Preface

We are pleased you have chosen to enjoy the 1978 National Computer Conference (NCC). Frequently the NCC is judged to be "too large" to have a theme. This year we bring you two themes: the primary theme is the national energy problem and how computers can contribute to its alleviation; the secondary theme is the growth of the computer industry, especially its fastest growing segment, personal computing.

The energy and computation theme is highlighted in the keynote address and in a powerful panel for the Tuesday evening's Symposium on Developing Energy and Computing Technology. It is continued by the luncheon speakers and by more than 10 percent of the Technical and Professional Program.

On coping with growth in the computer industry, a portion of the Technical and Professional Program deals with personal computing and with developing education curricula. The principal highlight is the Personal Computing Festival, with exhibits, sessions, and contests all its own. This is the first time the National Computer Conference has had separate registration with no age limit on attendance for a portion of its program.

This document forms the principal permanent record of the Technical and Professional Program of this conference. As such, it is a vital part of the documentation and information-dissemination system in our community. The explosive growth of literature in the last decade makes it imperative that this dissemination system be examined carefully. One such examination has been conducted by Thomas J. Allan, in his interesting NSF-funded, ten-year study of this information-dissemination system and reported in *The Management of Technology Flow* (MIT 1977). Most such studies lump scientific and engineering literature; however, he draws a careful distinction between them. One part of that distinction is that a given topic generally appears earlier in time in scientific literature than in engineering literature. During this time delay three very important things occur: *diffusion* of the information through the community; *translation* into the language of current technical practice; and *evaluation* of the concepts. This evaluation tends to be related to enterprise objectives and, hence, of strong interest to technical management.

Despite the explosive growth in the number of conferences, symposia, seminars, and workshops dealing with the

computer industry, the National Computer Conference has remained the premier conference to enhance this diffusion, speed this translation, and sharpen this evaluation. NCC is supported by 15 individual technical societies which provide it with the multidisciplinary support that makes it the focal point of excellence in the literature for technology and management.

To this end, in 1978 we have not equated originality with quality. Rather, we have brought the *best judgment* of a very strong technical and professional program committee together to ensure that the topics of importance to the community at large are represented. The best of these topics are presented in either paper or panel form. You will note there are two papers in this proceedings that have been presented earlier for a smaller audience. "The art of artificial intelligence—Themes and case studies of knowledge engineering," by Dr. Edward A. Feigenbaum and "The ubiquity of discovery," by Dr. Douglas B. Lenat. Within the AI community these have been judged "best papers" and hence are repeated here to speed the translation process and to enhance the diffusion throughout the larger information processing community.

Likewise, we have attempted to present both sides of controversial issues so that society itself can participate in the evaluation. Only in a large multidisciplinary forum of this type can we begin to provide approaches to solutions of the very pervasive problems, such as the national energy problem, the facets of a public information policy, the problems of federal regulation, etc., that face us today.

My undying thanks go to the literally hundreds of people whose efforts have gone into bringing you this fine conference, but especially to those who have dedicated their time, talent, and effort to serve on its many committees. The names of most of them are acknowledged in the back of this proceedings.

Introduction

SHAPING THE PROGRAM

Of the many criteria that were followed in creating the technical program committee of 1978, the one that played the dominant role was "excellence." We believed that attracting top people to participate in the technical program committee would result in an excellent technical program. We were indeed fortunate in attracting top technical and professional people from industry, government, universities, and other parts of society which are associated with the computer industry. We also included in our committee top professionals from our sponsoring societies; IEEE Computer Society, ACM, SCS, and DPMA. Cooperation from each of the non-sponsoring constituent societies of AFIPS was requested through their Presidents by our conference vice-chairman.

The program committee in its first meeting in December 1976 established the following philosophy and aims: (i) The number and reactions of attendees are the major criteria for measuring the success of the conference; (ii) Seek broad base appeal—do not concentrate on applications for industrial usage and ignore the system questions. Do not concentrate on the systems architecture problems and ignore the general public; (iii) Orient the program toward industrial and commercial audiences. With this charter in hand, the technical program committee began identifying appropriate technical areas for the program and created a broadly structured program with built-in adaptability to accomodate unsolicited high quality papers.

PROGRAM STRUCTURE

The program is structured into four major areas: Applications, Methodology, Systems and People and Society. Each major area is subdivided into multiple basic areas. Each member of the program committee was responsible for at least one basic area. Each basic area was headed by an area director; some area directors were also a member of the program committee. The area directors were selected for both their professional reputation and motivation. The basic areas cover most of the traditional important aspects of computer knowledge. We have tried to capture some emerging important areas such as Computer Models in Solving World's Energy Problem, Electronic Fund Transfers, Special Purpose Terminals, Office Automation, Home and

Hobbying Computing, Evolution of New Hardware Technology, and Legislation and Its Impact. For the first time in NCC's history, we have asked a sister nation, namely Japan, to organize an area in our conference.

One of the primary responsibilities of the area directors was to solicit high quality papers. The rule "every paper will be refereed" was applied universally to all solicited and unsolicited papers with the exception of two invited papers. The program contains many panel sessions. Each panelist was asked to prepare a position paper and have it approved by the session chairperson. In some cases the position papers of panelists participating in a session were combined into a panel paper and are included in these proceedings. Most of the area directors have included an overview of their area.

We hope you will find these proceedings of the program valuable and rewarding for many years to come.

PART I—APPLICATIONS

Area Director:

Lawrence Livermore Laboratory
Livermore, California

Computer models in solving the world's energy problems

The '73-'74 Oil Embargo and the more recent shortages of natural gas have made the general public energy conscious. Moreover, depleted oil and gas resources, energy conservation legislation, and higher energy prices are creating problems in industry. Significant government programs have been initiated; more, possibly much more, is yet to come. However, causes and cures of our energy problems are controversial. Complexity of energy supply and use play as big a role in this confusion as differences in economic and political philosophy. The complexity makes it difficult to accurately assess the impact of corrective action or even if any is needed and is forcing many policy analysts to turn to computer models for help in making major public and private energy policy decisions. More conventional applications of computers to energy are also expanding with the objectives of finding or recovering more oil and gas or making energy systems more efficient.

These sessions on the applications of computers in solving the worlds energy problems can only sample the many possibilities. Two sessions, "Energy Decision Analysis" and "Energy Modeling Panel," are devoted to the very significant application of computer modeling techniques to energy policy analysis. Two other sessions, "Computers in Petroleum Exploration" and "Computers in Energy Technology," provide examples from the technological and engineering side.

"Energy Decision Analysis," chaired by Robert Karsan, has papers by working policy analysts. Tani's paper reviews an analysis of President Ford's proposed synthetic fuels commercialization program that seemed to have had a major impact—to kill the program. Brock's paper addresses the economic theory used to construct several of the large energy models. Schweizer describes a model developed to predict peak electric load demand—a very important quantity in planning electric power system expansion and energy use. Rice and Meeske describe a model for natural gas demand forecasting based on interfuel competition. Although computers are not emphasized in these papers, the work described would not be practical without them.

"Computers in energy technology" chaired by Julius Chang, provides examples of computer use to improve existing technology. Kamel and Wolf show how computers are being applied to build safer and more energy efficient automobiles. Westbrock and Haselman describe work on modeling what goes on in the cylinder

on an internal combustion engine for computer simulation. Price presents a model which relates to improved oil recovery from existing wells.

"Computers in Petroleum exploration," chaired by Pierre L. Goupillaud, has papers on several aspects of oil and gas exploration. Hoffman and Ternus discuss application of computers to petroleum exploration in general. Savit predicts enormous data processing requirements for geophysical data. Selzler gets into seismic modeling.

"Energy Modeling Panel," chaired by William F. Rousseau, addresses several significant questions raised by the widespread use of energy models in policy analysis. Participants all have wide experience with energy modeling and policy analysis. Questions include why the models were constructed, what questions they answer, historically the significant insights they have provided, how the models are being judged for credibility, and the extent to which these models are meaningful representations of the real world.

Forecasting national gas demand by modeling fuel purchasing decisions for end-use customer groups

by THOMAS R. RICE
Applied Decision Analysis
Palo Alto, California

and

C. JOHN MEESKE
Private Consultant
Troy, Michigan

INTRODUCTION

Rapidly rising domestic natural gas prices and the development of higher-priced synthetic fuels have made marketability a key issue for the natural gas industry, both for distribution companies and for producers and interstate pipelines in making reserve acquisition decisions. This paper describes the methodology underlying a detailed model that characterizes the interfuel competition between gas, oil, coal, purchased steam, and electricity.

The model forecasts the quantity of various fuels demanded in a utility company's service territory by considering the fuel-purchasing decisions of customer groups. Each market is segmented into customer groups according to equipment types and operating characteristics. For example, residential customers are divided according to their heating system (forced air systems, gravity systems, boilers, and heat pumps). Commercial customers are divided by Standard Industrials Classification (SIC) codes such as restaurants, laundries, schools, and hospitals. The industrial customers are also divided by SIC codes, and further subdivided by major installations. In some cases, both commercial and industrial customers are further broken down by actual device. For example, large boilers at a major industrial power plant form a separate market segment.

Consumers switch from one fuel type to another when it becomes economically desirable to do so, based on a net present value calculation that takes into account the following factors:

- "hard" economic costs associated with each fuel type
- subjective preferences for various fuels
- availability of alternate fuels
- efficiency of each fuel in providing usable energy
- relative importance of present and future costs to each consumer
- effect of government conservation programs and regulations
- risk of fuel shortages

Alternate gas rate designs included in the model provide for measurement of the impact of gas rates on gas demand. The model allows customers to switch to alternate (or multiple) fueled equipment when it is technically possible and economically desirable, taking into account the possibility that a consumer may be technically or contractually required to use a minimum amount of fuel with such equipment. The forecasted demand for each fuel type is produced by summing the demand for that fuel type for each consumer sector.

MODEL OVERVIEW

The major elements of the Interfuel Competition Model are shown in Figure 1. The central logic of the model deals with the manner in which customers expand the capacity of their energy consuming equipment and with their choice of fuel for both new and existing equipment. This central logic is supplied with information from several submodels. The Gas Rate Model computes the retail price of gas by sector based on projected cost of gas, sales volume, and distribution costs. Alternate fuel prices for coal, oil, and electricity depend on sulfur content, annual usage, and proximity to rail and water transportation. The Industry Growth Model considers economic growth by SIC code, the corresponding impact upon energy growth, and the relative growth of different technologies within a sector.

The Capacity Growth Model contains logic to deal with new energy consuming capacity added to keep pace with changes in economic activity level. It calculates the amount of energy consuming capacity existing, added, retired, and refurbished within each sector for each year under consid-

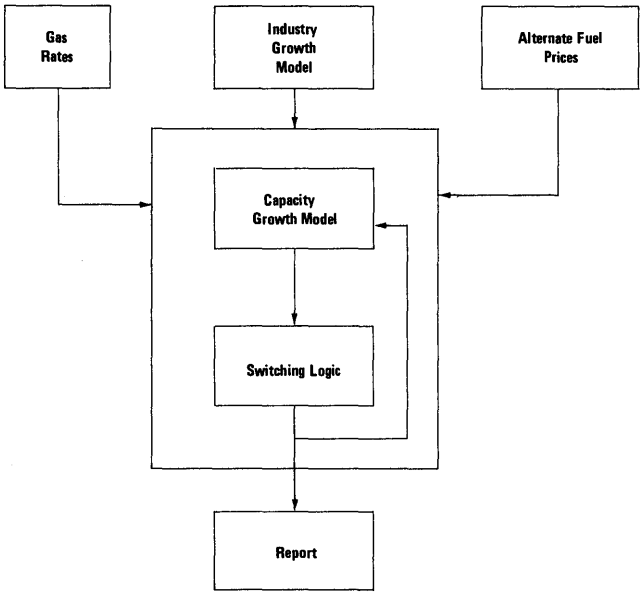

Figure 1—Overview of interfuel competition model

eration. Refurbishment is important since it represents a point where the incremental cost of converting fuel types is low.

The heart of the Interfuel Competition Model is the Switching Logic shown in Figure 1. This logic analyzes consumer decisions regarding possible fuels to meet energy needs during each of the 20 years considered in the study. The customer's decision is based on minimizing the net present cost associated with each possible fuel, including the cost of converting from one fuel to another as well as future prices of various fuels. Net present cost (NPC) is one component of the more general quantity, net present value (NPV). The net present value of a stream of investments, returns, and variable costs at some time period t is given by:

$$\text{NPV}_t=(1-\text{INCOME TAX RATE})\sum_{j=t}^{N}\frac{R_j-VC_j}{(1+)^{j-t}} - (1-\text{INVEST. TAX CREDIT})\sum_{j=t}^{N}\frac{I_j}{(1+r)^{j-t}} \quad (1)$$

where I_j is any investment made in time period j, R_j is the gross return or revenue in period j, VC_j is the variable cost in period j, r is the discount rate, and N is the decision maker's planning horizon.

This equation states that the net present value is equal to the net after-tax value in each period (revenue minus any investments, all weighted by the appropriate tax rates), discounted by the appropriate rate and summed over all time periods. The equation for the net present value can be written as the difference of two quantities, the net present return (NPR) and the net present cost (NPC):

$$\text{NPV}_t=\text{NPR}_t-\text{NPC}_t \quad (2)$$

The net present return is equal to the sum of the discounted returns in each time period weighted by 1 minus the income tax rate:

$$\text{NPR}_t=(1-\text{INCOME TAX RATE})\sum_{j=t}^{N}\frac{R_j}{(1=r)^j} \quad (3)$$

The net present cost is equal to the discounted variable costs and investments in each time period, weighted by the appropriate tax rates:

$$\text{NPC}_t=(1-\text{INCOME TAX RATE})\sum_{j=t}^{N}\frac{VC_j}{(1+r)^{j-t}} +(1-\text{INVEST. TAX CREDIT})\sum_{j=t}^{N}\frac{I_j}{(1+r)^{j-t}} \quad (4)$$

If a consumer switches from one fuel to another and continues to use the same amount of energy, the benefit or return that he derives from that energy in each period will be unchanged. Thus, the net present return does not depend on the fuel chosen.*

However, switching from one fuel to another will probably require a capital investment determined by the type of fuel selected; the variable costs associated with each fuel will be different.

The variable cost associated with using a particular fuel in time period j can be written as follows:

$$VC_j=[P_j(1+\text{CONVENIENCE PREMIUM}) +(\text{O\&M})_j]/\text{FUEL EFFICIENCY} \quad (5)$$

where P_j is the price of the fuel in time period j, $(\text{O\&M})_j$ is the operations and maintenance cost associated with using the fuel in time period j. "Convenience Premium" is a subjective term used to scale the actual price of a fuel up or down to reflect a consumer's bias for certain fuels. This subjective preference can be based on aesthetics, perceived safety, or relative ease of contracting. Since the net present return is the same for each unit of energy, regardless of the fuel chosen, a consumer can maximize his net present value by choosing the fuel that minimizes his net present cost. This is the economic criterion that is used in the Interfuel Competition Model.

Although the above equations give the correct definition for the net present cost associated with a particular type of fuel, a more convenient form is used in the Interfuel Competition Model. This definition is recursive; the net present cost in one time period is defined in terms of the net present cost in the following period:

$$\text{NPC}_t=(1+\text{INCOME TAX RATE})VC_t +(1+\text{INVEST. TAX CREDIT})I_t+\frac{\text{NPC}_{t+1}}{(1+\text{r})} \quad (6)$$

Although Equation (6) is equivalent to Equation (4) above, this equation for the net present cost does not require a sum of variable costs and investments over time. However, to

* This assumes that by switching from one fuel to another, a consumer does not face the risk of finding himself with an inadequate energy supply. The possibility of a general energy shortage and its impact on the decision making of energy consumers is discussed later.

calculate the net present cost in any time period with this equation, we must first calculate the net present cost in the following time period. In the Interfuel Competition Model the net present costs associated with each fuel and each time period are computed by working backwards through time, starting with the last year considered by the model and working backwards to the present.

DECISION PATH OUTPUT FROM SWITCHING LOGIC

The Interfuel Competition Model calculates the net present cost associated with switching from every possible fuel to every other possible fuel (or keeping the same fuel) in each year. The program then selects the fuel that minimizes the customer's net present cost. Using this information, the model produces an array of decisions showing which fuels the customer should use over time for each possible initial fuel type. This array of decision for a hypothetical customer is represented graphically in Figure 2.

If the consumer was initially using gas, the decision arrows in Figure 2 indicate that he should continue to use gas through the third year and then switch to oil. On the other hand, if he started with coal, he should continue to use his initial fuel for at least the first four years. Figure 2 also indicates that customer using gas in year 4 should switch to oil, even though a customer who had started with gas in the initial year would have switched to oil the third year. Thus, if the decisions shown in Figure 2 are followed, it would not be possible for this customer to be using gas in the fourth year.

ILLUSTRATIVE EXAMPLES OF THE SWITCHING LOGIC

The model's switching logic can best be illustrated by simple examples. To keep the examples manageable, fuel choices are limited to gas (G), oil (O), coal (C), and dual-fired gas and oil (G/O). In the actual model additional fuel types are possible, including electricity, purchased steam, dual-fired gas and coal. In addition, we will ignore the distinction between refurbished and remaining equipment in these examples.

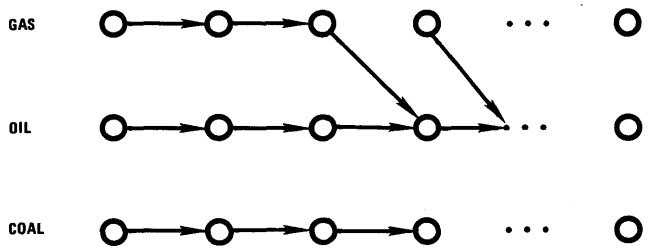

Figure 2—Decision paths—Switching logic output

Example without fuel availability uncertainty

The decisions that a customer with four possible fuel types must face in any given year are shown in Figure 3. At the end of year the customer could be using any one of the four possible fuels, as indicated by the four hexagons at the left of Figure 3. In fact, he may have several different types of equipment using different fuels. Some of his existing equipment will have to be retired, and he may need to add some new equipment to his inventory. For each type of equipment—new, currently using gas, currently using oil, currently using coal, and currently dual-fired gas/oil—he must decide which fuel to use in the future. Decisions are shown in Figure 3 by small squares. Separate decisions are made for new equipment and for equipment currently using each of the possible fuels because the economics of switching fuels is different in each case. Once the customer has made all decisions for year I, the various pieces of energy consuming equipment can be aggregated by fuel type. Thus, if the customer decides to continue using gas for his gas-fired equipment, and to purchase some new equipment that uses gas, the amount of gas-fired equipment carried over to the next year will include the total of both these equipment categories. In the following year, I+1, the customer, after retiring some of his old equipment and purchasing some new equipment, is again faced with the same set of decisions. In each case the decisions are based on minimizing the net present cost associated with each possible fuel.

Figure 4 illustrates how the consumer might make his decisions for new equipment, equipment currently using gas, and equipment that can use either gas or oil. It is assumed that the consumer starts in year I−1 with ten units of capacity in gas-fired equipment that can burn either gas or oil, as represented by the 10's above the hexagons at the left of Figure 4. If four new units of capacity are purchased to replace two units of capacity for each type of equipment which must be retired, the three decisions for year I, represented by the boxes at the left are: What is the best fuel type for: (1) the new equipment, (2) the eight units of capacity currently using gas, and (3) the eight units of capacity currently using gas and oil?

The Interfuel Competition Model treats equipment capable of using more than one fuel (such as the gas/oil equipment in this example) as if it were a separate fuel type. After the model has allocated demand to dual-fuel equipment, a separate calculation determines the cheapest available fuel that the equipment can use in each year. Thus, gas and gas/oil equipment may both use gas in a particular year. In this case the allocations to gas and gas/oil equipment must be summed to determine the total gas demand. However, if oil becomes less expensive than gas in the following year, the dual-fueled gas/oil equipment will automatically switch to oil without incurring any additional investment costs. Equipment based on gas alone will switch to oil only if the discounted cost savings are sufficient to outweigh the required investment.*

* Multiple-fuel equipment may be required to use a minimum amount of each of its possible fuels.

