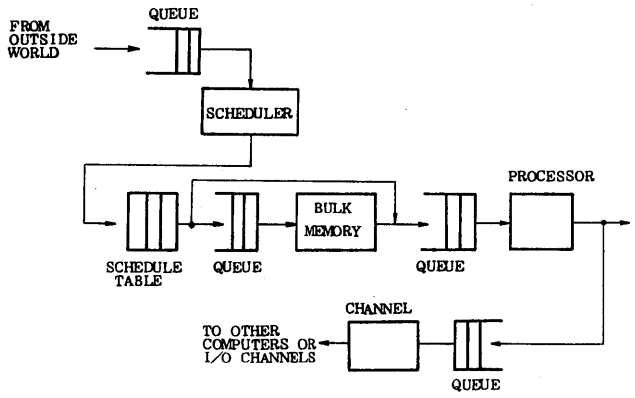

Figure 4—Task procedure model for a computer

nicating with the computer, e.g., the load cell and the hot metal detector.

The modelling for tasks inside of the computer is made as shown in Figure 4. The paths which activated tasks take through the following resources are simulated.

- Scheduling queue
- Bulk to core transfer channel
- Processor
- Peripheral device control

The tasks are terminated after passing through some of these resources.

Input data to the analysis tool

All items which are necessary to model hardware configuration and their abilities, all of task names and their attributes such as average execution times, average frequencies of I/O requests, average sizes of input/output data are inputs to the automated analysis tool.

Average intervals by which interrupts from the outside world occur are also input data to the analyzer.

The analyzer is described with Simscript.

Output data obtained

The following data are obtained as the output of the analyzer.

- Main memory occupancy rate
- Bulk memory transfer channel utilization rate
- Arithmetic unit utilization rate
- System load rate
- Response time of each task
- Execution time of each task
- Bulk transfer time of each task
- Device control time of each task
- Waiting time for execution

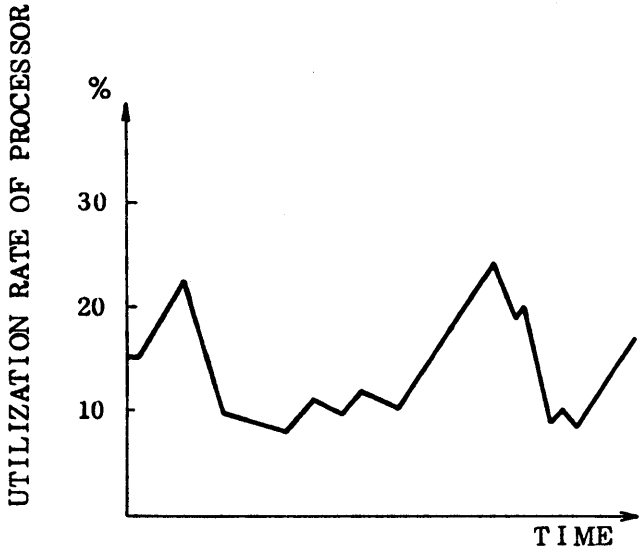

Figure 5—A result of simulation

The maximum and average values of each of these items are obtained.

The result of analysis

An example of results of analysis is shown in Figure 5, Figure 6 and Table II.

In order to obtain the peak load condition in the worst case load, the simulation for some duration of time ranging from 20-25 minutes is required.

According to our experience, a system can be acceptable as having sufficient response if it has an average processor utilization rate below 30 percent and the utilization rates of channels below 70 percent.

Table II shows the accuracy of the analysis tool in the values of response times. The values given by the simulator are compared with the ones measured in the actual operation after the installation. Figures 5 and 6 are the examples of the plotter output.

Utilization rates of the processor corresponding to time are drawn in Figure 5. In the system related with Figure 6, the response time of an activity is required. The activity consisting of six tasks as shown in the figure is activated at time O and terminated at time T. The figure shows that T is the required response time.

TABLE II.—A Comparison of Simulation and Measured Response Time

TASK	AVERAGE OF RESPONSE TIME	
	SIMULATION	ACTUAL
ROLLER TABLE CONTROL	0.27 sec	0.20 sec
MILL CONTROL	0.15 sec	0.20 sec
MILL SET UP	1.01 sec	1.00 sec