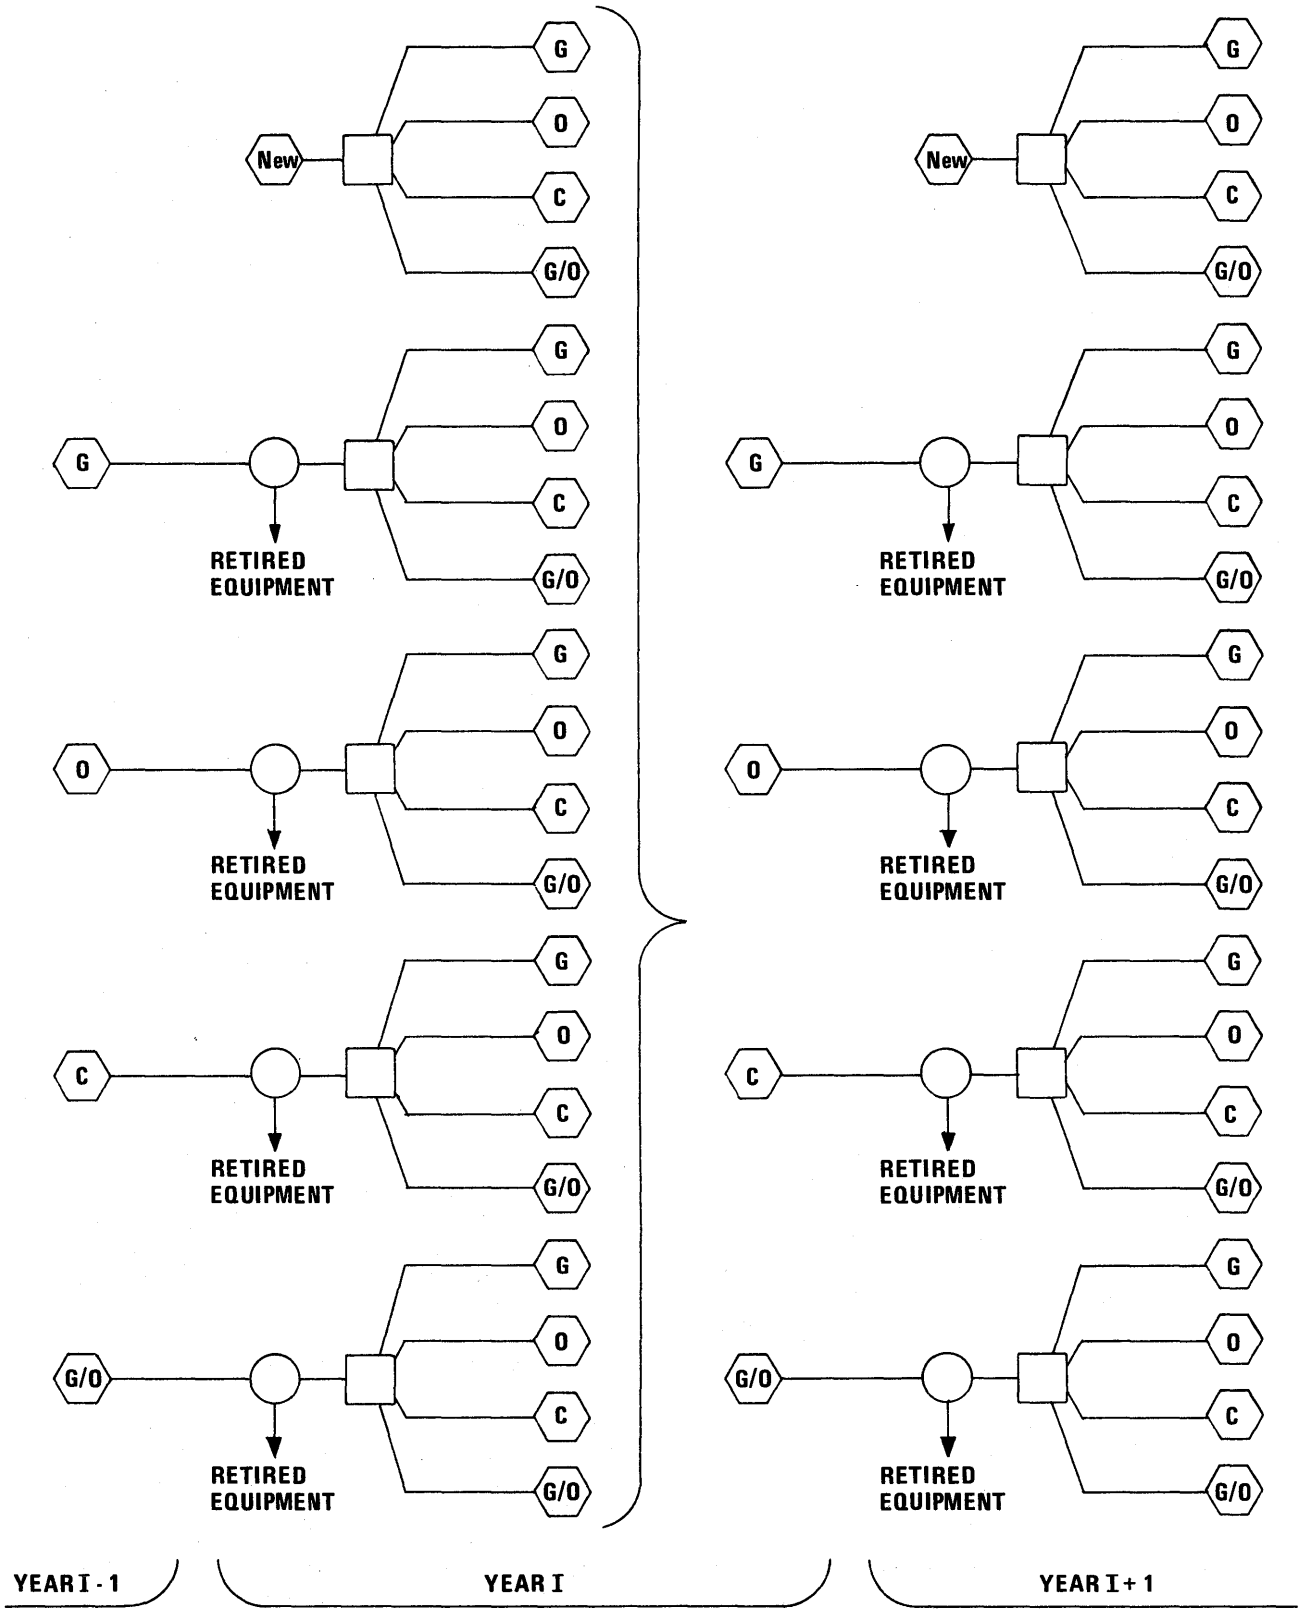

Figure 3—Basic switching logic

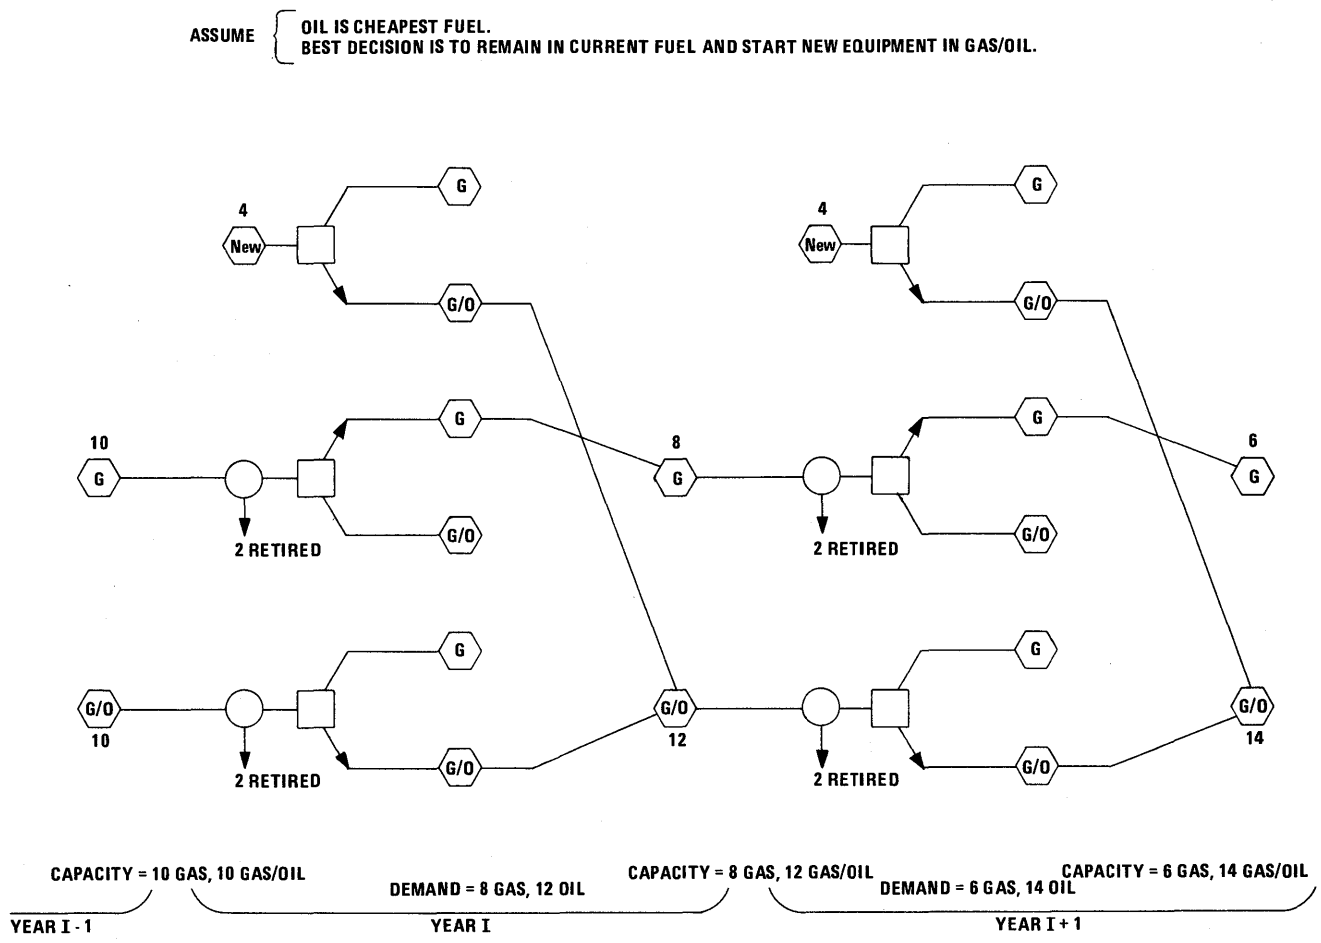

Figure 4—An example of the basic switching logic

Let us assume that oil is the cheapest fuel and that the best decision at each point is to continue using the existing type of equipment or to purchase new equipment that is capable of burning both gas and oil. The consumer's decisions and their effect on the capacity of his equipment and his demand for various fuels is shown in Figure 4. In year I−1 two of the initial ten units of capacity in equipment using gas only are retired, and the remaining eight units continue to burn gas only. Similarly, eight of the initial ten units of capacity in dual-fuel gas/oil equipment are maintained through year I and combined with four new units of capacity capable of burning both fuels. Thus at the end of year I there are eight units of capacity in gas only and twelve units of capacity in gas/oil. Since the dual-fuel equipment is used with the cheapest fuel, oil, the fuel demand in year I is for eight units of gas and twelve units of oil. In year I+1 the process repeats itself, with the capacity of dual-fired equipment increasing from twelve to fourteen.

Example with uncertain fuel availability

To generalize the example to uncertain fuel availability we must differentiate between three general categories of unavailability. The first is *operational reliability*; this can be modeled by adjustments to O&M expenses to reflect inventory carrying costs and stockouts, as in any inventory problem. The second is *long-term shortages* of specific fuel types caused by government regulations or scarcity; this uncertainty is treated explicitly in the model by introducing the probability of unavailability as illustrated in the example below. The third is a *general energy shortage*, where total supply is insufficient to meet demand. This is modeled by adding a term to the variable cost equal to the product of three terms: (1) the probability that a general energy shortage will occur in each future year, (2) the probability that a consumer will be forced to do without energy if he is using a particular fuel when an energy shortage occurs, and (3) the net cost to the consumer that results from doing without energy for the expected duration of the shortage.

Figure 5 illustrates a simplified numerical example of the switching logic contained in the Interfuel Competition Model when fuel availability is uncertain. Only two types of equipment are considered in the example: that using gas only, and that capable of burning either gas or oil. For simplicity, it is assumed that there is no new, retired, or refurbished equipment; thus all of the existing equipment is carried over from one year to the next without additions, losses, or sep-

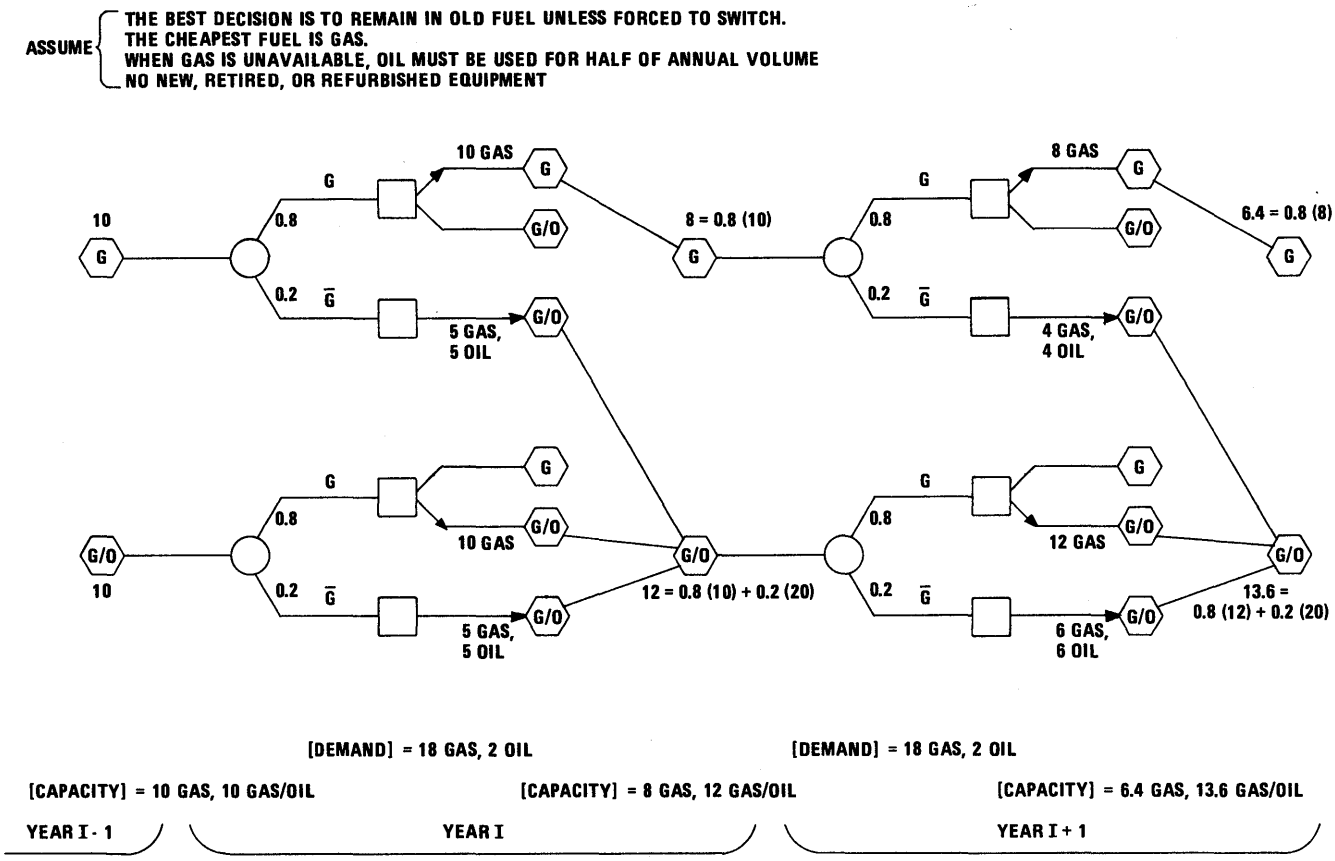

Figure 5—An example of switching logic with uncertain fuel availability

arate decisions for refurbished equipment. It is also assumed that: (1) the best decision in each year is to remain with the current fuel unless that fuel becomes unavailable, (2) gas is the cheapest fuel, and (3) in a year when gas is unavailable, the duration of the shortage will force consumers to use oil for half their annual volume. In addition, it is assumed that there is a 20 percent chance that gas will be unavailable in each year. This is illustrated in Figure 5 by the probability node shown as a circle.

The example starts at the end of year (I−1) with ten units of equipment capable of using gas only and ten units of equipment capable of using either gas or oil. In this case, the ten units of dual-fired equipment are run on gas since it is the cheapest fuel. If gas is available throughout the year I, none of the equipment is modified and twenty units of gas are demanded. However, if gas is unavailable in year I, the ten units of equipment on gas only are converted to allow them to burn either gas or oil. All the dual-fueled equipment is then operated on oil for half the annual volume, and on gas for the rest of the year. At the end of year I, either ten units of capacity will operate on gas and ten on gas/oil, or all of the equipment will have been converted to gas/oil, depending on whether or not gas was available during the year. The expected capacity at the end of year I is eight units of equipment capable of burning gas only, and twelve units of dual-fuel equipment. During year I there is an 80 percent that the entire demand will be for gas, and a 20 percent chance that the demand will be split evenly between gas and oil. Thus, the expected demand will be split evenly between gas and oil. The expected demand during the year is for 18 units of gas and two units of oil.

In the year I+1, the process repeats itself. The expected capacity of equipment capable of burning only gas drops from 8 to 6.4, while the expected capacity of dual-fuel equipment rises from 12 to 13.6. However, there is still an 80 percent chance that the entire demand during year I+1 is for 18 units of gas and two units of oil, unchanged from the previous year. This example illustrates the fact that the possibility of fuel shortages may cause consumers to protect themselves by switching to dual-fired equipment without changing the expected demand for individual fuels. This type of consumer behavior, which is incorporated into the Inter-fuel Competition Model, leads to volatile energy markets marked by large fractions of total energy demand that switch rapidly from one fuel to another.

OTHER ISSUES

Fuel availability is just one of many issues considered in designing and implementing the Interfuel Competition Model. Other phenomena of importance include:

- Lags in consumer response to energy market changes
- Different planning horizons used by energy consumers
- Legal and physical constraints that limit a consumer's ability to switch from one fuel to another
- Rate structures employed by electric utilities
- Effects of conservation, regulation, and growth within the gross national product on energy demand
- Interdependence of prices and volumes of all fuels.

CONCLUSION

This model is among the first models to predict market demand and market share by examining the behavior of specific customer groups. Most other demand forecasting methodologies rely on price elasticities or market share curves, and, consequently, they predict a smooth response of demand to price differentials between fuel types. Of course, price response depends on specific data used in the model, but typical demand curves derived from the model are not smooth. Gas demand forecasts from the model based on dynamic programming, probabilistic decision theory, and detailed market segmentation should be more accurate than forecasts from traditional models.

General equilibrium models for energy policy analysis

by HORACE W. BROCK
SRI International
Menlo Park, California

INTRODUCTION

In this paper we shall provide an elementary overview of the concept of general economic equilibrium in the concrete context of the U.S. energy market.* With this aim in mind, we shall introduce and discuss several important, large-scale energy models which embody the assumptions of the methodology of economic equilibrium. The models which will be discussed were all developed since the OPEC embargo of 1973—an event which has provided the impetus for development of sophisticated computer models useful in energy planning and policy-making.

In the first section, the models of Hudson and Jorgenson[1] and Hnyilicza[2] are introduced. The discussion here will hopefully provide the reader with a clear diagrammatic exposition of the concept of general economic equilibrium. By "economic equilibrium" we mean a state of the economy in which prices are such as to equate the supply and demand for all commodities under consideration. These two particular models provide a good starting point for our discussion since they are very broad in scope, encompassing both the energy and the non-energy sectors of the U.S. economy. In doing so they take account of the important linkages which exist between the energy and non-energy sectors.

Then in the second section, we introduce the SRI National energy model, sometimes referred to as the SRI-Gulf model since it was originally developed with the collaboration of the Gulf Oil Corporation. Our focus in this section is on the *algorithm* through which economic equilibrium is determined in a dynamic economic context. An understanding of the algorithm not only sponsors an in-depth understanding of the SRI model and "how it works," but permits an appreciation of the important role of *computation* in large-scale models. Finally, in the last section, we conclude with some remarks on the role of economic models in energy policy analysis.

* The research discussed in this paper was sponsored by the Office of Policy Research and Analysis of the U.S. National Science Foundation. The report[3] on which this paper is based was co-authored by the present author, and by Dr. Dale M. Nesbitt of Decision Focus, Inc. of Palo Alto, California.

THE HUDSON-JORGENSON/HNYILICZA MODELS—AGGREGATE MODELS OF ENERGY AND ECONOMIC GROWTH

Background

In 1974, Edward Hudson and Dale Jorgenson[1] introduced a model of energy and economic growth. The Hudson-Jorgenson model consisted of two somewhat separate submodels: a macro-economic model of economic growth, and a multi-sector interindustry model. The model was the first to make use of a new and advanced methodology for econometric estimation in a general economic equilibrium context. This methodology is known as "translog economic modeling" in the technical literature.

An ostensible problem with the Hudson-Jorgenson model was its failure to integrate its two submodels in a completely satisfactory way. It was not clear that the inputs and outputs of the two submodels were compatible. This difficulty provided the motivation for Esteban Hnyilicza[2] to develop a model which, while very similar to the Hudson-Jorgenson model, differed from it in its treatment of economic growth. Specifically, Hnyilicza has attempted to build a model in which the multi-sector inter-industry model and the macro-economic growth model are satisfactorily integrated. The Hnyilicza model also differs from the Hudson-Jorgenson model in being much more highly aggregated. Specifically, it consists of only two sectors, namely the energy and non-energy sectors of the economy. In other important respects, such as use of the "translog" methodology, the two models are much the same.

In this section, we are going to discuss the Hnyilicza model at some length. The purpose of discussing this model rather than the Hudson-Jorgenson model is that our diagrammatic mode of exposition of the methodology used in both models requires that we limit ourselves to a simple model with very few sectors.

Introduction

Hnyilicza has constructed an integrated model for the purpose of analyzing the relationship between economic

growth, and the (equilibrium) prices and quantities of both energy and non-energy goods. His model provides the basis for computing a trajectory of future market clearing (i.e., "equilibrium") prices and quantities of the following commodities:

1. Energy consumption goods
2. Non-energy consumption goods
3. Energy intermediate goods
4. Non-energy intermediate goods
5. Capital services to the energy sector
6. Capital services to the non-energy sector
7. Labor services
8. Energy imports
9. Non-energy imports

These outputs are generated on a period-by-period basis as the solution to a model consisting of fifty-five (nonlinear) simultaneous equations. By analyzing time-series projections of the prices and quantities of these goods, Hnyilicza can diagnose the relationship between economic growth on the one hand, and the relative prices of energy and non-energy goods on the other hand. It is also possible to study the rate of substitution of capital and labor for energy, as well as the economic impact of alternative tax and conservation policies.

Overview of the model

Figure 1 displays the overall structure of the Hnyilicza model. There are three basic model sectors: industrial production, consumption, and investment.* The fact that these sectors are enclosed by solid as opposed to dashed lines is supposed to describe the fact that the outputs of these sectors are determined endogenously within the model. This is not the case with the government sector and the foreign sector. The latter two (which are enclosed by dashed lines) are largely exogenous to the model.†

Before delving into the details of the three sectors, let us briefly summarize what takes place in the model in hopes of better motivating Figure 1 and in hopes of providing the reader with a guide to the model. One preliminary word of warning is in order. It is extremely difficult to describe what "goes on" in any general equilibrium economic model on a sector-by-sector basis. The reason for this is simply that what happens in any one sector affects every other sector. Nonetheless, we have tried to motivate the model by means of a sector-by-sector discussion since there seems to be no satisfactory expository alternative.

Two things happen in the consumption sector. First, the "national household's" inter-temporal utility function determines the split between *present* consumption and *future* consumption (i.e., savings). More specifically, the household is assumed to determine a utility-maximizing split between consumption and savings as an (econometrically estimated) function of wealth, the wage rate, and government transfer payment levels. Second, the consumer decides upon an *intra*-period split between leisure, energy consumption goods, non-energy consumption goods, and capital services. The optimal split is that which is utility-maximizing, subject to the consumer's budget constraint. This split will of course be a function of the relative prices of the various consumption goods, and the wage rate, among other things.

The two industrial production sectors—energy and non-energy—determine an optimal (profit-maximizing) level of outputs, *and* an optimal (profit-maximizing) configuration of inputs used in producing the equilibrium output levels.

Finally, the investment sector determines the level of capital services which will be available in any given period. As we shall see, this level depends on both the efficiency of capital, and on the level of capital stocks in the preceding period. The investment sector also determines the overall level of gross investment in any given period, as well as the fractions of gross investment going to the energy sector, the non-energy sector and the household.

A diagrammatic exposition

An important question arises concerning the best way in which to explain and motivate a model which is as general as the Hnyilicza model. Two approaches seem to be possible: a mathematical approach and a diagrammatic approach. We have settled upon a diagrammatic exposition of the model. More specifically, we shall motivate the model by discussing each of the three sectors (production, consumption, and investment) from the standpoint of the *demand curves* and the *supply curves* which are implicit in the equations which characterize economic behavior in each sector. This strikes us as a compact and intelligible mode of exposition. Furthermore it permits us to conclude our discussion with what we hope to be a highly appealing summary of the model: namely, a picture (Figure 5) in which we superimpose the various supply and demand curves which we "extract" from each of the three sectors. The price-quantity pairs of *all* of the points of *intersection* of these supply and demand curves will clearly constitute a general economic equilibrium. And these equilibrium prices and quantities coincide with the values of the endogenous variables which are determined when the model is solved.

In light of our decision to explicate the model in terms of the supply and demand relationships that are implicit in the equilibrium equations of the model, a caveat must be issued from the outset. Whenever the reader sees a picture of a supply curve or a demand curve, he should realize that he is beholding an illusion. For in point of fact, there are no such things as supply and demand curves *per se*. There are only *conditional* supply and demand curves. Let us illustrate this point since it often engenders confusion. Consider a two

* It is perhaps a bit artificial and unnecessary to identify an "investment sector" which is distinct from the consumption and production sectors. We have only done so in order to facilitate a description of what goes on in a "growth" model.

† Specifically, the behavior of the government sector is almost completely exogenous. In the import markets, whereas the supply curve for imported goods is exogenous, the demand curve for imports (energy and non-energy) is endogenous.

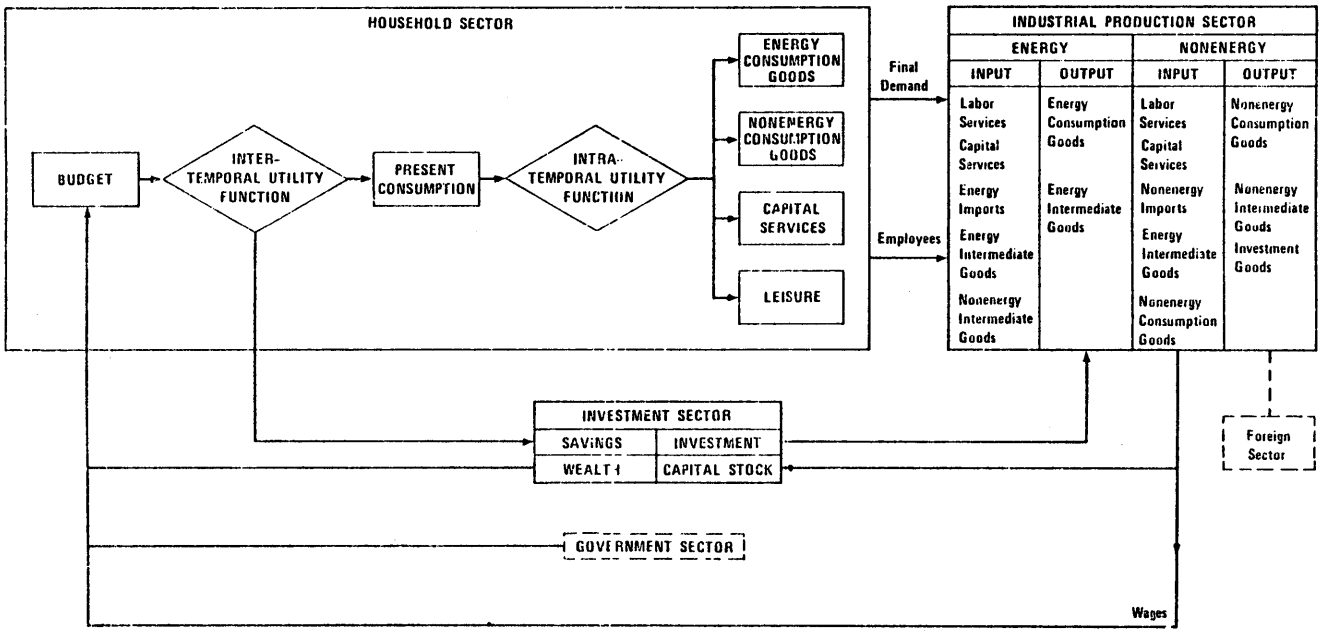

Figure 1—The Hnyilicza model structure

commodity world consisting of coffee and sugar. In general, the reader would be hard pressed to spell out his price-demand relationship for coffee. He would only be able to do so if he knew how much sugar he would be allotted. Thus we can speak of a demand curve for coffee *conditional* upon a particular consumption level of sugar. For this reason, it is somewhat artificial to characterize market equilibrium below in terms of a set of supply curves and demand curves.‡

Methodology of the model

Industrial production sector

The function of the production sector in the context of the larger model is twofold:

a. to determine an equilibrium factor input mix which is optimal (profit maximizing) for each industry in producing its total output;
b. to determine the total (equilibrium) output levels that meet the demands of the intermediate market *and* of the final goods market.

As we saw in Figure 1 and as we see in more detail in Figure 2 on the next page, we can think of the production sector as an input-output structure. We summarize this input-output structure in Table I.

‡ Nonetheless, it will be true that *if* we somehow knew the equilibrium quantities of all commodities, then we could sketch a set of conditional supply and demand curves whose points of intersection *do* constitute the market equilibrium. The problem of course is that one does not know the equilibrium in advance.

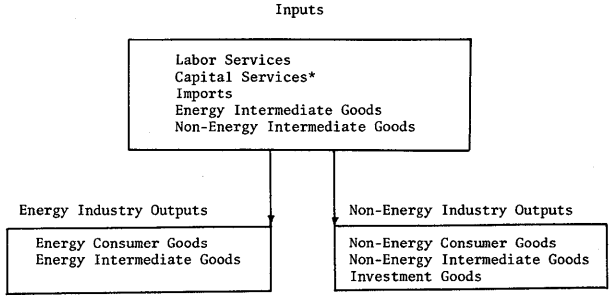
It is important to realize that even though we are speaking of production in "input-output" terms, the Hnyilicza model is not an input-output model in the classical sense of that term. Rather, it is a *generalized input-output* model. In such models the input-output (transactions) coefficients, rather than being given exogenously (as would be the case in the economy whose technologies permitted no substitutability among inputs), are *functions* of the prices of all inputs *and* the configuration of final demand. Specifically, we can write

$$a_{ij} = f(w,p,y,x)$$

where: w is the vector of input factor prices
p is the vector of output prices
y is the vector of final demands
x is the vector of gross outputs.

The *equilibrium* coefficients $\{a_{ij}^*\}$ that are implicitly solved for by the model designate the profit-maximizing

TABLE I



*Capital services are the annual services generated by existing stocks of capital goods. These services are provided to the productive process. "Capital goods" have a life exceeding one year, by definition, whereas "intermediate goods" are consumed by the production process within a year.

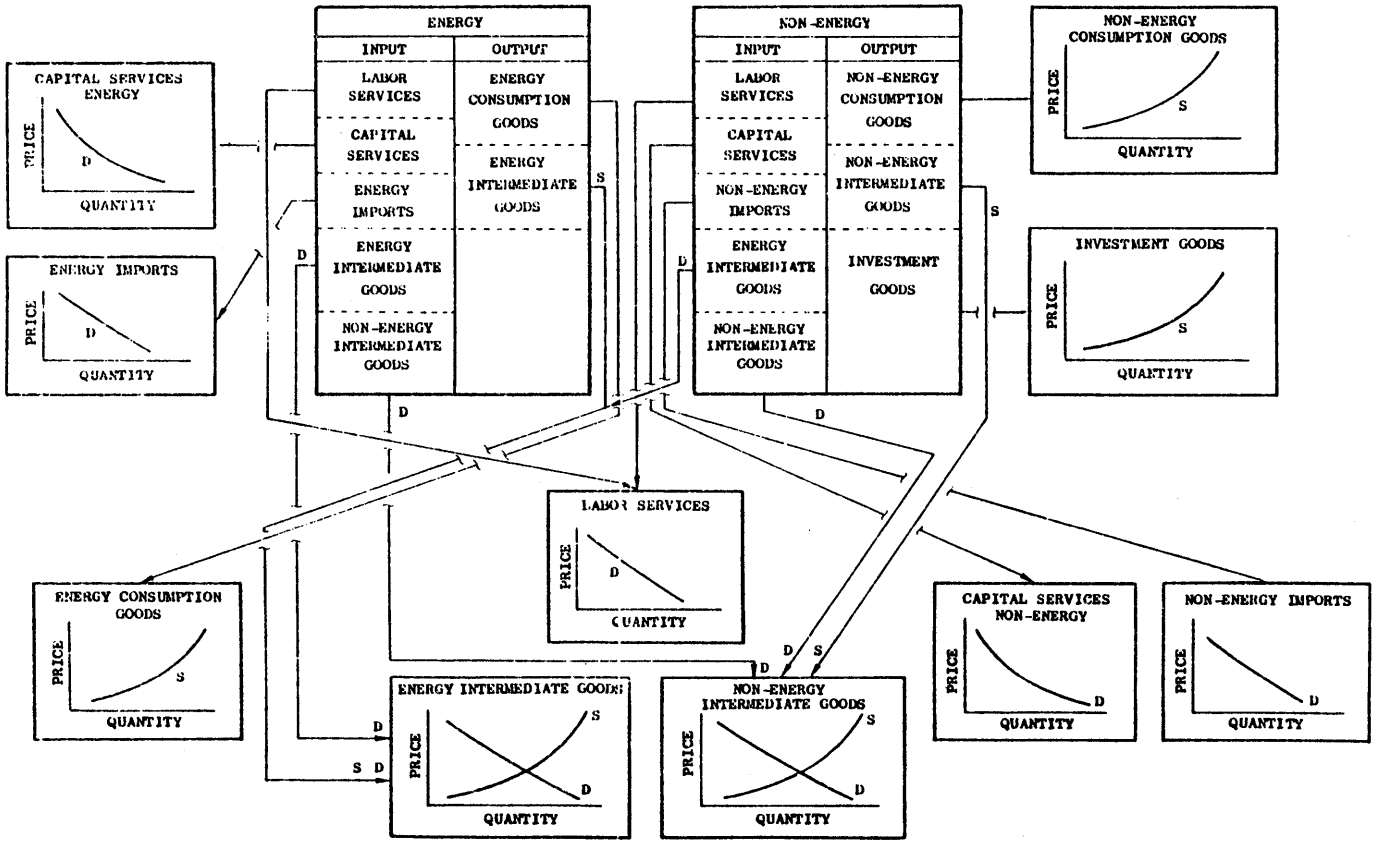


Figure 2—Industrial production sector

number of units of commodity i which are utilized in the production of each unit of commodity j. Let us now press towards a deeper understanding of what is going on in the production sector. A result of this will be an enhanced understanding of the equilibrium coefficients $\{a_{ij}^*\}$.

The most straightforward way in which to characterize what goes on in the production sector of the model is to depict the various supply curves and demand curves which are implicit in the equilibrium equations which characterize rational economic behavior on the part of the two industries: energy and non-energy.

The entrepreneur must make essentially two different types of decisions. He must decide upon a profit maximizing *level of output* of the commodities he manufactures; and he must decide upon a profit maximizing *mix of inputs* to be used in meeting his (optimal) production schedule.

Clearly his optimal choice of output levels and input mixes will be a function of the relative prices of outputs and inputs. Indeed, it is customary to speak of the relationship between the price of a given input and the quantity demanded by the entrepreneur at that price as the *derived factor demand curve* of the input (or "factor") in question. And the relationship between the optimal output level of a given output and the price of the output is summarized by the *supply curve* of the output.

With this in mind the reader is referred to Figure 2, where we identify the various derived demand curves and supply curves that are generated within the production sector. Let us summarize the information contained in the figure.

The derived factor demand curves and the supply curves

There is one derived factor demand curve for each input. Since both the energy and the non-energy sector use five inputs, there are therefore ten derived demand curves in all:

	Energy	Non-Energy
Demands:	Labor Services	Labor Services
	Capital Services	Capital Services
	Energy Intermediate Goods	Energy Intermediate Goods
	Non-Energy Intermediate Goods	Non-Energy Intermediate Goods
	Imports	Imports

The derived demand curves associated with these input demands are illustrated in Figure 2.

With respect to supply, the energy sector produces only two goods whereas the non-energy sector produces three

goods:

	Energy	Non-Energy
Supply:	Energy Consumption Goods	Non-Energy Consumption Goods
	Energy Intermediate Goods	Non-Energy Intermediate Goods
		Investment Goods

The associated supply curves are indicated in Figure 2.

An input-output interpretation

We are now in a position to give an interpretation to the equilibrium Input-Output coefficients $\{a_{ij}^*\}$. Note in Figure 2 that in two (and only in two) of the markets pictured there do we have well-defined supply and demand curves. This is the case in the markets for energy intermediate goods and non-energy intermediate goods. Suppose now that we could "complete" our description of the remaining eight markets by obtaining the missing supply and demand curves. (As will be seen, these missing curves are generated in the other two sectors of the model to which we shall turn shortly.) Suppose finally that we were to take note of the equilibrium point in these ten markets, that is, the equilibrium prices and quantities of the ten commodities.

It would then be straightforward to compute the equilibrium input-output coefficients either in dollar terms or in physical terms—using simple arithmetic. The collection of coefficients so obtained would coincide with the collection $\{a_{ij}^*\}$. That is, these are the equilibrium input-output coefficients associated with profit-maximizing behavior on the part of the industries with respect to the choice of input mix and the choice of output level.

The consumption sector

Figure 3 portrays the consumption sector in some level of detail. Looking at the top part of the figure it is clear that two things take place in the consumption sector model. First, an "intertemporal" utility function determines a utility-maximizing split between present and future consumption. This utility function is an econometrically estimated function of:

Time
Interest rate
Existing wealth
Wage rate
Government payments to household (e.g., welfare)

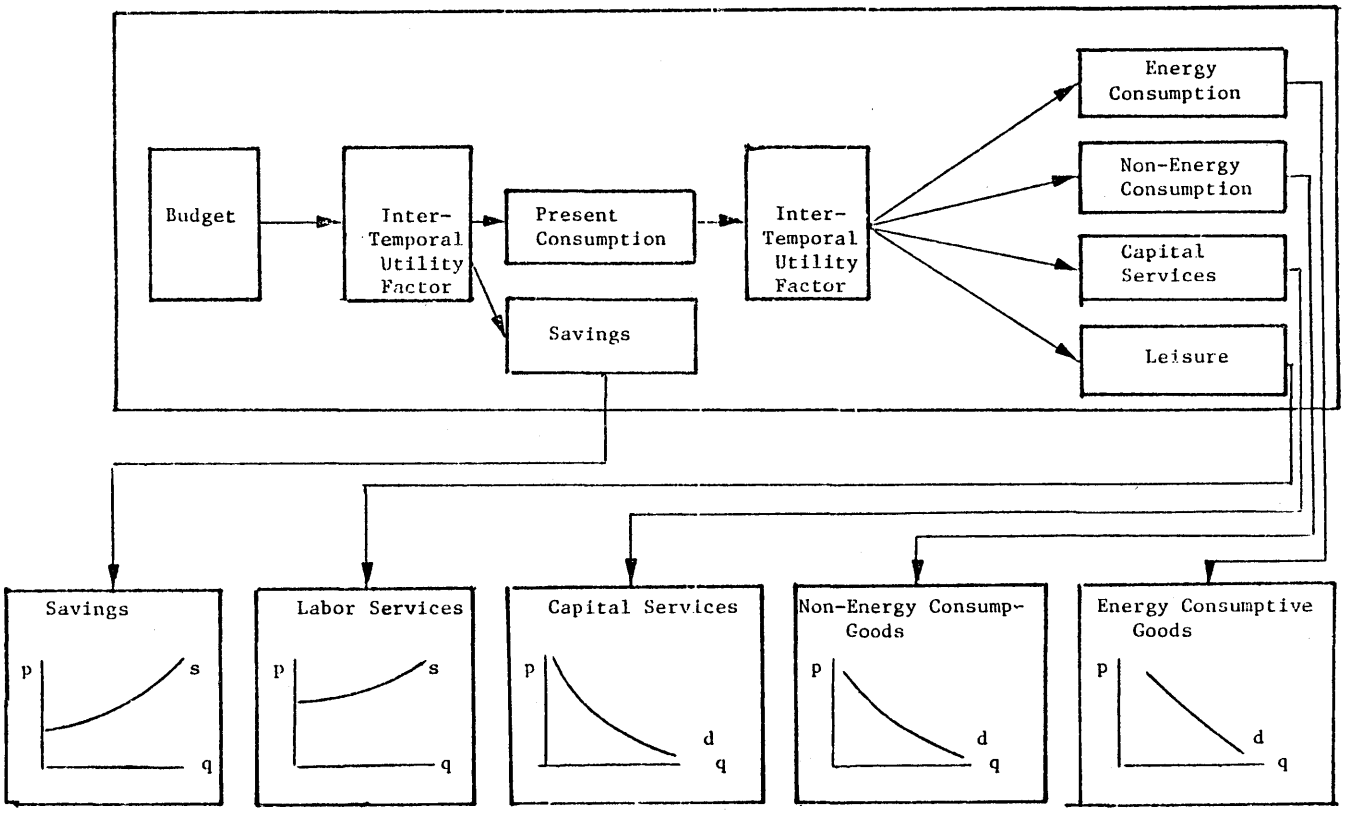

Figure 3—The household sector

Second, an "intratemporal" utility function determines the split *within* a given period of household expenditures between the four consumption goods, namely energy consumption goods, non-energy consumption goods, capital services, and leisure. By capital services we mean the annualized value of the services which flow from consumer durables or residential stock. The intratemporal utility function which performs this split is an econometrically estimated function of price, the level of consumption of each good, and time.

A supply and demand curve interpretation

A deeper understanding of the consumption sector can be obtained by considering the supply and demand curves which are implicit in the equilibrium equations characterizing utility-maximizing behavior on the part of the household. These price-quantity relations are shown in the lower portion of Figure 3. Interpretation of all of these curves is straightforward with the exception of the supply curve of labor services. This curve is in fact the inverse of the demand curve for leisure services. As the wage rate increases, leisure becomes more expensive. Work is substituted for leisure, which increases the supply of labor.

Investment and capital accumulation

Formally speaking, the investment sector is part of the production sector. Nonetheless, it is useful to isolate it as a separate sector for the purposes of enhancing an understanding of capital accumulation in the Hnyilicza model. The situation is pictured in Figure 4. Consider the upper part of the figure. The supply of new investment goods that come on stream in a given year t appears on the left. Next, the supply of new investment goods is split three ways into the shares of investment goods going to the energy, non-energy, and domestic sectors. This split is realized by the use of a multiplier which reflects historical ratios in the apportionment of investment goods.

Moving further to the right, we add in the depreciated value of capital stock for the respective sectors. These are the values of stocks at the end of the *previous* year. The result of this addition is the *current level of capital stock.*

Moving yet further to the right in Figure 4, the values of the current level of capital stock in the two industrial sectors are multiplied by the efficiency of capital. The result of this operation is defined to be the *level of capital services* in period t.

We exhibit the current supply of capital services generated in this fashion within each of the two industries as two supply curves. The reader will note that these supply curves are perfectly inelastic. The reason for this is that the level of capital services is not a function of any current prices. One might think that this level would be a function of the current price of new investment goods. This is not the case, for in this model there is a one period *lag* between the time when capital goods are produced and the time when they begin to generate capital services. The investment goods which come "on stream" in year k and which appear in the upper left of Figure 4 were actually produced in year $(k-1)$.

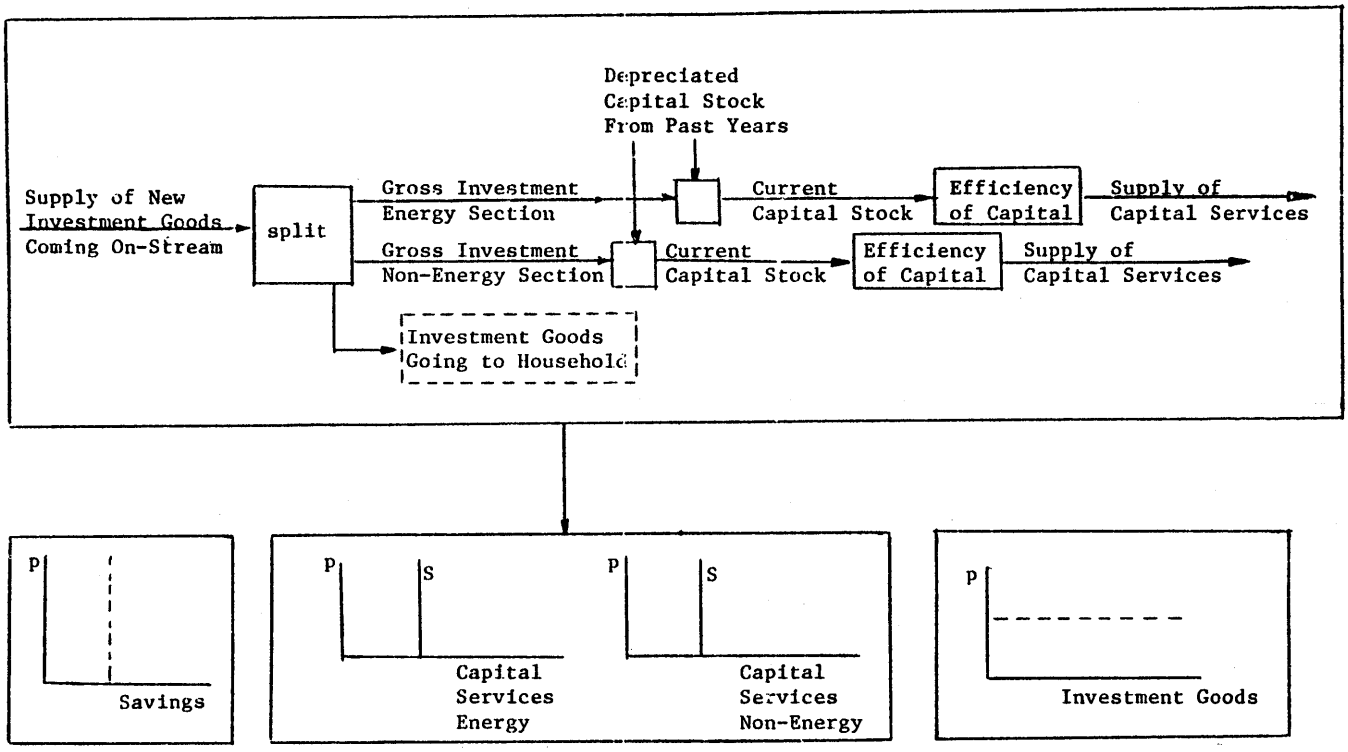

Figure 4—Investment sector

Two other price-quantity curves appear in the figure. First, there is a demand curve for investments goods. This demand curve is seen to be perfectly elastic. Moreover, it appears as a dashed line. Why? We have used a dashed line to indicate that this demand curve is an artificial construct. For in the Hnyilicza[2] model, the (equilibrium) level of investment goods is, in fact, "supply-determined." Whatever quantity of investments goods is supplied is *assumed* to be absorbed—irrespective of own price. It is for this latter reason that the curve appears as perfectly elastic.