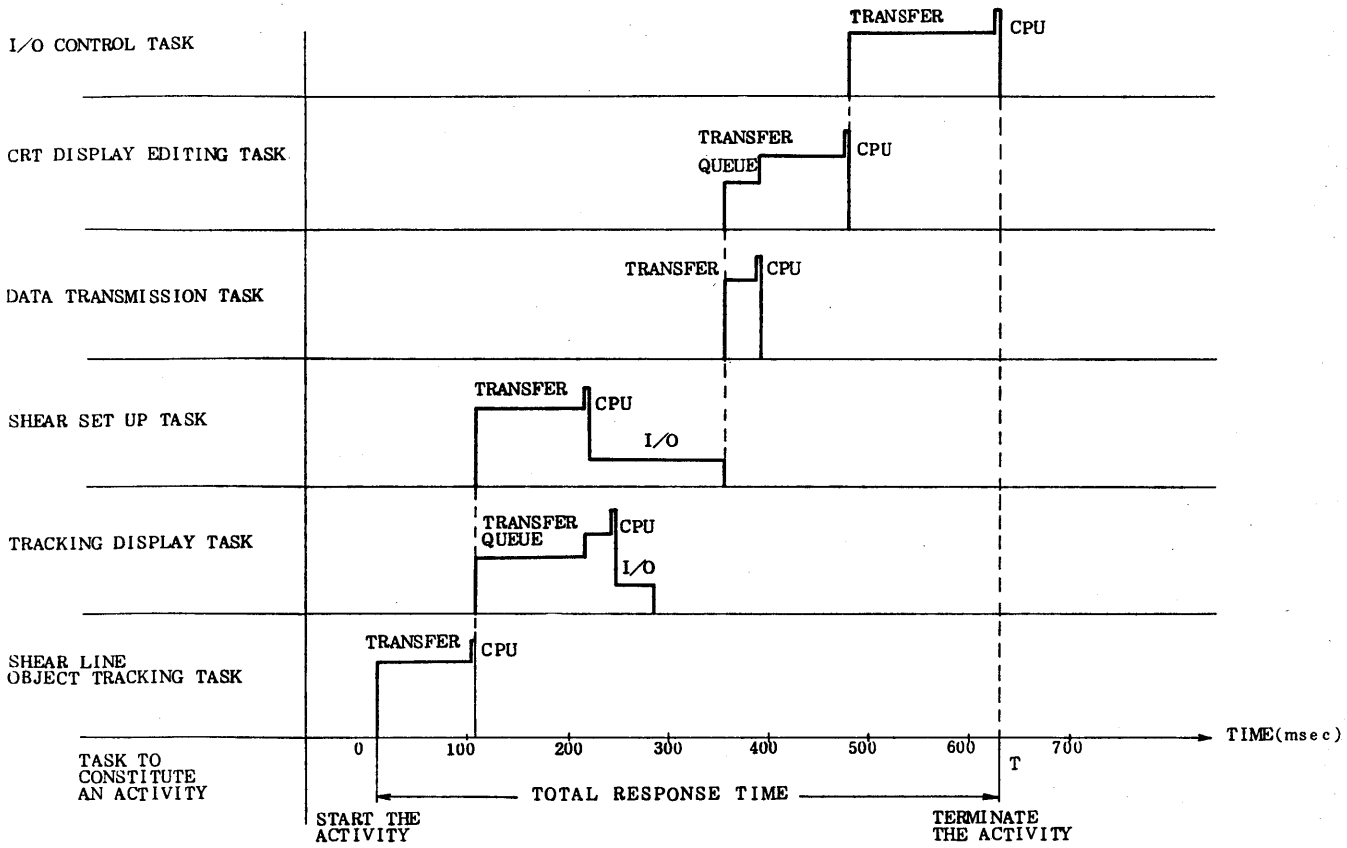

Figure 6—A result of simulation

The second milestone is allocated in the testing cycle. We have in-house computers which are the same types as the computers to be shipped to customers. These in-house computers are connected with a data high-way. Distributed systems to be shipped are able to be simulated with some modifications just for the purpose of test, by this in-house testing facility. We have another computer which we call a dynamic simulator. The programs run in this computer simulate industrial equipment or dynamic behaviors of industrial processes. The dynamic simulator is connected to each one of the above related in-house computers. The programs implemented in the previous cycle are loaded to in-house computers and simulated execution is made.

The structure of the dynamic simulator

The plant processes are classified into continuous processes, batch processes, and dynamic characteristics of individual elements. These are modularized. All kinds of processes can be simulated by combining selected modules.

For continuous process, such a function module that obtains an output from a plural input data through logical or arithmetic procedure is provided.

Elementary modules for the batch process, in case of a rolling mill process for example, simulate roller tables, rolling mills, transfers and shears according to rolling speed, length, width, and rolling directions. It also simulates sensor outputs and the metal detector signals.

How to combine these elementary modules are programmed by using a macrolanguage.

Execution of dynamic simulation

Each of the elementary modules are invoked in the timing generated by the scheduler, and are decoded and executed.

At the execution stage, simulated process data are sent out to the in-house computers, and outputs from the in-house computer are received by the dynamic simulator.

The simulated process data include, for example, metal detector ON/OFF, rolling speed, rolling torque and slab positions.