In point of fact, it is possible to introduce a demand *function* for investment goods in the Hnyilicza model. For one of the basic equilibrium conditions of the model is that investment equals income minus consumption. [This equilibrium condition is imposed on the model.] Consumption, in turn, is a function of income and of the price of labor, capital, etc. Thus, the demand for investment goods is indeed a function of "prices" in the Hnyilicza model. Our point above is simply that it is not helpful to characterize a market of investment goods *per se,* and to plot the demand for investment goods as a function of the price for investment goods. For, as we said above, whatever quantity of investment goods is produced is assumed to be demanded.

Last of all, there is a demand curve for savings. This appears as a dashed vertical line. Why? The reason for this is that there is no "demand curve" for savings *per se* in the model. Rather, savings is *assumed* to equal investment. Once again, just as in the case of the demand for investment goods above, it is possible to assert that there is a demand *function* for savings embedded in the Hnyilicza model. For the so-called "static equilibrium condition" of this type of growth model is that savings equals income minus "desired" consumption. This relationship is imposed on the model, and serves to relate industry demand for savings to consumption and hence to relative prices, since consumption depends in part on prices.

The reader who finds the rather arbitrary treatment of investment and savings perplexing should be aware of the motivation for the static equilibrium conditions such as "Savings=Investment" that are imposed on the model. The rationale for these assumptions is simply to insure consistency between the aggregate savings decisions by individuals on the one hand, and the aggregate investment decisions of producers on the other hand. There would be no *need,* in principle, for imposing static equilibrium conditions if the model included a full set of futures markets, and if an equilibrium set of prices and quantities across time were computed simultaneously, as is the case in the SRI model. Of course, to point this out is not to make a value judgment about the quality of the SRI model versus the Hnyilicza model, since the emphases of the two models are different.

General equilibrium in the Hnyilicza model

Figure 5 shows the result of collecting together the various supply and demand curves that we have extracted from the production sector, the consumption sector, and the investment sector. The point of intersection of all of these curves coincides with the equilibrium prices and quantities that Hnyilicza's fifty-five simultaneous equations are solved for. We can thus interpret equilibrium in terms of supply-demand balance in the following markets:

1. Capital Services to the Energy Industry
2. Capital Services to the Non-energy Industry
3. Labor Services
4. Energy Imports
5. Non-energy Imports
6. Energy Consumption Goods
7. Non-energy Consumption Goods
8. Energy Intermediate Goods
9. Non-energy Intermediate Goods
10. [Investment Goods]
11. [Savings]

Time-series projections of these equilibrium prices and quantities are the principal outputs of the Hnyilicza model. The following variables are exogenous to the model and are required as inputs:

- Inventory investment
- Labor force
- Tax rates
- Government expenditures
- Exports
- International financial claims
- Government transfer payments (e.g., welfare)
- Rate of unemployment
- Import prices
- Rate of replacement of capital stock
- Initial year private national wealth
- Initial year capital stock
- Quality of capital (a constant, multiplied by capital stock to give capital services)

A note on the new version of the Hudson-Jorgenson model*

Hudson and Jorgenson have recently reworked their original model. Their new model is very similar to the Hnyilicza model, especially as regards the use of the variable coefficient input-output methodology in an economic equilibrium context. Where the two models differ is in the degree of disaggregation of the production sector. As we saw, the Hnyilicza model's production submodel consisted of two sectors: energy and non-energy. The Hudson-Jorgenson production submodel consists of six sectors:

- Coal
- Crude petroleum
- Refined petroleum products
- Electricity
- Natural gas (crude)
- Delivered gas

* The author is grateful to Dr. Edward Hudson for a helpful discussion.

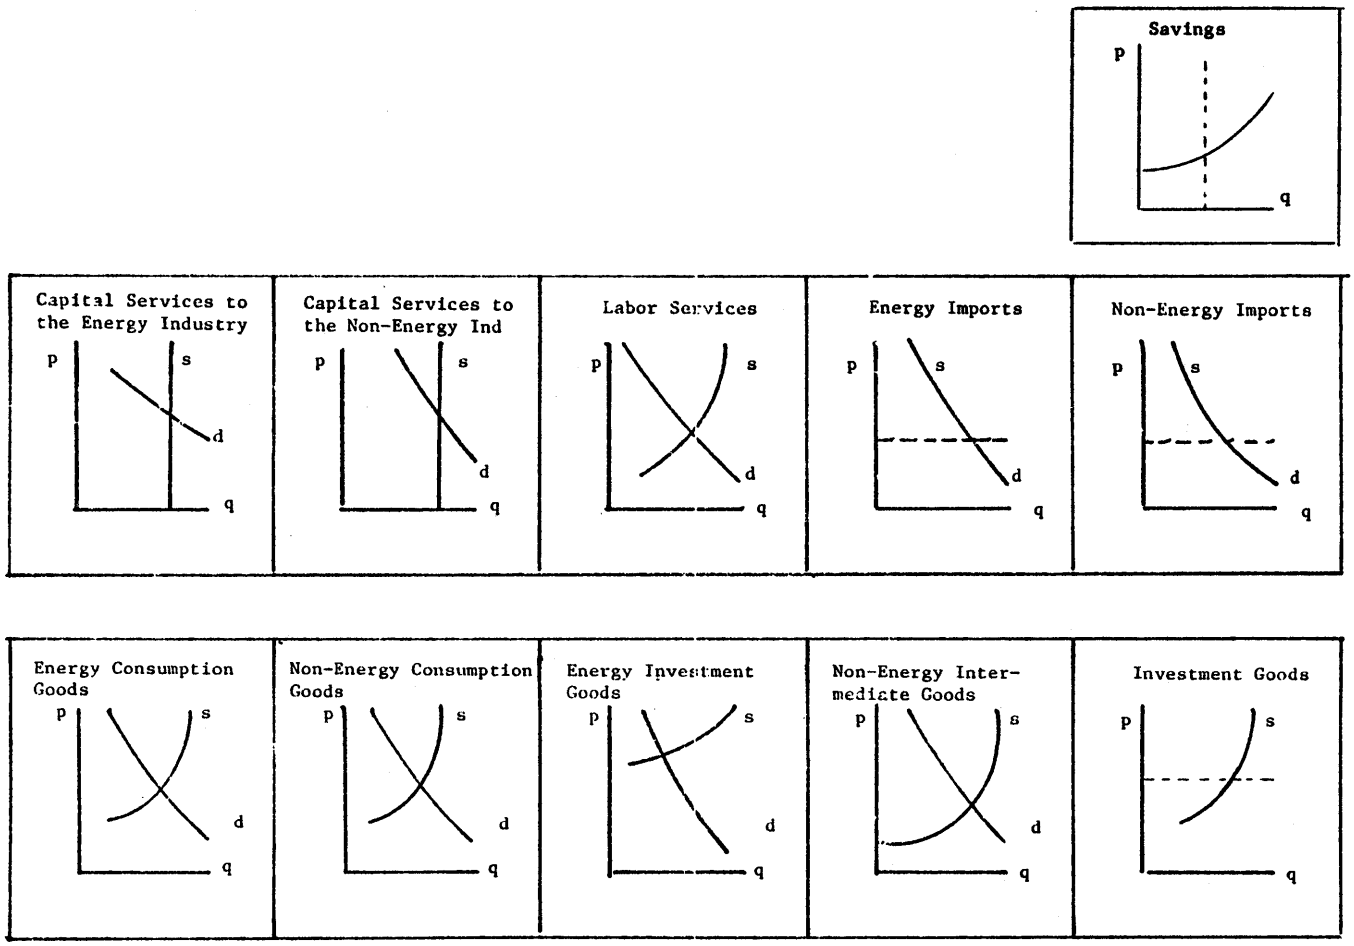

Figure 5—Summary of markets in the Hnyilicza model

THE SRI NATIONAL ENERGY MODEL

Introduction

The SRI National Energy Model is an economic equilibrium model of the U.S. energy system covering all major fuels from primary resources to end use energy consumption (i.e., energy service demands) over the period 1977 to 2025. The model is regionally disaggregated with nine demand regions (such as New England), twenty primary resource supply regions (such as Alaska North Slope), and 600 transportation and distribution links. Conversion technologies such as coal gasification, crude oil refining, and electric power generation by type of fuel are explicitly modeled. The model computes regional prices and quantities of all energy forms, as well as energy technology requirements over the period of 1977 to 2025 by balancing supply and demand.

The SRI model differs in several important respects from the models considered in the previous section. To begin with, the Hudson-Jorgenson and Hnyilicza models are highly aggregated models of the overall economy. In contrast to this, the SRI model is a very disaggregated and detailed model of the energy sector of the U.S. economy. All this detail can be represented graphically by means of a "spatial network." We shall discuss this network just below. Above and beyond this, the SRI model makes use of a different methodology. While the model is an economic equilibrium model in the sense that it determines prices and quantities which are in supply-demand balance,—just as the other models do—it does not make use of the "translog" methodology. There are no variable input-output coefficients. Rather, economic equilibrium is characterized in a much more direct manner. One solves *directly* for prices and quantities which are in balance. Moreover, we can visualize "equilibrium" in this model in terms of a supply-demand balance *at each point* in the spatial network referred to above.

Partly for this reason, we shall start off by discussing the spatial energy network which lies at the heart of the model. Next we shall describe what is meant by "equilibrium" in this context. Finally, we shall gain a deep understanding of the model by analyzing the algorithm used to achieve a supply-demand balance throughout the network.

A spatial network representation of the energy market

The essence of the SRI model is a spatial network representation of the energy system. In the network, the major elements of the U.S. energy system—from the primary resource supplies through the end use energy demands—are described in relationship with each other. A sample energy network is shown in Figure 6. In this figure, the resource supply curves are at the bottom; the usable energy demand curves are at the top. Between these curves is the network describing the entire energy system. The current network has about 2400 materials, processes, and transportation links. A *material* is a primary resource product, or usable energy form *at a specific location*. A material is represented by a *node* in Figure 6. A *process* represents a sector of the energy industry such as coal mining or gasification at a specific location or a class of consumers using a particular energy-consuming device. A *transportation link* represents the process of moving a material from one location to another.

To get a sense of the many paths in the network, consider first the path where coal is mined, converted into synthetic (high Btu) gas, piped to a demand center in a demand region, distributed to industrial users, and consumed as boiler fuel to produce steam. The same end use market could be supplied by coal transported by unit train, distributed to the same industrial users, and used in a coal boiler to produce steam. These two paths can be traced in Figure 6. In the SRI National Energy Model, there are 24 end uses (such as industrial steam) in each of the nine demand regions, and thirty primary resource supplies (such as coal) in the various resource basins. The alternative conversion technologies in the model include all important types of electric power generation (in base, intermediate, and peak load applications), crude oil refining, coal gasification, methanol from coal, hydrogen production from coal, transportation, distribution, and end use conversion.

The model explicitly considers the evolution of the energy system through time—it calculates prices and quantities in a number of time periods. It is important to recognize that the solution to this "dynamic" model is not equivalent to using a "static" model in each of the time periods. Rather,

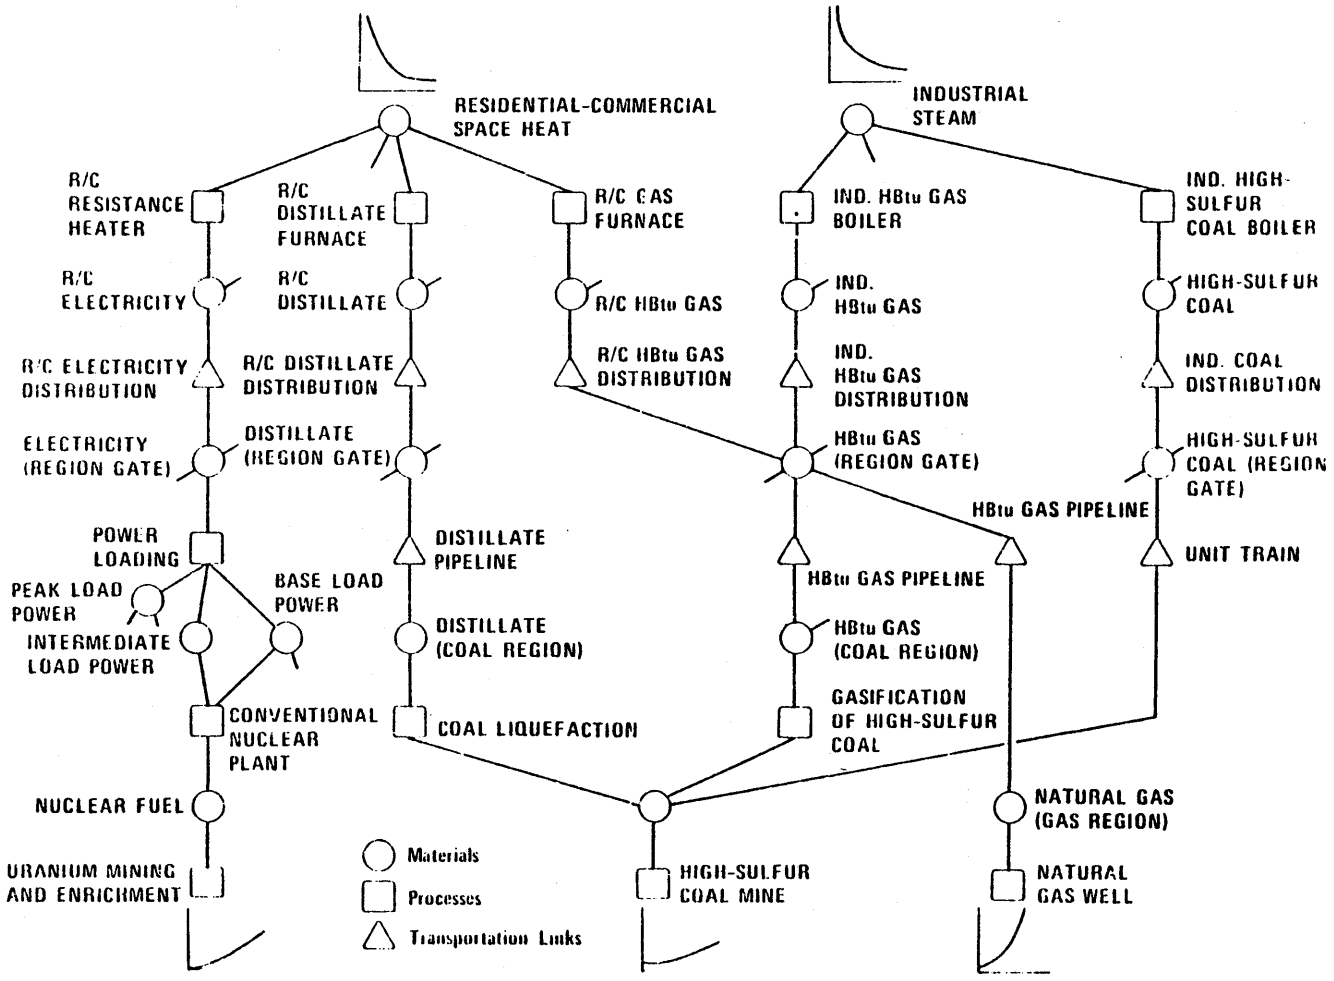

Figure 6—Example of elements of the energy model

the prices and quantities in each period are described by equations interrelating both past and future prices and quantities.

On the meaning of economic equilibrium in the SRI model

In their earlier research, Brock and Nesbitt[3] have drawn upon economic theory to establish the following results concerning economic equilibrium in spatial networks:

1. There exists an *aggregate demand curve* and an *aggregate supply curve* at every *material node* (circle) in the network;
2. There exists a supply curve and a demand curve on every *link* in the network. Any such pair characterizes the supply/demand conditions governing the behavior of the (unique) conversion or transportation process attached to the link.

The *equilibrium prices and quantities* are those for which all *aggregate* supply/demand curve pairs are simultaneously balanced at all material nodes; or *equivalently* for which *all* supply/demand curve pairs are balanced on all the links of the network.

The operation of the model

The SRI model is best described in terms of the algorithm used to solve for equilibrium, and in terms of the relationship of the algorithm to the spatial network and its components. Therefore, in this section we shall describe the algorithm in considerable detail. When we say that this algorithm "solves" the spatial network we simply mean that it determines the set of equilibrium prices and quantities which obtain at each point (link and node) in the network.

The algorithm consists of four essential steps which are repeated at each iteration. The procedure is illustrated at a fairly abstract level in Figure 7. Beginning with an initial "guess" at the equilibrium quantity q_{k-1}, the four steps of the algorithm are:

1. To apply (inverse) resource supply function*

   $p_k = S^{-1}[q_{k-1}]$

2. To proliferate prices up the network (supply function transformation)

   $p_{k+1} = T_s[p_k]$

3. To apply usable energy demand function

   $q_{k+1} = D[p_{k+1}]$

4. To proliferate quantities down the network (demand function transformation)

   $q_{k+2} = T_D[q_{k+1}]$

* An inverse supply function expresses price as a function of quantity.

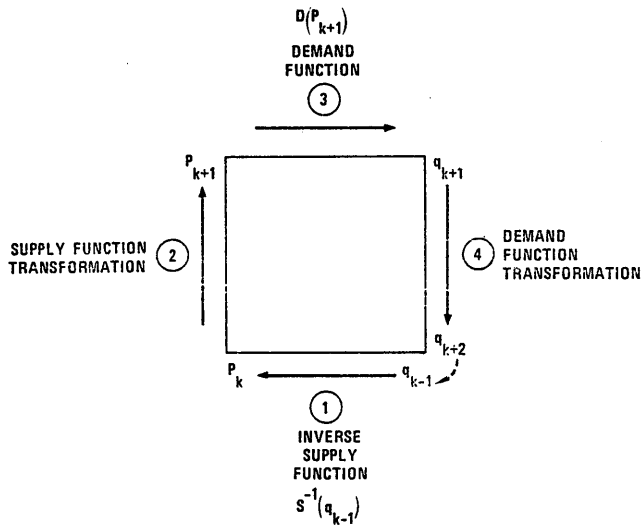

Figure 7—SRI model algorithm

We will now discuss each of these four steps in some detail, and in a less abstract manner.

1. *Inverse Supply Function:* In the first step of the algorithm, the inverse supply function describing each of the primary resources at the *bottom* of the network in Figure 6 is applied. The algorithm begins with a "guess" at the pro-

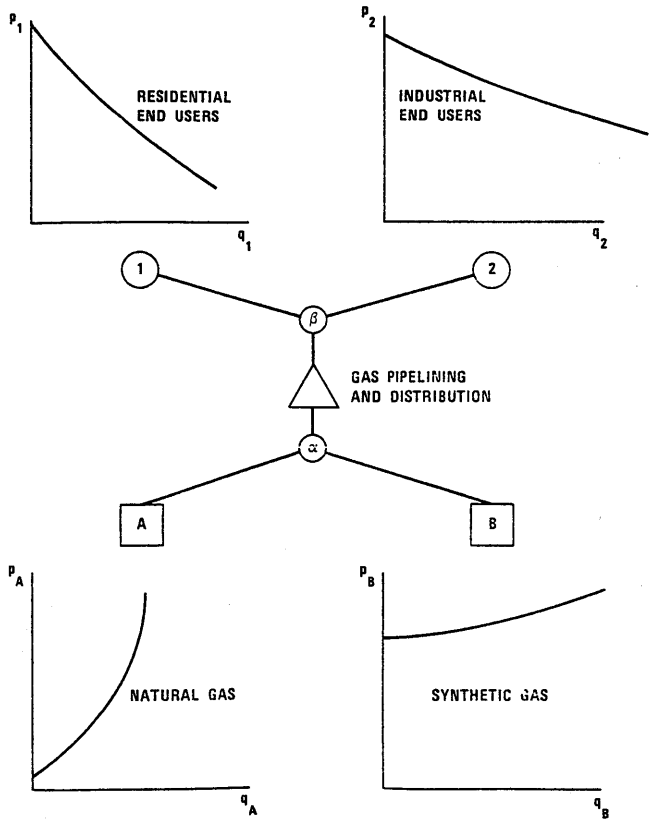

Figure 8—Illustrative gas network

duction level over time for each of the primary resources (denoted $q_{k-1}(t)$ as in Figure 7, where the t denotes a vector over time).

Using the guess $q_{k-1}(t)$, the inverse supply function is applied to give $p_k(t)$, the price of the corresponding primary resource. Schematically, Step 1 is given by

$$p_k(t)=S^{-1}[q_{k-1}(t)]$$

The inverse supply functions are given exogenously, one for each primary resource.

The first step of the algorithm is to guess initial quantities $q_A{}^0$, $q_B{}^0$ of natural gas and synthetic gas respectively and, using the natural gas and synthetic gas supply curves, to calculate the corresponding prices $p_A{}^1$ and $p_B{}^1$ for natural and synthetic gas. These prices apply at the process boxes A and B in Figure 8.

2. *Supply Function Transformation:* In the second step of the algorithm, the intermediate technology submodels are used to compute product prices given input fuel prices.

The technology models begin by assuming that the measure of profitability to a firm which builds a unit of capacity at time t is given by the net present value of the cash flow generated by that unit of capacity:

$$NPV(t)=-c(t)+\sum_{T=t}^{t+L}\frac{p(T)-\phi(T)}{(1+r)^{T-t}}$$

where

$c(t)$=capital cost of the new unit of capacity built at time t;
$p(T)$=product price at time T;
$\phi(T)$=operating cost (including fuel cost) at time T;
r=discount rate (cost of capital)
L=life of technology.

In order to simplify our discussion, we will assume that technologies have a useful life of three years ($L=3$) and that we wish to consider the interrelationship of prices over a three-year time horizon.

It is known from elementary economic theory that at equilibrium, profit maximizing firms earn zero profit. Expressed in terms of net present value, the zero profit assumption is equivalent to:

$$NPV(t)=0 \qquad t=1,2,\ldots$$

where we have assumed that the cost of debt and equity capital are included in the discount rate r. Assuming $NPV(t)=0$ for new plants built in Years 1, 2, and 3, we can write:

$$c(1)=p(1)-\phi(1)+\frac{p(2)-\phi(2)}{1+r}+\frac{p(3)-\phi(3)}{(1+r)^2}$$

$$c(2)=p(2)-\phi(2)+\frac{p(3)-\phi(3)}{1+r}+\frac{p(4)-\phi(4)}{(1+r)^2}$$

$$c(3)=p(3)-\phi(3)+\frac{p(4)-\phi(4)}{1+r}+\frac{p(5)-\phi(5)}{(1-r)^2},$$

which interrelates the equilibrium prices (and, of course, the capital and operating costs and the discount rate). If the firm which is trying to decide whether to add new capacity at time $t=3$ *knew* with certainty what future prices [$p(4)$ and $p(5)$] and future operating costs [$\phi(4)$ and $\phi(5)$] would be, it could, by rearranging the third equation above, calculate the minimum price in Year 3, $p(3)$, below which it would not add capacity and above which it would add more capacity.*

$$p(3)=\phi(3)+c(3)-\underbrace{\frac{p(4)-\phi(4)}{1+r}-\frac{p(5)-\phi(5)}{(1+r)^2}}_{\text{capital charge}}$$

Knowing $p(3)$, $\phi(3)$, $p(4)$, and $\phi(4)$, the second equation of the above three can be used to solve for $p(2)$. A similar calculation gives $p(1)$.

To summarize, for each technology, given the fuel prices (contained in $\phi(t)$), given assumptions about prices and operating costs past the end of the model horizon, and given process economic data ($c(t)$ and $\phi(t)$), product prices are calculated recursively backward in time

$$p(3),\ p(2),\ p(1)$$

as indicated above. When we arrive at the top of the network, we will have calculated the prices $p_{k+1}(t)$ in Figure 7. We have denoted this upward proliferation of prices by using the notation $p_{k+1}(t)=T_s[p_k(t)]$.

Returning to Figure 8, Step 2 of the algorithm involves taking the prices $p_A{}^0$, $p_B{}^0$ (and the quantities $q_A{}^0$, $q_B{}^0$) and determining the corresponding prices $p_1{}^0$, $p_2{}^0$ at the top of the network. The first step is to compute the average price of gas entering the pipeline at α in Figure 8 as follows:

$$\bar{p}=\frac{p_A{}^0q_A{}^0+p_B{}^0q_B{}^0}{q_A{}^0+q_B{}^0}$$

The price of gas delivered to the two end users (i.e., to β in the figure) and would simply be

$$p_1{}^0=p_2{}^0=\frac{\bar{P}}{e}+c.$$

3. *Demand Function:* The third step in the algorithm is to apply the direct demand function at the top of the network using the prices $p_{k+1}(t)$ computed on the way up in Step 2. That is, an estimate of demand is obtained by applying the demand function

$$q_{k+1}(t)=D[p_{k+1}(t)].$$

Returning to Figure 8, this step of the algorithm involves taking the price $p_1{}^0$ of residential gas determined by Step 2 and finding the residential demand $q_1{}^0$ at that price using the residential demand curve. A similar procedure yields the industrial demand $q_2{}^0$ corresponding to the industrial gas price $p_2{}^0$ determined in Step 2.

4. *Demand Function Transformation:* In the fourth step of the algorithm, the technology submodels are used to compute fuel requirements given product demands, and market share submodels are used to divide demand among compet-

* Equilibrium would obtain at the price $p(3)$ itself because the firm would just be indifferent between adding and not adding capacity.

ing technologies based on the price computed for those technologies in Step 3. We will discuss both calculations briefly.

First, each technology is characterized by a thermal efficiency $e(t)$ for new units built at time t and thus by an average efficiency $\bar{e}(t)$ for all plants in place at time t. Hence, the fuel required is given by

$$q_{k+2}(t)=q_{k+1}(t)/\bar{e}(t).$$

Second, if the quantity $q_{k+2}(t)$ is to be split among a number of competing suppliers, a "market share" model is applied to the quantity $q_{k+1}(t)$ to split it among competing supply technologies based on the prices computed for those technologies in Step 2. We do not have space enough to discuss this market split model here.

This step of the algorithm is better explained in terms of the network in Figure 8. Referring to that figure, the fourth step of the algorithm actually consists of two operations. First, the residential and industrial quantities $q_1{}^0$ and $q_2{}^0$ respectively determined in Step 3 are added to give the total demand for gas $\bar{q}=q_1{}^0+q_2{}^0$ at β in the figure. In order for the pipeline to deliver $\bar{q}$ units of gas at β, it must take in $\bar{q}/e$ units of gas at α, where e is the thermal efficiency of the pipeline, including transportation losses.

Given the demand $\bar{q}/e$ of gas at α, we then apply the market share model to compute how much of that gas would be synthetic and how much would be natural at the prices $p_A{}^0$, $p_B{}^0$ determined in Step 2. That is, we would compute

$$q_A{}^1=MS_A(p_A{}^0, p_B{}^0)\times\bar{q}/e$$

$$q_B{}^1=MS_B(p_A{}^0, p_B{}^0)\times\bar{q}/e$$

where $MS_A(p_A{}^0, p_B{}^0)$ is the fraction of the demand that would be satisfied by Process A (natural gas) if the prices of natural and synthetic gas were $p_A{}^0$ and $p_B{}^0$ respectively, and similarly for Process B.

Characterization of equilibrium in the network

If $q_A{}^1\cong q_A{}^0$ and $q_B{}^1\cong q_B{}^0$ equilibrium has been achieved (recall that $q_A{}^0$ and $q_B{}^0$ were our initial guesses in Step 1). If not, we return to Step 1 with the new guesses $q_A{}^1$ and $q_B{}^1$, and repeat the four steps, as many times as necessary to achieve equilibrium.

THE ROLE OF ECONOMIC MODELS IN NORMATIVE POLICY ANALYSIS

We shall conclude the present essay by issuing some precautionary remarks about the role of economic models in normative public policy analyses. The interested reader will find an elaboration of these remarks in Chapter I of Brock and Nesbitt.[3]

It must be appreciated that the models discussed in this report are economic in nature. That is, their aim is to project *prices* and *quantities* of energy (and, sometimes, non-energy) commodities. Yet normative policy analysis is interested not only in the *economic* dimension of alternative policies, but also in the *political* and the *ethical* dimensions.

For example, a policy maker might well wish to have at least probabilistic information about the likely price/quantity impacts of pursuing alternative strategies. For an example of this, see the companion paper presented by Dr. Steven N. Tani. Tani points out how price quantity data generated by an energy model can be used to make economic welfare judgments about alternative policies by means of the criterion of "net social surplus." This is important—indeed, it is far the most important role of strictly economic models in *normative* policy analyses.

But the same policy maker might also wish to know the political implications of pursuing alternative strategies. For example, a policy which looks good on economic grounds may for various reasons be "politically unacceptable." Game theoretic models can in principle be used to determine which policies are politically acceptable in a balance-of-power sense. But economic equilibrium models are not game theoretic models, and should not be confused as such.

Finally, there are the distributional concerns which are central to normative ethics. Economic planning models in and of themselves cannot furnish us with the answer as to which policy is most "fair." President Carter has repeatedly emphasized his concern with equity. But in this matter we have a problem for ethics—not for price/quantity models.

While these points may seem too obvious to need explicit statement there is often confusion about the proper role of economic data in normative policy analysis. For this reason, we felt it worthwhile to close with a reminder. There is one other important limitation to economic models of the kind reviewed above. This concerns the use of an "equilibrium" methodology in the context of regulated commodities such as natural gas. Many problems of interpretation arise here; but they are outside the scope of the present paper.

Decision analysis of the synthetic fuels commercialization program

by STEVEN N. TANI
SRI International
Menlo Park, California

INTRODUCTION

In his State of the Union Message in January 1975, President Gerald Ford called for the accelerated development of U.S. energy technology and resources and proposed a comprehensive set of energy supply and conservation measures to reduce U.S. requirements for imported oil. As one of these measures, the President proposed a federal incentive program whose goal would be the commercial production of one million barrels per day of synthetic fuels by 1985. In such a program, the Federal Government would provide suitable financial and regulatory incentives to stimulate private sector investment in commercial-scale plants to convert coal, oil shale, and other relatively abundant domestic resources into clean liquid and gaseous fuels. It was generally believed that without such incentives, industry would be unlikely to undertake the large risks of synthetic fuel plant investments.

The benefits to be achieved by the synthetic fuels program would be the following:

1. An accelerated accumulation of experience and information on the technical, environmental, economic, and institutional aspects of commercial-scale synthetic fuel production for better-informed private sector investment decisions.
2. The development of an industry infrastructure to support subsequent expansion of the synthetic fuels industry.
3. Insurance against high world oil prices and against early depletion of domestic sources of conventional fuels.
4. Protection against the losses of an oil embargo.
5. Improvement in the U.S. international bargaining position.

These benefits, however, would be counterbalanced by the possible costs of subsidizing synthetic fuels relative to less expensive energy sources such as imported oil and other domestic resources and by the environmental and socioeconomic costs associated with rapid development of coal and oil shale reserves.

In response to the President's message, the Interagency Task Force on Synthetic Fuel Commercialization was formed to evaluate the economic and environmental costs and benefits of the program and to recommend to the President a program of appropriate size and scope. The Task Force was chaired by the Office of Management and Budget and included members from the Federal Energy Administration, the Environmental Protection Agency, the Departments of State, Commerce, and Treasury, the Council on Environmental Quality, and the National Science Foundation. We, in the Decision Analysis Group at Stanford Research Institute (now SRI International), were engaged to assist the Task Force in conducting an analysis of the program.

STRUCTURE OF THE ANALYSIS

The fundamental question addressed by this analysis was whether the U.S. should have a synthetic fuels commercialization program and, if so, how large the program should be. The Task Force defined four distinct program alternatives to be evaluated:

1. No Program—No federal funding of synthetic fuels commercialization but continuation of research and development.
2. Informational Program—A minimal program designed primarily to generate technical, environmental, and economic data on various resource-to-fuel conversion processes, with synthetic fuel production of about 350,000 barrels per day by 1985.
3. Medium Program—A program designed to generate more complete information on a wider range of processes and to meet the President's goal of 1,000,000 barrels per day by 1985.
4. Maximum Program—A program designed to achieve the greatest amount of synthetic fuel production in 1985 possible without causing major dislocations in the economy: 1,700,000 barrels per day.

The object of the analysis was to determine which of these alternatives would be of greatest net benefit to the nation as a whole, where net benefit includes both economic and noneconomic impacts.

We defined four components of net national benefit for the evaluation of the program alternatives: economic impact on consumers, economic impact on producers, embargo protection, and environmental and socio-economic impacts.

To measure the economic impact on consumers, we utilized the concept of consumer surplus. Consumer surplus is the difference between the value of a good to consumers and the amount of money they must pay for it. This is shown graphically in Figure 1. The demand curve, by definition, is the most consumers would pay for each unit of the good, which is the value of that unit. If the market price is p, then q units will be purchased. For every unit except the last one, the value of the good exceeds the price paid for it. The shaded area between the price line and the demand curve represents the total excess value the consumers receive from this good; this is called the consumer surplus.

In the case of the synthetic fuels program, it was felt that a demonstration that synthetic fuels could be produced cheaply, if achieved, would have the effect of holding down the price of imported oil. The resulting increase in consumer surplus would then be credited as a positive benefit of the program.

To measure the impact on producers, we used a concept analogous to that of consumer surplus—producer surplus. This is the difference between the amount producers receive for a good and their marginal cost of producing it. Clearly, producer surplus is directly related to the idea of profitability. Figure 2 shows producer surplus graphically. The supply curve represents the marginal cost of producing each unit of the good, which is the least amount of money the producers would accept for it. The shaded area between the price line and the supply curve is equal to the total producer surplus for that good.

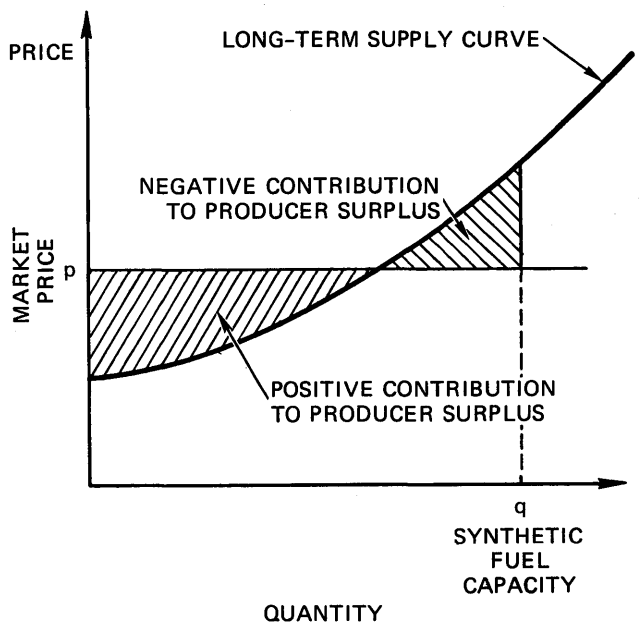

Figure 2—Producer surplus

We assumed in this analysis that synthetic fuel would be a substitute for imported oil. Therefore, if the cost of the synthetic fuels turned out to be less than the cost of imported oil, the industry would accrue positive producer surplus, which would be credited to the program as a benefit. How-

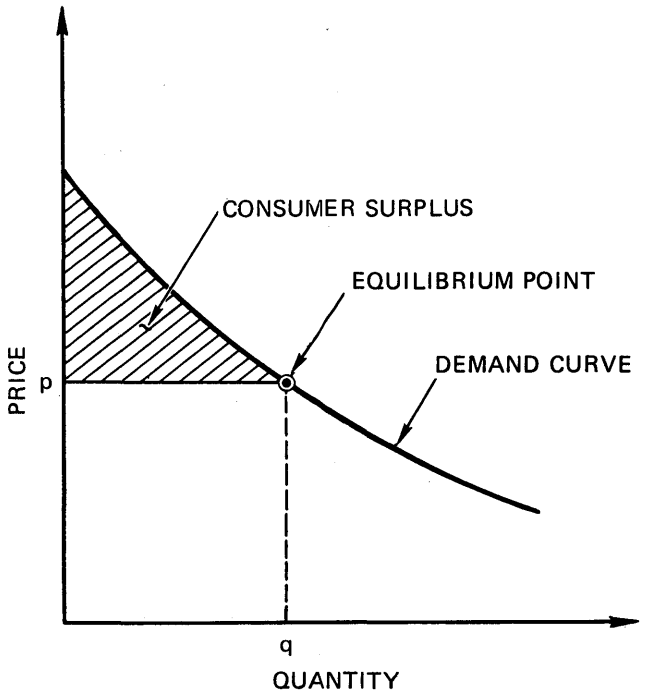

Figure 1—Consumer surplus

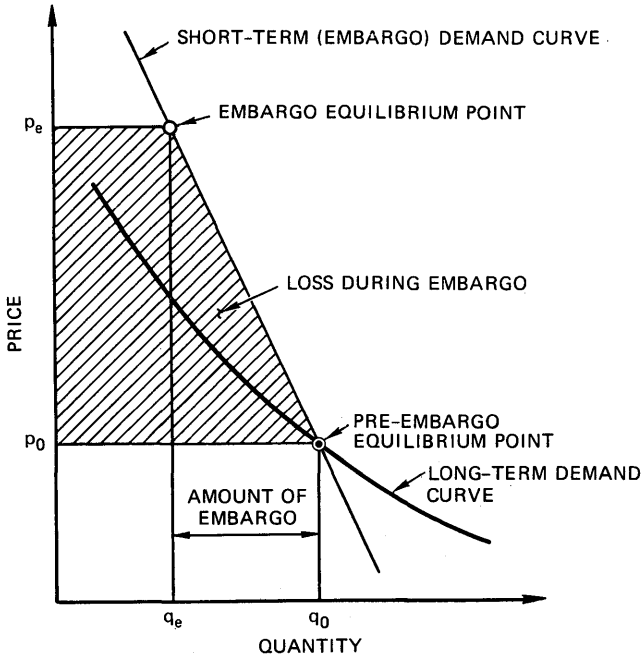

Figure 3—Embargo loss

ever, if synthetic fuels turned out to be costlier than imported oil, producer surplus would be negative and industry would require a subsidy from the government to cover its losses. The amount of this negative producer surplus would be charged as a cost of the program.

The algebraic sum of consumer and producer surplus is a measure of the total economic impact of the program on the nation assuming normal market conditions. However, it does not include the impact of the program in the event of an oil embargo. The situation during an oil embargo is illustrated in Figure 3. The pre-embargo price and quantity of oil are established on the long-term demand curve. If an embargo occurs, the quantity of oil available for consumption decreases abruptly. Because of short-term inflexibilities in consumption patterns, the marginal value (or shadow price) of oil is much higher than the long-term demand curve indicates. Here we use a linear short-term demand curve to show this effect. The economic cost of the embargo is the loss of consumer surplus during the embargo and is represented by the shaded trapezoidal area.

The synthetic fuels program, by providing a substitute for some of the imported oil, would reduce this embargo loss by increasing the amount of fuel available for consumption during the embargo. This reduction of embargo loss, weighted by the probability of occurrence of an embargo, is credited to the program as a benefit.

Finally, the synthetic fuels program would result in non-economic costs in the form of environmental damage (e.g., increased air pollution) and socio-economic disruption (e.g., "boom towns" near mining and conversion facilities). These costs, to the extent that they are not internalized in the producers' costs (e.g., pollution control costs), are charged to the program.

The sum of these four components of program impact is the measure of net national benefit we used in the analysis to evaluate the alternatives.

Clearly, to determine the net benefit of each program alternative, we need to know something about the energy supply and demand situation in the future. There was, of course, considerable uncertainty about the future energy picture, so we used probabilistic modeling techniques to quantify and incorporate the uncertainty in the analysis.

Figure 4 shows the decision tree structure that we ultimately developed for this analysis. We treated the dynamics in a simple manner by looking at three discrete time periods. In 1975, the government would make its program decision,

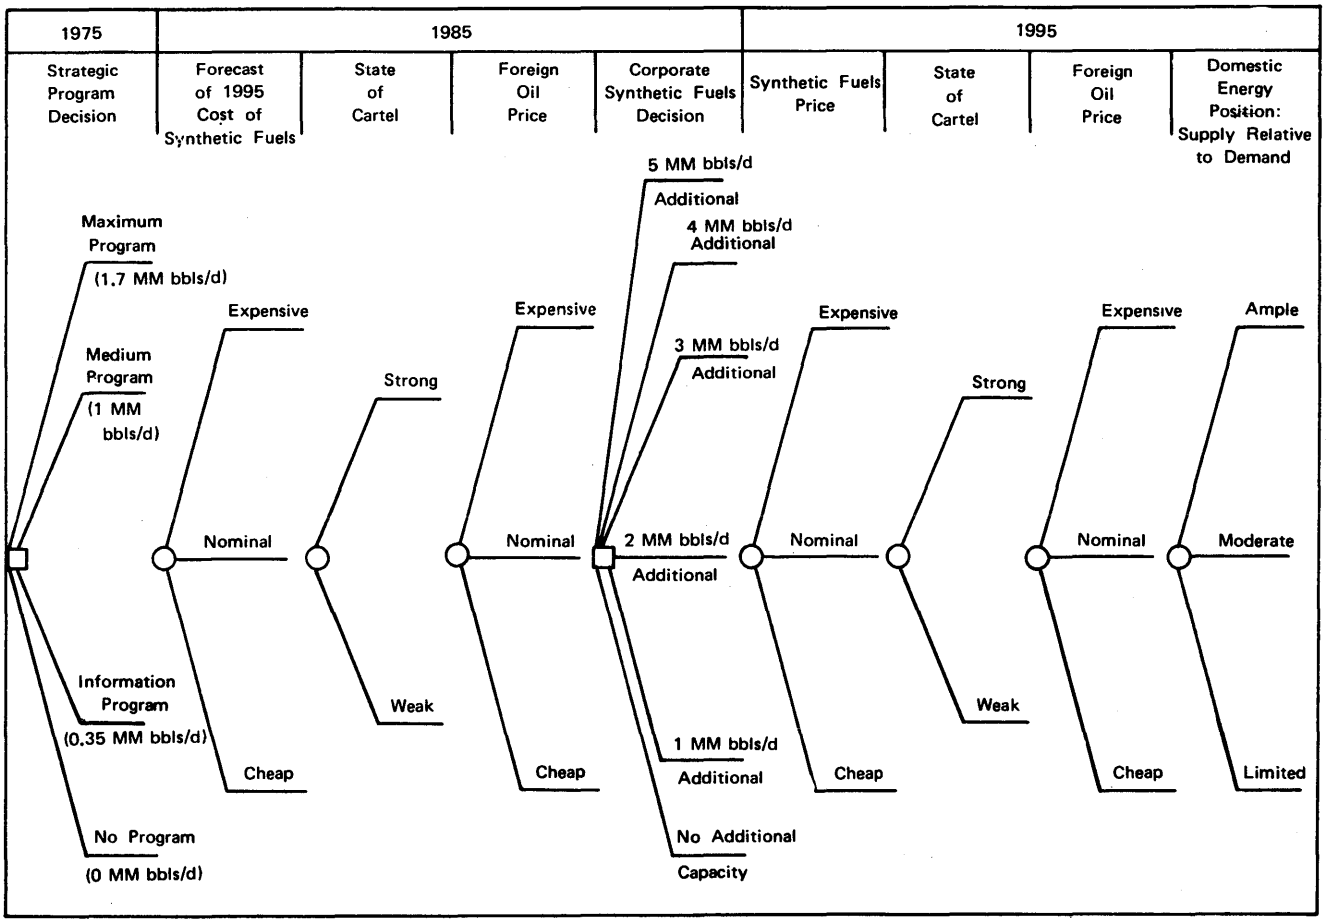

Figure 4—Decision tree

choosing one of the four alternatives. Then, in the mid-1980's, the program would result in information about the ultimate cost of synthetic fuels production. Based on this information and on the prevailing and projected price of imported oil, the industry would make its decision on further investment in synthetic fuel plants. The price of imported oil would, of course, depend on whether or not the oil producers' cartel remained effective in controlling prices. Finally, in the mid-1990's, when the new synthetic fuel plants are on-stream, the program impacts can be determined by looking at the cost of synthetic fuels, the price of imported oil, which again depends on the current state of the cartel, and the U.S. energy supply and demand balance.

The year 1985 was used to typify the decade of the 1980's and the year 1995 to typify the decade of the 1990's. Program cost and benefits were measured in constant 1975 dollars and were discounted in 1975 using a discount rate of ten percent.

The decision tree in Figure 4 shows how uncertainty was explicitly incorporated in the analysis. Uncertainty about each of the factors shown was quantified in the form of probabilities. Then, for each combination of factors, which defined a unique scenario of the future, both the probability of occurrence for that scenario and the discounted net national benefit associated with it were calculated. Finally, for each alternative, the *expected* net benefit was calculated by weighting the outcome of each scenario by its probability and summing. Note that the decision tree in Figure 4 defines 5,832 different scenarios for each of the four program alternatives.

The industry decision in 1985 of how much further investment to make in synthetic fuels plants required special treatment. While the government decision would be made on the basis of overall national benefits, the private sector decision would be made on the basis of corporate profits only. Therefore, in the analysis, the level of corporate investment that maximized expected future producers surplus was selected.