The outputs from the in-house computers include rolling directions, mill roll gaps, and mill speed set up values. Over 80 percent in number of test items can be validated by this off-site testing facility.

TYPICAL APPLICATIONS[2,3]

From among the currently installed distributed processing systems, some latest examples are picked up with brief

description. The selected fields are:

(1) Iron and steel industry
(2) Water supply and sewage works

Iron and steel industry

This industry in Japan has hitherto pursued high productivity and high yield rate in regard to the products with the targets:

- Enlargement of plant scale with continuity of operation
- Quantitative enlargement of products; diversification of species for products
- Speed up of material handling
- Energy saving.

Success will not be obtained unless we have a total system covering from the management level throughout the works to product planning, process automation and minor physical control.

As an example, herein cited is a large-scale total automation system for a rolling mill. The system shown in Figure 7 is a four-level hierarchy system, comprising the following:

A-level—central on-line system
B-level—mill area on-line system
C-level—process control system
D-level—local controller using a microprocessor or a minicomputer

These subsystems, linked with each other through looped data high-ways, perform high-speed exchange of information.

The process control system is composed of four large-scale process computers with allotted tasks as follows:

No. 1 computer—mill line area,
No. 2 computer—shear line area,
No. 3 computer—refining line area,
No. 4 computer—backup for No. 1, 2, 3.

The peripheral equipment for these computers, totaling 80 units installed at every key point, are controlled through the looped data high-way surrounding the plant.