Figure 5 illustrates the techniques we used to quickly

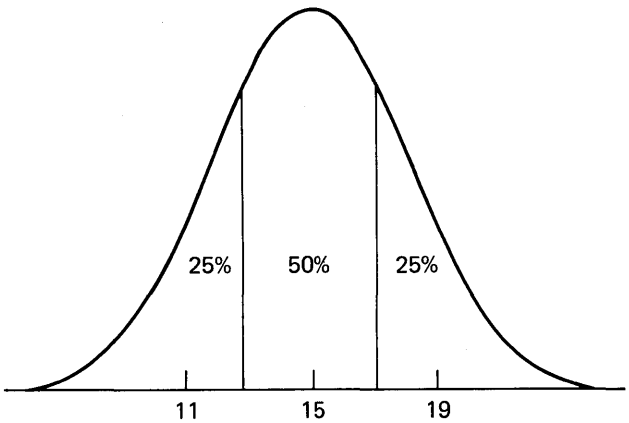

Figure 5—Simple encoding technique

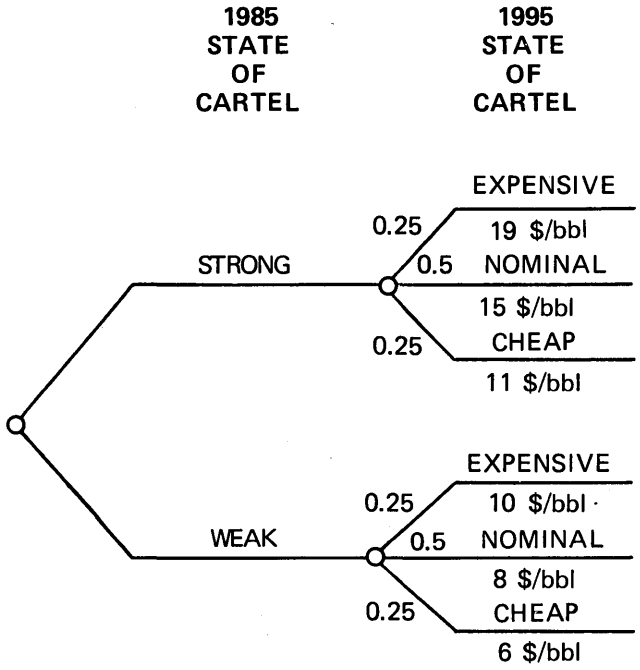

Figure 6—Probabilities of 1985 imported oil prices

encode uncertainty in the various factors. The probability distribution shown represents uncertainty in the 1985 imported oil price given that the cartel is strong. According to this distribution, it is equally likely that the price will be above or below $15 per barrel (the median value). Also, there is a ten percent chance that the price will be below

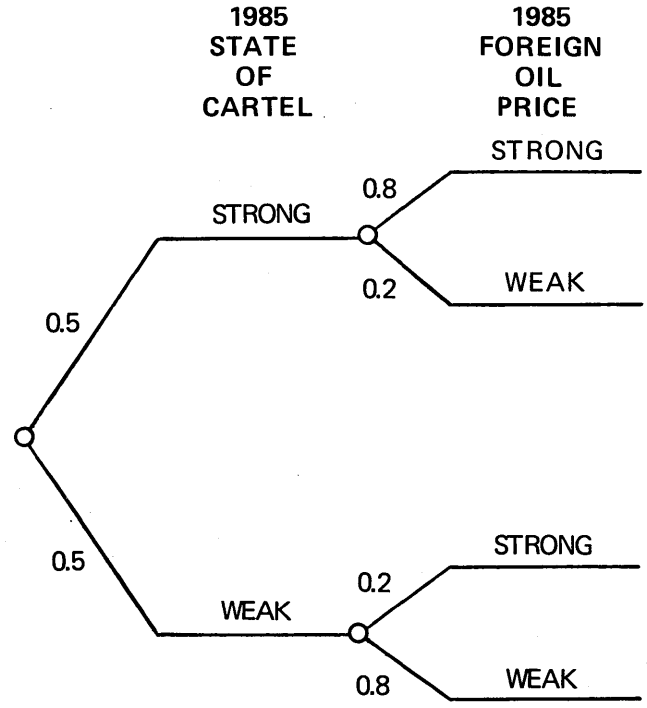

Figure 7—Probabilities of state of cartel

$11 per barrel (the 10 percent fractile) and a ten percent chance that it will be above $19 per barrel (the 90 percent fractile). We divided the distribution into three sections having areas of 25 percent, 50 percent, and 25 percent and used the median value to represent the middle section and the 10 percent and 90 percent fractiles to represent the two tails. Thus, as shown in Figure 6, we said in the analysis that there is a 25 percent chance that the 1985 imported oil price would be $19 per barrel, a 50 percent chance that it would be $15 per barrel, and 25 percent that it would be $11 per barrel, given that the cartel is strong. The imported oil price given that the cartel is weak is assessed to be much lower—$10, $8 and $6 per barrel, respectively.

Using this simple technique, we encoded the uncertainty of the Task Force members about each of the factors shown in the decision tree. Of particular interest are the assessments of the future state of the oil producers' cartel. As shown in Figure 7, the chances of the cartel remaining strong through 1985 were assessed by the Task Force to be 50-50. Given that it is strong in 1985, the probability that it would remain strong through 1995 was assessed to be 80 percent, while if it is weak in 1985, the chance that it would become strong by 1995 was assessed to be only 20 percent.

RESULTS OF THE ANALYSIS

After we had structured the problem with the decision tree, constructed a computer model to calculate the net national benefit for each of the thousands of scenarios in the tree, and encoded the uncertainties of the Task Force, we were ready to compute the analytic results.

Figure 8 summarizes these results. The total expected discounted net benefit (in billions of 1975 dollars) is shown, along with its components, for each of the three synthetic fuels program levels relative to having no program at all. These results indicated that, on balance, the synthetic fuels commercialization program was not in the best national interest and that the bigger the program, the greater the national loss. The small informational program had an expected impact on minus $1.65 billion. The larger program had expected impacts of minus $5.41 billion and minus $10.98 billion, respectively.

We can get more insight by looking at the components of total net benefit. While the synthetic fuels program is expected to have positive impacts on consumer surplus

	Expected Discounted Net Benefit (billions of 1975 dollars)				
Program Alternative	Consumer Surplus	Producer Surplus	Embargo Protection	Environmental and Socioeconomic	Total
No Program	0	0	0	0	0
Information Program (0.35 mm bbl/day)	1.07	-2.71	0.43	0.44	-1.65
Medium Program (1 mm bbl/day)	3.29	-8.74	1.18	-1.14	-5.41
Maximum Program (1.7 mm bbl/day)	4.55	-15.77	2.23	-1.99	-10.98

Figure 8—Expected program impacts

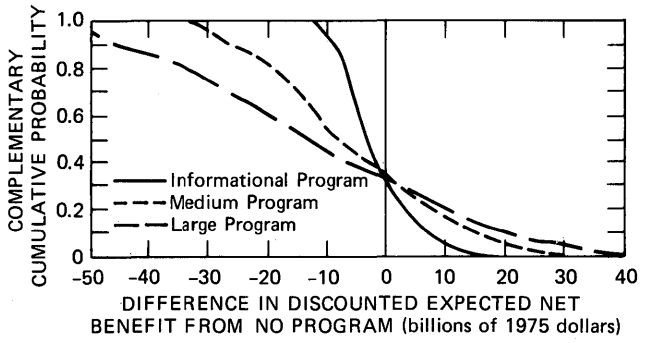

Figure 9—Uncertainty in program impacts

through the possible moderation of future imported oil prices and on embargo losses through a slight reduction in oil imports, these benefits are far outweighed by the negative impact on producer surplus. Basically, it was far more likely than not that synthetic fuels would be more expensive than imported oil and therefore need a subsidy. The negative impact of environmental and socio-economic costs is relatively minor.

The results shown in Figure 8 are the expected values of program impacts. There is, of course, considerable uncertainty about the impact of the program, as shown in Figure 9. While the expected impact of the informational program is $1.65 billion, there is a 30 percent chance that the net impact will be positive and a 10 percent chance that it will be as much as +$7 billion. On the other hand, there is a 10 percent chance that it will be as negative as −$9 billion. It is equally likely that the impact will be worse than or better than −$4 billion. The uncertainty in the impact of the larger program is even greater.

Figure 10 is a partial expansion of the decision tree that shows how two of the factors affect the results of the analysis. The −$1.65 billion expected impact of the information program consists of a 50 percent chance of −$4.86 billion if the cartel in 1985 is weak and a 50 percent chance of +$1.55 billion if it is strong. Note that a weak cartel, which leads to generally lower imported oil prices, is bad for the syn-

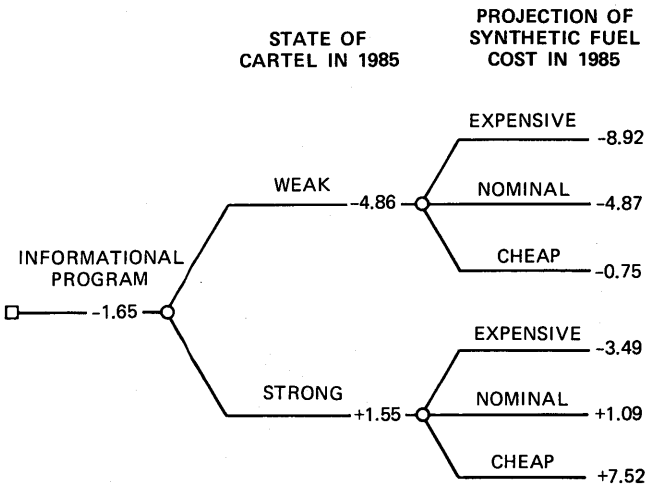

Figure 10—Partial expansion of tree

thetic fuels program while presumably very good for the nation as a whole. Conversely, a strong cartel, with higher imported oil prices, makes the program look good while being bad for the nation. This emphasizes that the synthetic fuels program is a hedging strategy—it pays off when other things are going badly. Note also that if the cartel is weak, the program looks bad even if synthetic fuels turn out to be cheap to produce. On the other hand, if synthetic fuels turn out to be expensive, the program looks bad even if the cartel is strong. That is why, on balance, the program looks bad.

The assessment of a 50-50 chance that the cartel would remain strong through 1985 turned out to be pivotal and more than a little controversial within the Task Force. To show the implications of different probabilities for this factor, we performed a sensitivity analysis, which is shown in Figure 11. This gives the expected net impact of each program level relative to no program as a function of the probability of a strong cartel in 1985. It assumes that with 80 percent probability, the cartel will remain in the same state from 1985 to 1995. Figure 11 shows that only if the probability of a strong cartel in 1985 exceeds 75 percent does the information program look better than no program and that the probability must exceed 82 percent for the medium size program to be the best alternative. An interesting result is that the maximum size program is never optimal for any value of this probability.

So far, the analytic results have been presented only in terms of expected values. It might be argued that the decision should not be made on the basis of expected values but rather on the basis of values that are adjusted for risk. To show how various levels of risk aversion would affect the

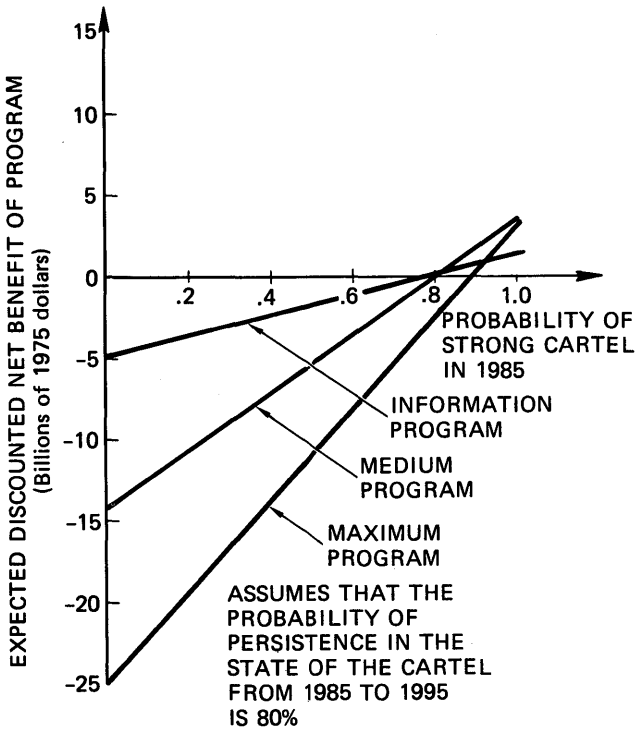

Figure 11—Sensitivity to cartel probabilities

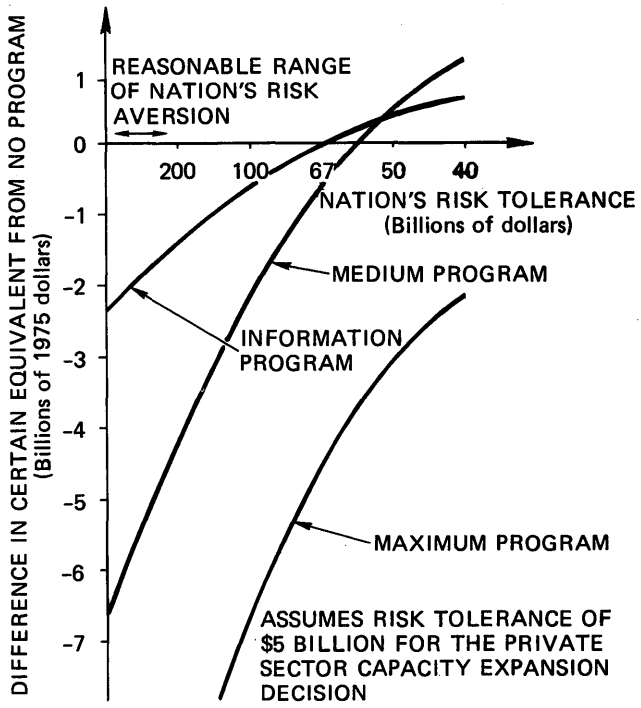

Figure 12—Sensitivity to nation's risk aversion

results, we prepared the sensitivity profile shown in Figure 12. Here, we have assumed that the nation's risk attitude is expressed by one of the family of exponential utility curves. The degree of risk aversion expressed by this curve is given by its one parameter, called the risk tolerance; the smaller the risk tolerance, the greater the degree of risk aversion. In personal terms, an individual's risk tolerance is the largest amount of money he would willingly risk in a gamble that is equally likely to halve or double that amount.

Figure 12 shows the value to the nation of each program level relative to no program as a function of the nation's risk tolerance assuming an industry risk tolerance of $5 billion for the private sector capacity expansion decision. Note first that the value of the program increases as the nation's risk aversion increases. This is characteristic of a hedging strategy, since it reduces overall uncertainty. However, the nation's risk tolerance must be less than $67 billion for the information program to be better than no program and it must be less than $56 billion for the medium size program to be the best alternative. We believe that a reasonable range for the nation's risk tolerance is from one-fourth to one-half of annual GNP, or about $300 billion to $600 billion. As Figure 12 shows, for any risk tolerance in this range, the ranking of program alternatives is the same as in the expected value case, with the best alternative being no program at all.

EPILOGUE

As far as we can determine, this is the first decision analysis to be presented in the White House. The chairman

of the Task Force presented it to the President's Energy Resources Council in July 1975. Citing benefits of the program that were not quantified in the analysis, such as the international leverage gained by the U.S. in asserting positive leadership in developing alternate fuel sources, as well as the "relatively small risk and expected cost" of the small program, the Task Force recommended that the government undertake the informational program alternative with a possibility that it could switch to the medium size program pending additional information on crucial factors. The Administration's bill incorporating this recommendation ultimately failed to pass through Congress.

COMPUTER UTILIZATION

For this analysis, we wrote a FORTRAN program for use on a commercial time sharing system. The program, which we created from scratch rather than use off-the-shelf routines, required approximately 400 lines of code and cost roughly fifteen dollars to run a complete evaluation of the decision tree.

One feature of the time sharing service that we found to be especially useful was the accessibility from different locations. We did most of the model development at SRI headquarters in Menlo Park, California, but we used the program extensively while working with the Task Force in Washington D.C. Indeed, one of the most valuable aspects of our assistance to the Task Force was our ability to answer almost immediately their many questions about the effect of changes on the assumptions and assessments in the analysis.

A computer model for examining regional peak electric load growth

by P. F. SCHWEIZER
Westinghouse R&D Center
Pittsburgh, Pennsylvania

INTRODUCTION

One of the critical factors affecting the electric utility and electrical manufacturing industries is the forecast of the long-term demand for electricity. Superficial forecasts based on either past time trends or very broad based factors for the entire United States do not provide sufficient confidence for long-range planning. This effort is an attempt to examine the basic factors in the U. S. which create the demand for electricity. Equally, or possibly even more important, is the examination of the sensitivity of the forecast to the basic driving factors. Through this sensitivity analysis, which relates the changes in input assumptions to output changes, the reasonableness of other forecasts can be established.

POWER SYSTEMS MARKET FORECAST MODEL

When one begins the development of a market forecast model, some important basic concepts must be resolved.[1] The time span of interest in the forecast must be specified. Whether the span is hours, days, months, years, or decades will influence the structure selected for the model. In general, for short time spans, the model structure can be closely patterned after the existing market. For long-term models, however, the dynamics of a changing market must be represented in the model.

Because of different climates, industries, economics, and traditions, geography plays an important role in an electric demand forecast model. The differing regional saturations of electric air conditioning and space heating, mixes of industry, and price of electricity compared with competing fuels require that geographical considerations be included to obtain better forecasts.

Nine data bases are presently maintained for each of the nine NERC regions. These regions are geographically located as shown in Figure 1. One obviously questions the selection of these regions versus some other delineation. When dealing with demand data, such as population, households, value added, etc., a state or census region division might seem more reasonable. However, when dealing with electric supply data, such as generation capacity, additions, costs, etc., an electric utility boundary or power pool area seems reasonable. The basic problem is that data collection for supply and demand is on a completely different geographic basis. Each NERC region is a grouping of Power Supply Areas which are, in turn, a grouping of utilities, many of which overlap state and political boundaries. To establish consistency in the data base, we decided that demand data given at the state level could be more easily transformed to a supply area, such as an NERC region, rather than vice versa. The NERC supply region was selected rather than the power supply areas or utility service areas simply because the model detail we were requiring would need excessive data storage and manipulation at the more disaggregated level.

A block diagram of the model is shown in Figure 2. Submodels for residential, industrial, and commercial are used to estimate kilowatthour (KWH) sales. Exogenous estimates of transportation, agricultural, governmental, and miscellaneous KWH sales are summed with residential, commercial, and industrial to obtain total sales. Total electrical energy output is calculated using transmission and distribution loss estimates determined from input data specifying losses as a percent of KWH sales. The peak load in each region is calculated from total output using a load factor which is estimated as a function of the mix of KWH sales. The installed capacity in each region is calculated from peak load using either an option that inputs the percentage of generation additions of each type or an option that uses generation capital, fuel price, and investment data to determine the least cost mix of additions. The capacity factor for each unit type is calculated by adjusting the KWH output from all units (capacity factor × installed capacity rating × 8760 hrs.) to be equal to the estimated KWH generation from the model. Input energy to all types of units is calculated using the estimated electrical generation and the heat rate for each type of unit. Additional detail on each of the calculational blocks and models depicted in Figure 2 is shown in Figures 3 through 6 and is discussed in the following.

Residential sector model

A block diagram of the model used to estimate residential KWH sales for each NERC region is shown in Figure 3. By

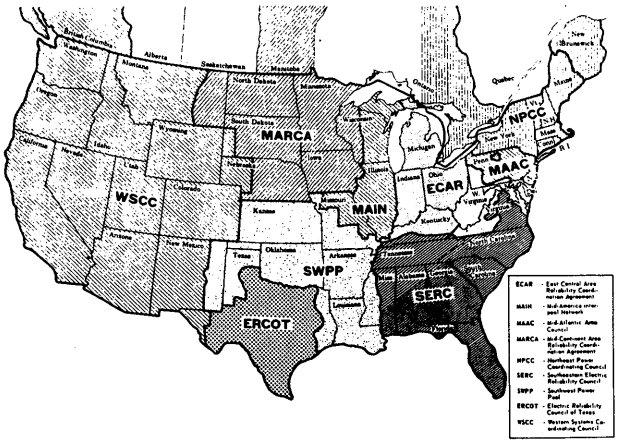

Figure 1—Regional electric reliability councils

multiplying population by headship rate, an estimate of households is obtained. Time trends for the saturation of appliances, air conditioning, and space heating are input to the model[2] and are used to calculate saturations in any given year. These saturations are then adjusted based on price effects and multiplied by the number of households to obtain an estimate of the number of electrical end-use units. Average annual use for each unit type is estimated by inputting time trends of annual use and adjusting annual use based on price effects. An estimate of annual KWH consumption is obtained by multiplying the number of end-use units by the annual use.

The three equations used to estimate residential KWH sales in any given year are:

$$RKWH = \sum_{\text{all appl-}} POP*HDR*SAT \quad (1)$$

$$*SATPA*USE*USEA$$

$$SATPA=\left(\sum_{LOA} RPE/LOA\right)^{\alpha_{SE}}*\left(\sum_{LOA} RPG/LOA\right)^{\alpha_{SG}} \quad (2)$$

$$USEA=RPE^{\alpha_{UE}} \quad (3)$$

where POP is regional population, HDR is regional headship rate, SAT is appliance saturation, SATPA is price adjustment of saturation, USE is annual KWH consumption, USEA is the price adjustments of annual use, RPE and RPG are the relative prices of electricity and gas with respect to the base year, LOA is the lifetime of an average appliance, α_{SE} and α_{SG} are electric and gas price elasticities used to adjust saturation, and α_{UE} is the electric price elasticity used to adjust annual use.

Industrial sector model

The industrial sector model, shown in Figure 4, uses Federal Reserve Board production indices as a national production indicator for two digit manufacturing and mining categories. Projected trends in dollars of value added by SIC code are used to calculate ratios which estimate the share of national production to be allocated to each NERC region in any given year. Input time trends are used to estimate electricity use per unit of production for each SIC code. Industrial KWH consumption is estimated using the regional production estimates and the energy intensiveness estimates corrected for price effects.

The equations used to estimate industrial KWH consumption are given by:

$$INDKWH=\sum_{SIC} FRB_{NAT}*(\$VAREGSIC/\$VANATSIC)$$

$$*USESIC*IUSEA_t \quad (4)$$

$$IUSEA_t=(1-\lambda)IUSEA_{t-1}+RPEI^{\alpha_{UIE}}RPOI^{\alpha_{UIG}} \quad (5)$$

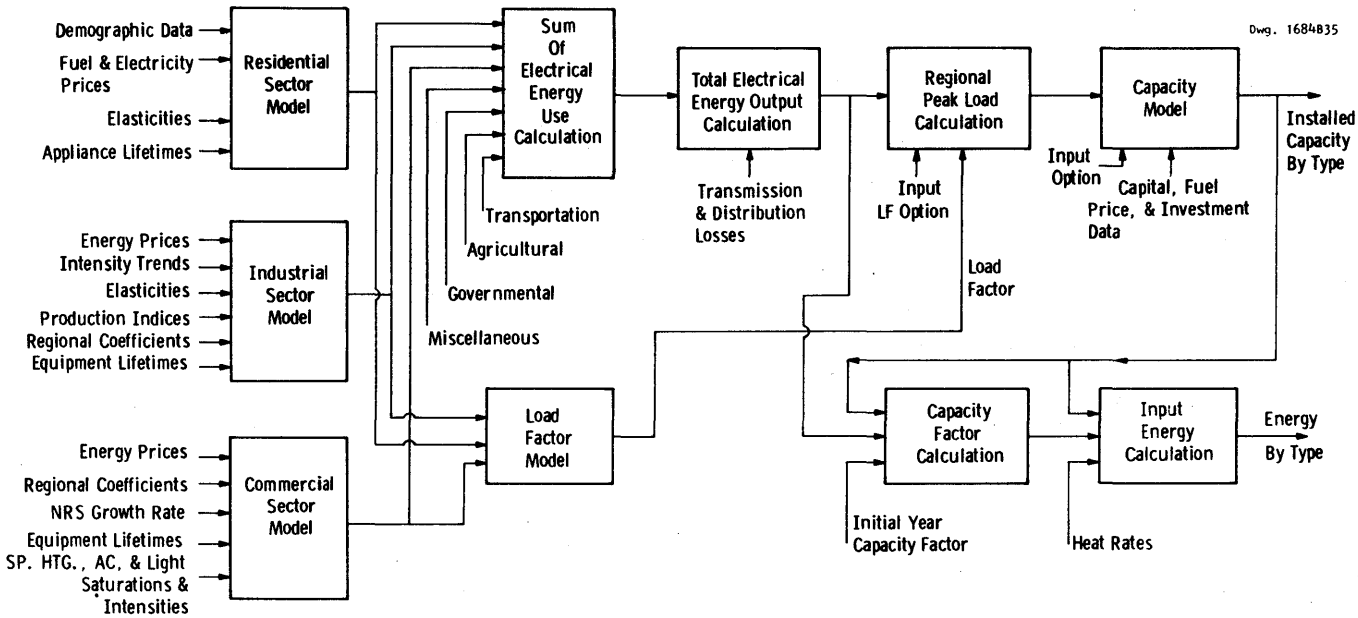

Figure 2—Power systems market forecast model

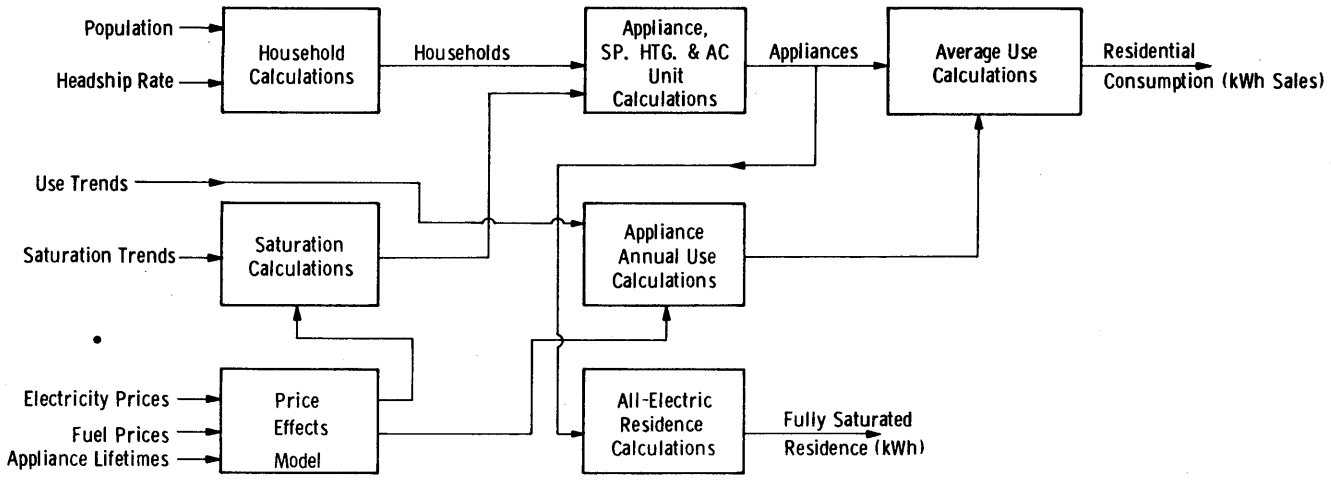

Figure 3—Residential sector model

where FRB_{NAT} is the Federal Reserve Board Indices, $VAREGSIC is the $ of value added by SIC by region, $VANATSIC is the $ of value added nationally by SIC, USESIC is the electricity use per unit output for each SIC, $IUSEA_t$ and $IUSEA_{t-1}$ are the industrial use price adjustments in years t and t−1, λ is the fraction of this price adjustment accomplished each year, RPEI and RPOI are the relative prices of electric and other fuels in the industrial sector to a base year, α_{UIE} and α_{UIO} are the price elasticities of use for electric and a composite for other fuels.

Commercial sector model

The commercial sector model, shown in Figure 5, uses national projections of non-residential structures or commercial buildings to estimate commercial floor space in use in any given year. Regional allocators developed from regional population and personal income forecasts[3] are used to estimate floor space in each NERC region. Input time trends are used to calculate both the lighting, space heating, air conditioning, and miscellaneous electricity use per square foot of floor space and the saturation of these uses. A price adjustment is made on total commercial demand. The equations used for the estimated KWH consumption are:

$$COMKWH=NRSGR*COMFLB*REGAL*\sum USEC*CSAT*COMPA_t \quad (6)$$

$$COMPA_t=(1-\lambda_c)COMPA_{t-1}+\lambda_c RPEC^{\alpha CE}*RPGC^{\alpha CG} \quad (7)$$

where NRSGR is national non-residential structures or com-

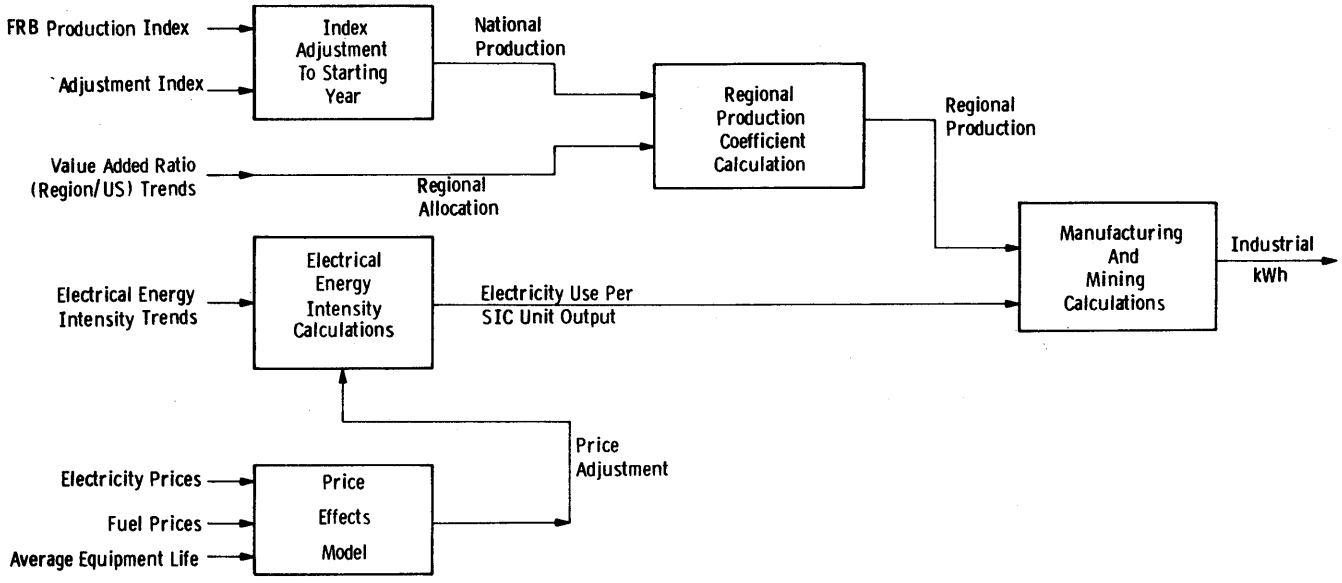

Figure 4—Industrial (mining & manufacturing) sector model

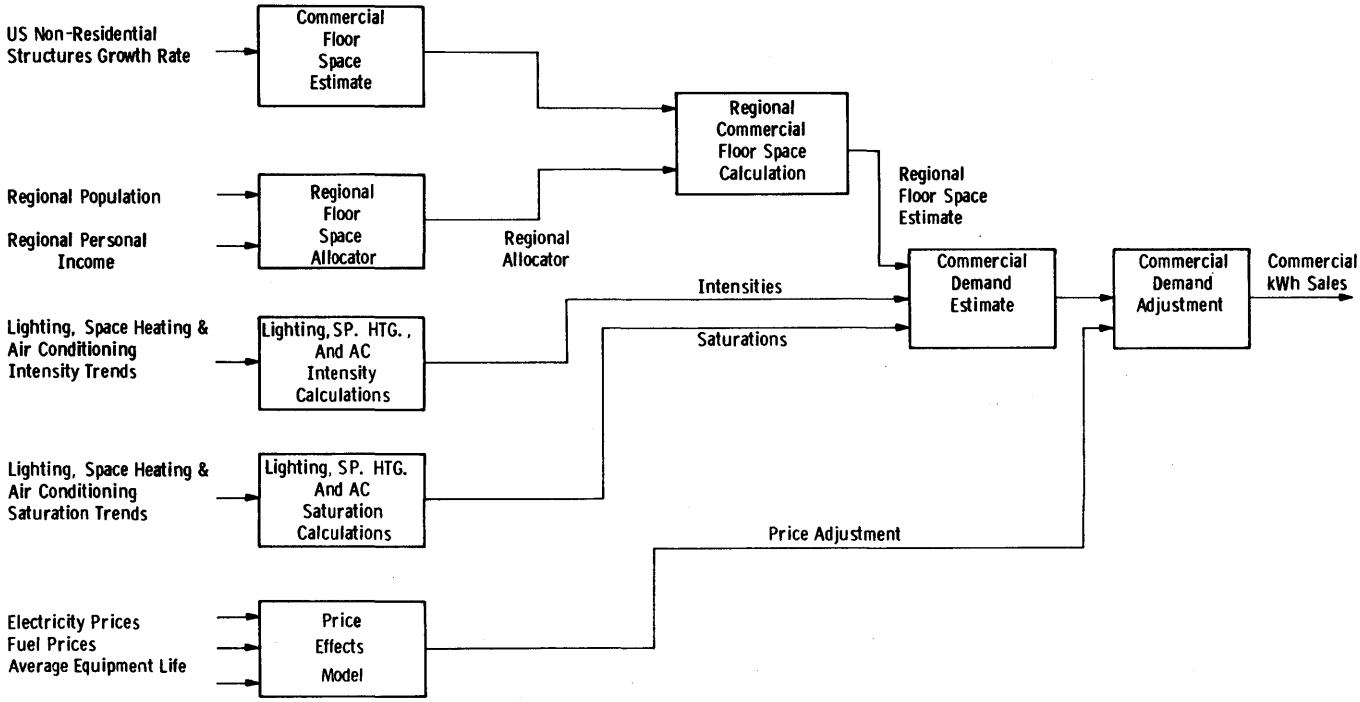

Figure 5—Commercial sector model

mercial buildings growth index relative to the base year. COMFLB is the commercial square feet of floor space in the base year, REGAL is the fraction of floor space allocated to each region, USEC is the KWH consumption per square foot of floor space for each specific use, $COMPA_t$ and $COMPA_{t-1}$ are the commercial price adjustments in year t and t−1, λ_c is the fraction of the price adjustment taking place each year, RPEC and RPGC are the relative prices of electricity and gas with respect to the base year, and α_{CE} and α_{CG} are the price elasticities of total use in the commercial sector.

Load factor model

Ideally, one would like to estimate and forecast the peak electric load independently from KWH sales. However, because of the scarcity of data with regard to individual loads and their coincidence on the system, this is impossible to accomplish in general. The approach used here is to relate peak load to residential, commercial, and industrial KWH sales, saturation of space heating and air conditioning, cooling and heating degree days. After obtaining peak load (PLW, PLS), the load factors (LFS, LFW) are calculated by relating to the total KWH output. The equations used are

$$PLW=\alpha_\omega RKWH+\beta_\omega COMKWH+\gamma_\omega INDKWH+\sigma_\omega RHS+\delta_\omega HDD \quad (8)$$

$$PLS=\alpha_s RKWH+\beta_s COMKWH+\gamma_s INDKWH+\sigma_s RAC+\delta_s CDD \quad (9)$$

$$LFS=(KWHOUT\div(8760\times PLS)) \quad (10)$$

$$LFW=(KWHOUT)\div(8760\times PLW)) \quad (11)$$

where PLW and PLS are winter and summer peak load, LFS and LFW are summer and winter load factor, KWHOUT is total KWH output, RSH is the saturation of residential electric space heating, RAC is the saturation of residential air conditioning, HDD and CDD are the regional average heating and cooling degree days.

The coefficients in equations (8) through (10) are estimated from historical data for each region. These independent variables were chosen because in the past, residential and commercial loads have contributed more to peak than industrial loads. Also, loads with larger weather-sensitive components have exhibited generally lower load factors.

Generation capacity model

Using total KWH output and regional load factor, peak load is computed for each region for each year of interest. With an estimate of peak load as input, the function of the generation capacity model is to determine how much capacity (if any) should be added in each region during each time period. If additions are required, then the model must calculate the type needed from a group of nine possible unit types: fossil (coal, oil, gas), nuclear, combustion turbine, combined cycle, hydro, pumped storage, and other.

The block diagram shown in Figure 6 demonstrates the functions performed by the generation capacity model. An initial estimate of the end-of-year capacity is calculated by

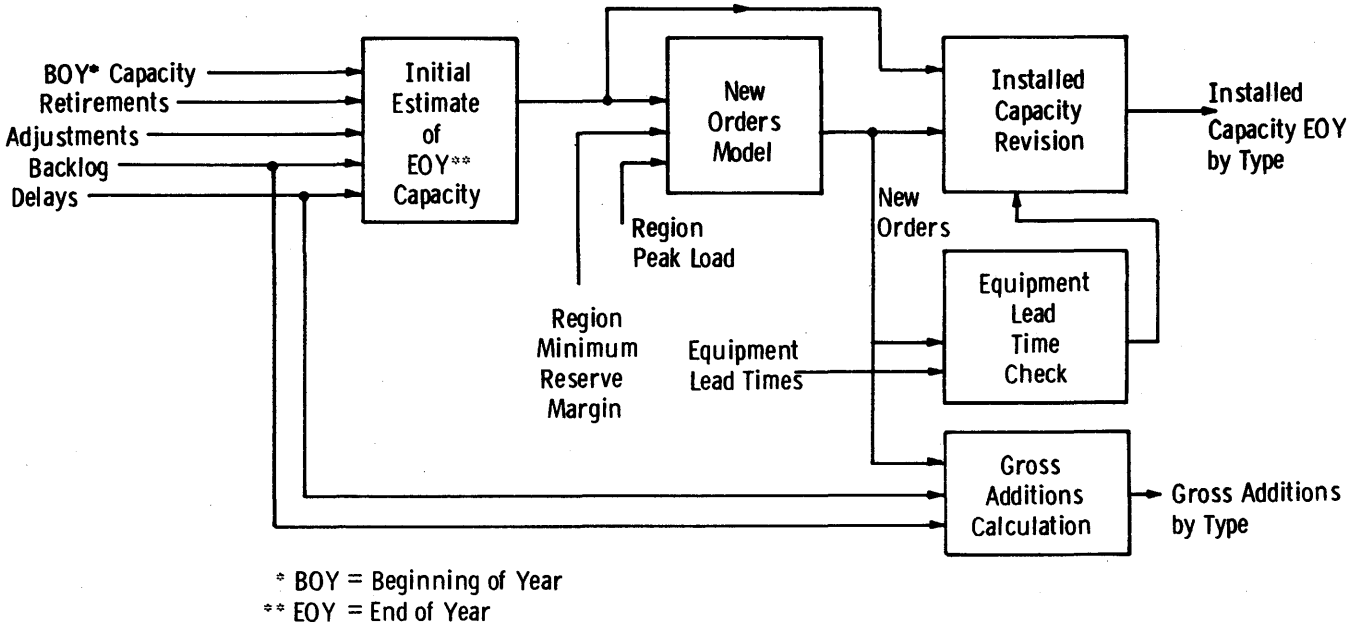

Figure 6—Generation capacity model

adding backlog, delays, and adjustments and subtracting retirements from the beginning-of-year capacity. Using this estimate of end-of-year (EOY) capacity with inputs of peak load and the minimum reserve margin in the region, a check is made to establish the sufficiency of the capacity. If the capacity is insufficient to meet peak load requirements with the minimum reserve margin, then new orders are generated for additional units. These new orders are then added to the initial estimate of the installed capacity to obtain the installed EOY capacity. These new order units are then checked against the equipment lead times to establish that sufficient time is available so that units being added can be delivered and installed. Gross additions for each type unit are calculated by adding backlog, delays, and new orders.

There are two options in the new orders model for calculating the type of units to be added. The first option simply provides for calculating the mix of new units using percentages estimated from the NERC reports. The second selects additional capacity from the nine types of units so that additions are matched to load requirements in a manner that minimizes cost.

BASE ELECTRICAL ENERGY AND PEAK LOAD FORECAST

To demonstrate the capabilities of the model, a base forecast has been prepared which uses the nine NERC data bases and aggregates the results from these regions to obtain a national forecast (Tables I, II and III). Because of space limitations, very little of the model output can be shown. Only a very brief summary of the base case is presented here.

The macroeconomic factors which drive the model are taken from the output of a macroeconomic model[4] so that consistency is established. For example, the industrial production, household growth, and commercial buildings growth are all consistent with a much larger set of economic conditions. The number of variables used directly as input to the electrical demand model from the macroeconomic model output is small (~25 time series). However, the macroeconomic model which derives these time series is comprehensive (over 1100 equations and identities), and, therefore, indirectly the influence of all pertinent economic factors are included.

National and regional KWH sales and output (sales+losses) are shown in Table I; historically for 1971-1976 and forecasted 1977-2000. Compounded annual growth in the period 1977-2000 is approximately 5 percent. This is considerably less than historic growth in the decades of the 60s and 70s where annual growth averaged 7 percent. The industrial sector is the major contributor to growth in this forecast based on the compounding effects of long-term expansion and increasing use of electricity per unit output in most industry groups. All NERC regions exhibit lower growth rates than historic and range from approximately 5.5 percent in the southwest to 3 percent in the northeast.

National and regional peak loads as forecasted by the model are shown in Table II. Actual values for the period 1971-1976 are shown in parentheses. Nationally, summer peak loads are forecasted to grow at about 4.6 percent annually and winter peak about 4.8 percent. Thus, peak is forecasted by this model to grow at a lower rate than KWH output. This can be explained by the major part of KWH output growth being industrial which contributes less to peak, and the application of load management techniques in controlling peak. Regionally, peak growth is highest in the

Southwest (6.2 percent) and lowest in the mid-Atlantic (3.5 percent) and Northeast (3.5 percent).

National and regional load factors are shown in Table III. Nationally, summer load factor is forecasted to improve for the same reasons mentioned previously, that summer peak load is growing less than KWH output, industrial growth, and load management. National winter load factor is forecasted to decline because of the considerable increase in electric space heating, especially in the more moderate climates.

The low summer load factors forecasted by the model for ERCOT, SPP, and MARCA may not actually occur because, most probably, additional load management equipment and incentives will be applied to arrest these declining load factors.

Computer modeling of automotive engine combustion

by CHARLES K. WESTBROOK and LEONARD C. HASELMAN

Lawrence Livermore Laboratory
Livermore, California

INTRODUCTION

Using a general outline of the physical and chemical events which occur in an automobile combustion chamber during a complete engine cycle, we discuss some of the achievements and some of the limitations of computer modeling of automotive engine combustion. We point out that this type of modeling is often limited by lack of physical knowledge and by computer software and hardware restrictions. Still, within these constraints many types of combustion models have been able to make important contributions to present understanding of automobile engine combustion.

Although the internal combustion engine has been in use in automobiles for about a century, the current need for increased fuel economy and reduced chemical pollutant emissions creates many new problems for automotive engine design. In order to provide support for engine designers and to provide additional theoretical analysis and insight into the physical and chemical processes which are part of engine combustion, increased attention has recently been given to detailed computer modeling of automotive engine combustion.

Computer models of combustion processes are limited in three principal areas. The first of these areas involves inadequacies in fundamental descriptions of relevant physical systems. For example, fluid mechanical turbulence has a profound influence on many aspects of internal combustion engine performance, but the theory of turbulence and its effects on chemical reactions and flame propagation are rudimentary at present. In addition, theoretical descriptions of processes such as liquid atomization and other multiphase flow systems are generally inadequate. The second major limitation for numerical models of complex physical and chemical systems is that, even when the physical description is relatively complete, often there are serious deficiencies in the numerical methods available for solution of the relevant systems of equations. The comparatively recent development of "stiff equation" solution methods has made a significant improvement in the ability to handle the chemical kinetic rate equations of combustion chemistry, but other problems remain. In computations which include the effects of spatial transport of mass and energy, there are very large systems of coupled partial differential equations to be solved, often between 25 and 50 equations for each of as many as 10000 computational cells, for a total of nearly half a million differential equations. Matrix solution techniques for such systems are not available and most problems must be greatly simplified in order to find solutions. The final major limitation for many numerical models is the result of basic computer hardware constraints, including available core size, memory access times, and arithmetic operation speeds. These limitations restrict the spatial resolution, chemical kinetic detail, and geometrical generality of the problems which can be addressed with computer models. The combustion models which have been developed to date are all subject to each of these major limitations, and it is unlikely that this situation will change substantially in the near future. Still, within these limits, a great variety of useful and valuable information has been developed through numerical modeling of combustion problems.

In the internal combustion engine, fuel is introduced into the combustion chamber in any of a variety of forms, in the gas phase, as a liquid, or a combination of the two phases. The resulting mixture of fuel and air is then ignited, again in any of several methods, and the resulting flame or flames propagate through the combustion chamber, consuming fuel and oxygen and producing, as products of combustion, water, carbon dioxide, and an often bewildering variety of chemical pollutants. The energy released by the reactions is converted to mechanical energy as the piston moves downward. The flame can be extinguished by a number of mechanisms, by contact with the cold walls of the combustion chamber, by the rapid expansion of the combustion chamber as the piston moves downward, or by consumption of available fuel. Many forms of flame extinction or quenching leave unburned fuel in the combustion chamber which can eventually result in hydrocarbon pollutants in the atmosphere. The combustion products are then passed through an exhaust system where the product gases are often subjected to additional reaction environments, such as catalytic converters, in order to modify the exhaust composition. Seen in this general outline, it is readily apparent that no single numerical model can be expected to deal adequately with the physical and chemical details of the entire process. One approach to modeling the combustion process is that which is characterized as thermodynamic models.[1] In these models the gases are divided into two regions, burnt and unburnt; empirical relations are then used to determine the rate at

which gases go from unburnt to burnt. These models provide little information on the spatial and chemical details of the combustion process. Another approach is to break the broad total problem into a sequence of overlapping smaller problems which can be analyzed separately. Only by this type of fragmentation can any of the physical subsystems be made tractable for analysis. It is also common to use symmetry assumptions to simplify the geometrical aspects of many problems, since fully three-dimensional problems usually require a prohibitive amount of computer memory and CPU time.