The process control system, based on the information

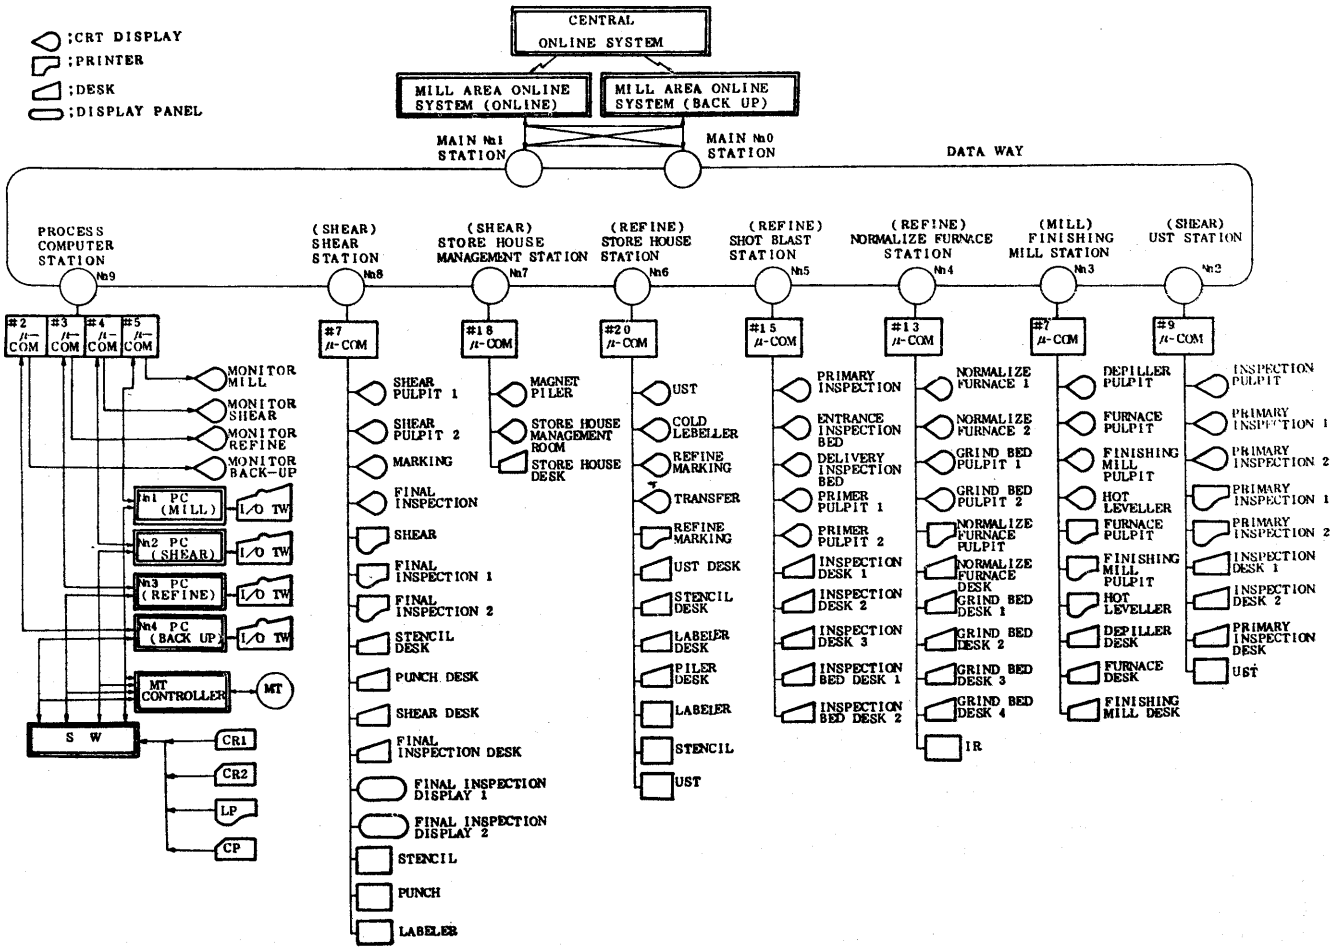

Figure 7—Block diagram of steel mill computer system

exchange with the production control system of the B-level, guides and monitors the total processes covering from the slab yard, which is the entry of the mill line, to the stock yard, which is the exit of the refining line, calculates the optimum setup value, and gives control information to local controllers of the D-level.

The principal functions of the process control system may be summarized as follows:

- Object tracking
- Slab yard mapping
- Furnace temperature control
- Mill Setup
- Cutting schedule calculation and shear setup
- Inspection and classification automation
- Refining automation
- Product-yard mapping
- Shipping schedule
- Automatic handling of objects through total line (roller tables, cranes, transfers and other material handling equipment).

The purpose of introducing this system lies in: improvement of productivity and yield rate, labor saving and improvement of process control accuracy in the range of order receiving to product shipping. This purpose is now being accomplished with excellent results.

Water supply and sewage works

For water supply systems, effective utilization of limited water resources and treatment of waste water have become an important social problem in Japan to be solved quickly.

On the other hand, to meet expanding of area to cover a growing complexity of equipment, increasingly higher techniques of operation are required. Shortage of operators as well as rise of cost of operation are also oppressing the management of projects.

Under such conditions, the introduction of computers is now indispensable to water supply facilities.

Figure 8 shows the total supervisory control system in a latest large-scale sewage works.

The supervision is conducted by the duplicated mega-minicomputer in the central control room, while the control is performed by the distributed systems employing a digital microcontroller or a soft-wired sequence controller linked with each other through the looped data way.

The major functions of this automation are:

Electrical power distribution control
In-house power generation control
Waste-water level control
Sewage pump control
Aeration control
Recirculation sludge control.

The automation for these objects enables the operation of 100 DDC loops and speed control of 20 pumps, etc. This

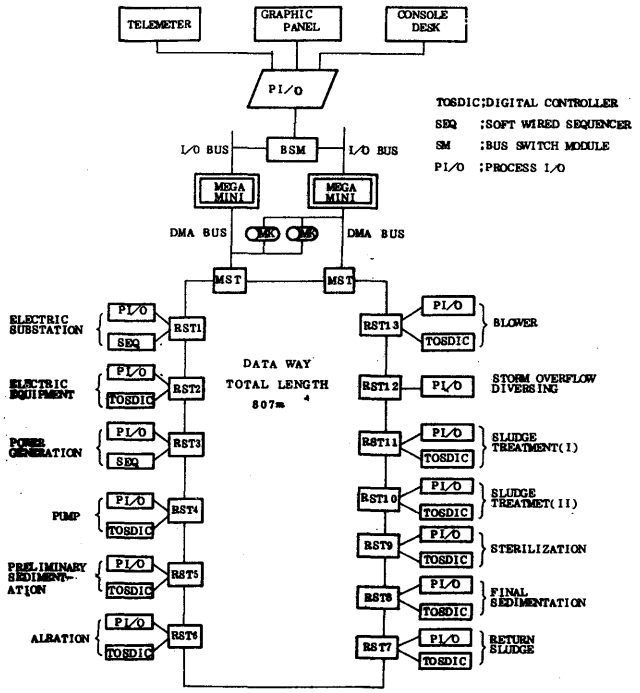

Figure 8—Block diagram of the centralized supervisory control system for a sewage works of Yokohama City

system is making great contribution to the rational operation of the largest sewage works in Japan that treats waste water of one million tons a day.

CONCLUDING REMARKS

There are inherent requirements to process control computer systems that are input and output capabilities both to physical objects and to human objects, restricted response time, safety consideration both to human beings and equipment, and reliability.

It is thought that the distributed system architecture has more capabilities to meet those requirements.

The major components to constitute the system are data high-ways, micro-controllers, mini-computers including mega-mini and remote scanners. These components are more or less modularized in the aspect of both hardware and software. The modularity will increase flexibility of design, quick shipment capability and good maintenance capability.

The concept is believed to be compatible with more complex system requirements in the future.