The problem of fuel injection into a combustion chamber provides an instructive example of a number of these points. Numerical models of liquid fuel sprays[2-4] have assumed that the liquid spray consists of an array of independent spherical droplets. This type of treatment ignores the important process of the atomization of the initially continuous liquid jet, since there is no physical theory which properly describes liquid jet atomization. When the assumption is made that the jet does break up into individual fuel droplets, a purely computational problem arises. In one of the more ambitious droplet models to date,[2] the liquid droplet distribution function becomes a variable in eight independent dimensions, including three space coordinates, three velocity coordinates, the droplet radius, and the time. With even the minimum resolution in each dimension, this treatment requires the computational manipulation of a variable with a dimension of more than 1.5 million (decimal) words at each time

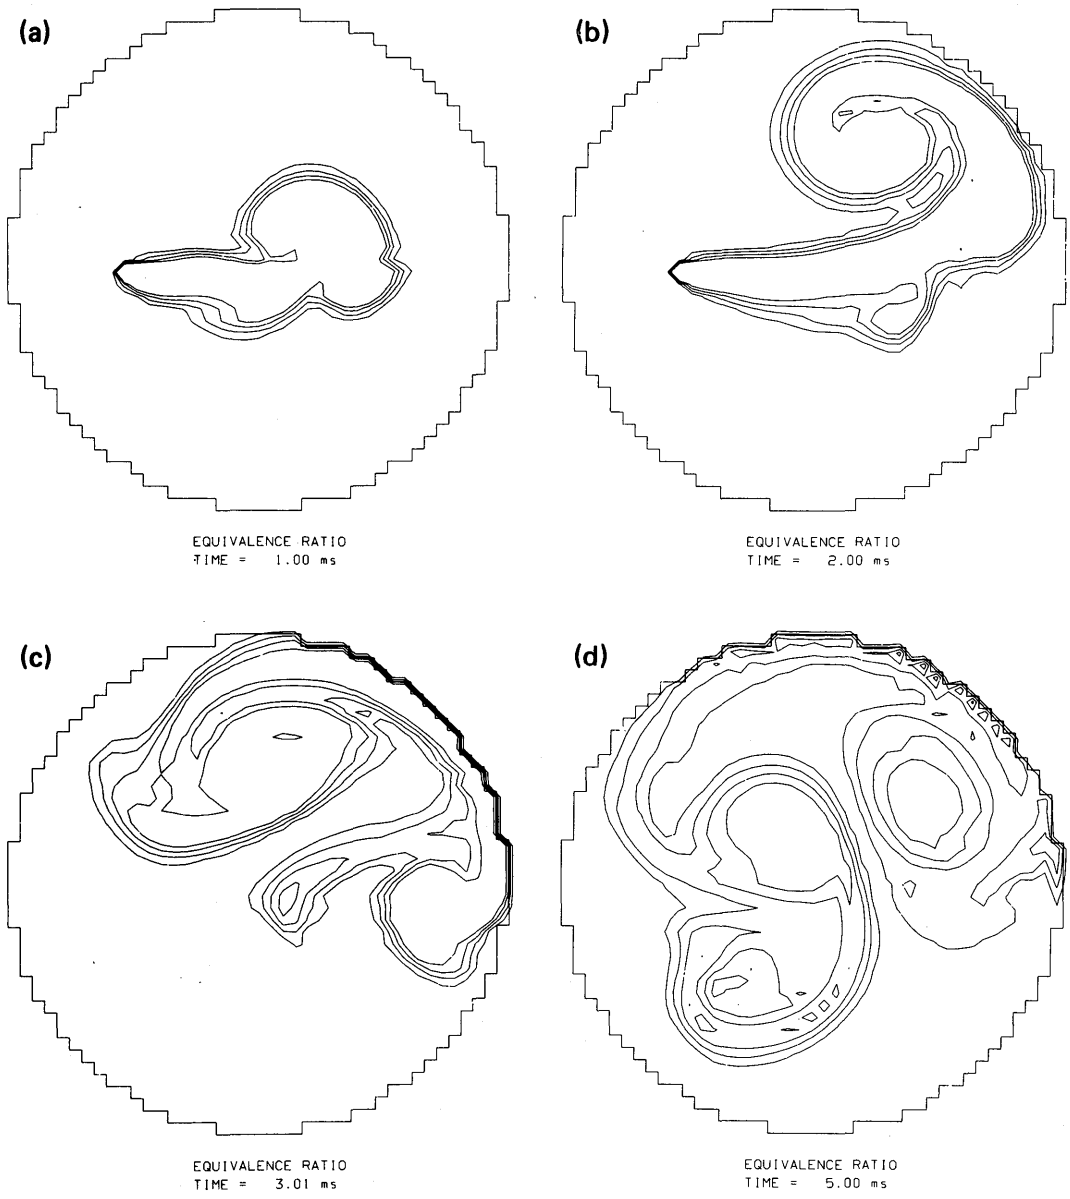

Figure 1—Contours of constant equivalence ratio for gas jet injection. Fuel-rich contours are near the center and fuel-lean contours are near the perimeter of the jet. Air swirl rate is 4000 RPM.

step. If assumptions are made with respect to physical symmetry, limiting the applicability of the model to somewhat idealized geometrical configurations, then the memory size requirements of the model are brought down to a more manageable 30,000-50,000 words, but some generality has been sacrificed.

Another injection model often used[3,5] consists of treating the injection as a gaseous jet into a gaseous medium. By eliminating the droplet phase a substantial reduction in the computational requirements is possible. In many practical applications, particularly in diesel engine chambers where conditions are close to the thermodynamic critical point of the fuel, the gas jet approximation is quite realistic. We can illustrate this approach with results computed by one of us (L. H.) for the case of a gaseous fuel jet injected into a swirling air flow. The combustion chamber is a thin circular disk representing a typical diesel combustion chamber near TDC, the point of maximum compression. Fuel is injected into the air flow which is swirling at a rate of 4000 RPM. The fuel is emerging from the injector at a velocity of 500 meters per second and is injected for 2 ms. As the gaseous fuel jet moves through the chamber, air and fuel gradually mix together. This mixing takes place preferentially at the edges of the gas jet where the shear force between the fuel and air is largest. In addition, the swirling air flow further enhances the fuel-air mixing. We can summarize the overall gas jet evolution by plotting contours of constant equivalence ratio ϕ in the combustion chamber at a sequence of times. The equivalence ratio is defined as the ratio of actual fuel concentration at a point to the fuel concentration which would exactly consume all of the oxygen at that same point. Therefore for $\phi>1$ the mixture is locally fuel rich, while for $\phi<1$ the mixture has excess oxygen. In Figure 1, we plot contours of constant equivalence ratio for values of $\phi=2.0$, 1.5, 1.0, and 0.5 at a sequence of times of 1 msec, 2 msec, 3 msec, and 5 msec after the beginning of injection. We see that the fuel jet travels across the chamber and gradually mixes with air. Large scale eddies are formed at each side of the jet due to air entrainment, and the swirling air flow deflects the jet in the direction of the swirl. These results have been compared and agree with experimental data.[3] The computer model has been used to examine the results of variations in a variety of quantities, including air swirl rate, injection velocity, and injector location. This type of parameter variation in a computer model can be much more economical than a corresponding experimental program and can be used to indicate promising conditions for a much smaller number of experiments. This process reduces the time and expense of a research program.

Once the fuel charge has been prepared, the mixture must then be ignited. The ignition process, either by compression as in the conventional diesel engine, or by spark discharge, presents many serious problems to a modeling effort. In the case of spark ignition, it is not yet clear how the electrical discharge initiates the combustion. It appears that, for a relatively short period of time, even the assumption of local thermodynamic equilibrium does not apply, i.e., that the translational, rotational, and vibrational temperatures of the gas are not all equal. There is an appreciable amount of ionization of the gas molecules, so the chemical kinetics properties of the gas are poorly understood. Also, fluid flow properties in the vicinity of a spark discharge are not always subsonic, and shock waves can be generated. In addition to these physical model inadequacies, ignition modeling presents serious numerical problems. The characteristic physical dimension of a spark region is very small, of the order of a millimeter or less. Yet the overall size of the combustion chamber is many times larger, indicating that lack of physical resolution may be a problem in computations. The ignition process is a difficult one for numerical modeling and a great deal of work is needed in this area.

Once the charge is ignited, a flame will propagate through the combustion chamber. The chemical kinetics of hydrocarbon fuel oxidation is another complex subject which is subject to both a lack of fundamental chemical information and by computational limitations. Detailed information on the reaction mechanism, intermediate chemical constituents, and elementary reaction rates is currently available for only the simplest of fuels. The chemical kinetics of methane (CH_4) involves as many as 25 chemical species and 50-100 elementary chemical reactions in a reasonably complete description of its oxidation and energy production.[6] Practical fuels such as gasoline involve many more constituents and reactions, many of which are unknown. As a result, simplifications are usually made in the expressions for the reaction mechanisms for almost all practical fuels.

Reaction mechanisms, exact or simplified, can then be coupled with fluid flow equations in a spatially varying, time dependent numerical model of flame propagation. Many such models exist. In one example, a comparison was made between combustion in a homogeneous charge engine and in a stratified charge engine.[7,8] Computed results indicate that charge stratification, combined with increased compression ratio, can make significant contributions towards reducing pollutant formation and improving fuel economy. Typical results are shown in Figure 2, indicating the reduction in carbon monoxide and nitric oxide levels as a result

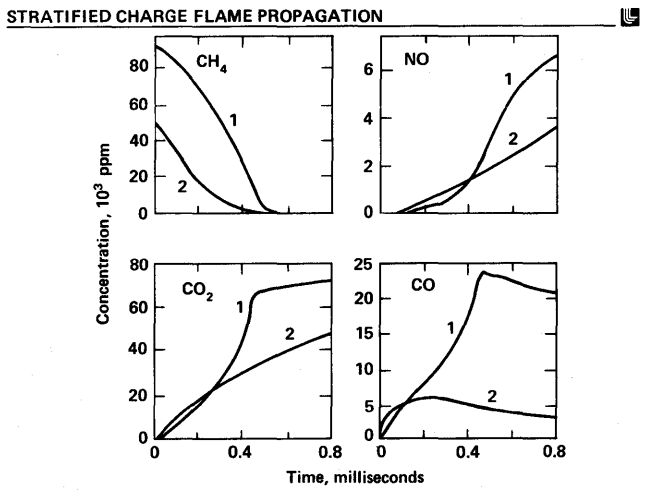

Figure 2—Total calculated concentrations of CH_4 (methane), NO, CO_2, and CO for homogeneous charge (1) and stratified charge (2) combustion.

of charge stratification. In addition, preliminary calculations[7,8] indicate that the stratified case may also provide increased fuel economy in terms of pressure increase per unit mass of fuel burned over the conventional homogeneous charge case.

In the analysis of stratified charge engine combustion, experimental techniques are not yet able to obtain enough data to adequately evaluate many performance characteristics. Time- and space-resolved information inside an engine chamber, including temperature, chemical species concentrations, and bulk fluid motion is not usually available, even with advanced laser diagnostic techniques. While this situation will eventually be remedied, at present computer modeling offers the only access to much of this type of information.

Another exceedingly important area of combustion research in automotive engines which is at present best approached by modeling studies, is that of flame quenching. Flame quenching can occur in several physically distinct regimes. Perhaps the best known quenching phenomenon results from a flame encountering a relatively cold wall of the combustion chamber. The gas temperature drops sharply in a boundary layer to the temperature of the wall; that temperature close to the wall is too low to sustain oxidation reactions, so the fuel which is in this region remains unburned. During the subsequent exhaust phase of the engine cycle these unburned fuel regions are swept out of the chamber and are a major source of the unburned hydrocarbon component of combustion pollutants. Modeling of this phenomenon is made difficult by two major factors. First, very fine physical resolution is needed in this type of problem, since the boundary layer has a thickness of less than a millimeter and this layer must be subdivided into a reasonable number of computational zones. Also, the mechanism of wall quenching almost certainly depends strongly on the details of the interaction between the thermal boundary layer and a number of elementary reaction rates, so this problem also requires a complete chemical kinetics model. Both the resolution and kinetics aspects of this problem require very large computers and sophisticated computational methods. Progress in modeling wall quenching processes is only now beginning to be made.

A physically distinct type of quenching can occur in a reciprocating engine, particularly under conditions of lean combustion and late ignition, where the piston motion rapidly increases the volume of the combustion chamber. This expansion lowers the reacting gas temperature and its density. Since the rates of the great majority of elementary chemical reactions decrease rapidly as the temperature and density are reduced, this volume expansion can significantly reduce the rate of fuel oxidation, even to the point of totally halting the flame propagation. Laboratory experiments and an accompanying numerical modeling study have together been able to provide a fairly complete physical description of this type of bulk quenching of hydrocarbon oxidation by rapid expansion of the reaction gases.[9]

Another type of numerical modeling of combustion processes in automotive engines is shown by an example of a multidimensional fluid mechanics model. It is currently not feasible to include a detailed chemical kinetics model with two or three independent space dimensions. This limitation can best be illustrated by remembering that in a typical kinetics model, approximately 20-30 differential equations must be solved, one for each chemical constituent. In a spatially varying model, these species equations must be solved for each computational cell, plus the usual fluid mechanics variables such as velocity and density. For a one-dimensional, time-dependent model with 100 cells this requires the solution of about 2500 coupled partial differential equations at each time step and takes up to an hour of CPU time on a CDC 7600 computer. For a computation with two space dimensions and 100 cells in each dimension, the same problem would consume over 100 hours, or four days of computer time, making such a computation practically unfeasible. As a result, almost all engine models which consider two space coordinates simplify the reaction model to one or two "global" reactions which are intended to give a reasonable representation of the chemical heat release which can be expected. Within this context, useful information about fluid flow properties which may not depend on the chemical kinetics details may be examined numerically. In an example of the use of this type of model, we compute the fluid mechanical motion of the gases in a motored engine chamber over a full four-stroke cycle. The engine is assumed to be axially symmetric, with a single intake-exhaust valve located on the chamber axis. The piston motion and valve timing represent an engine speed of 2500 RPM.

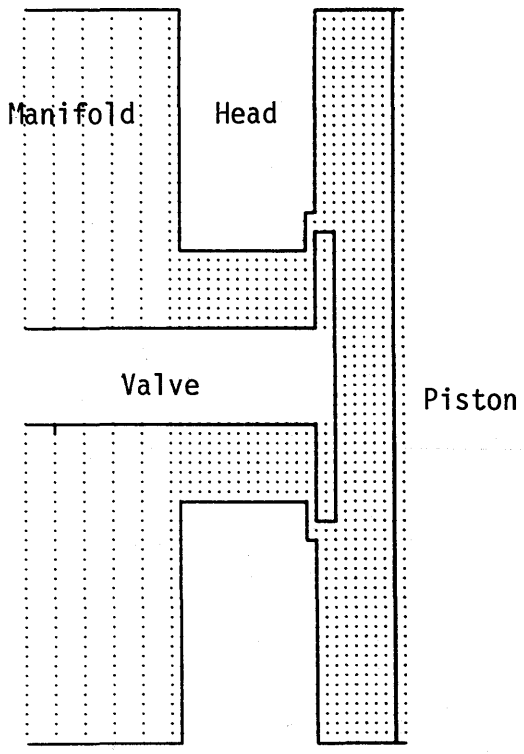

Figure 3—Initial grid for motored engine calculation. Only half of the grid is used for the calculation, it is reflected about the axis here for presentation purposes.

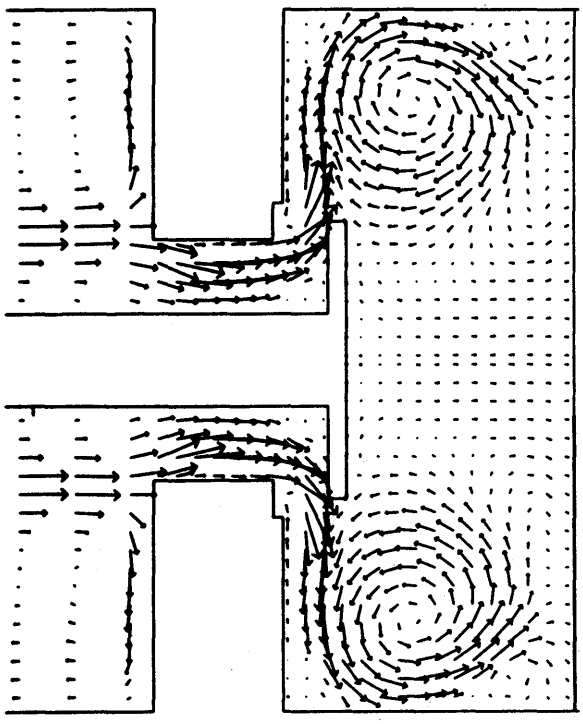

Figure 4—Time 4ms. Maximum velocity 174 m/s.

In Figure 3, we show the initial grid used in this calculation. The valve, head, piston, and cylinder walls are all represented as solid boundaries, with no heat conduction through them. The pressure at the left boundary is held constant at one bar, while the piston and valve move across the grid, which is stationary. This figure and the others in this series are taken from a sequence of computer-generated graphical output. This data has been put into the form of a continuous film which is a very useful and informative manner for presentation. Figures 4-15 are vector plots of the velocity for every other computational cell. For each plot the vectors are scaled linearly with the maximum velocity

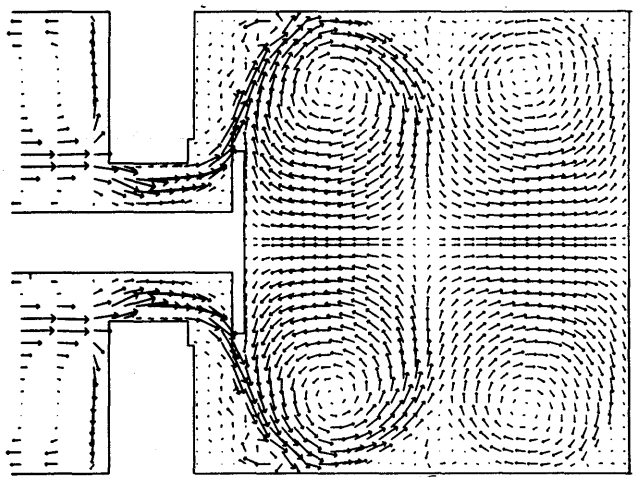

Figure 5—Time 8ms. Maximum velocity 178 m/s.

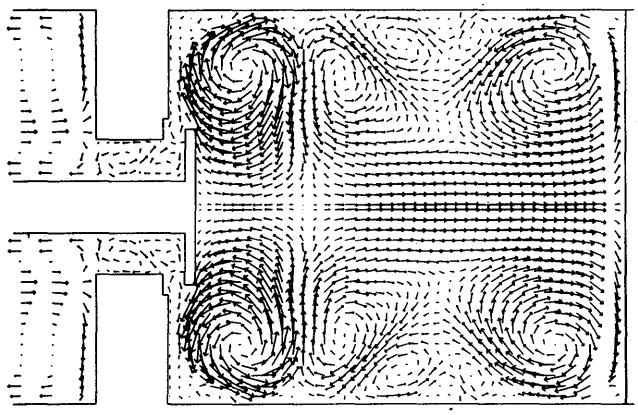

Figure 6—Time 12ms. Maximum velocity 70 m/s.

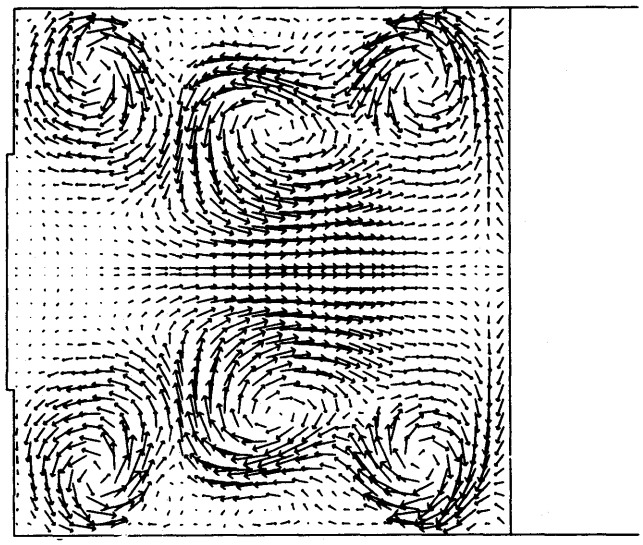

Figure 7—Time 16ms. Maximum Velocity 47 m/s.

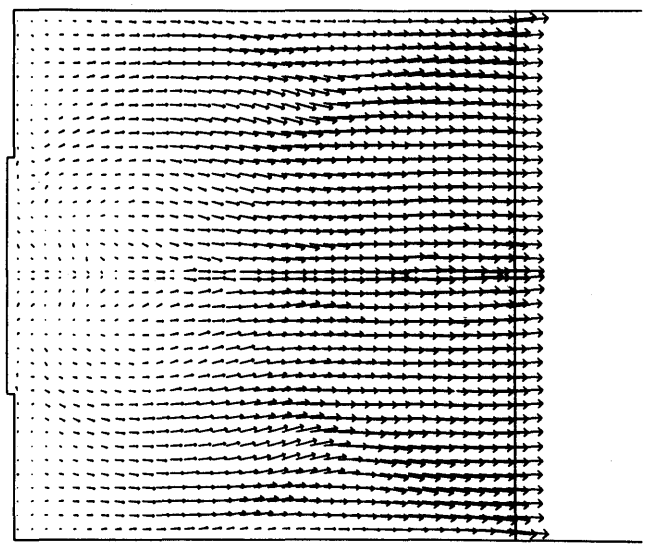

Figure 11—Time 32ms. Maximum velocity 10 m/s.

always being the same length. The plots are at 4 msec intervals, which is equivalent to 60° increments of crank angle.

The intake stroke is shown in Figures 4-6. At 4 msec a toroidal vortex is formed downstream from the valve and the flow velocity of the air through the valve has reached half the sound velocity of the air. This high velocity continues through 8 msec, by which time two toroidal vortexes have formed. At 12 msec, which is the bottom of the stroke, the flow through the valve has stopped and the peak velocity is approximately one fifth the sound speed. The flow in the cylinder chamber has now broken up into a number of small vortexes and is quite complex. At 14.4 msec the intake valve closes and it and the manifold are removed from the computational problem. At 16 msec the compression stroke has begun and the flow continues to decay since it no longer has the flow through the valve to drive it. Figure 7 and Figure 8 show the piston approaching the top and at the top of the compression stroke. At this time the grid resolution is fairly coarse and so the definition of the flow is rather poor. This could be corrected either by rezoning the grid or by using a grid which moves with the piston.

The expansion stroke is shown in Figures 9-11. On this stroke the gas motions caused by the intake valve have largely been dissipated, and subsequent gas motions are dominated by the motion of the piston. Through most of the expansion stroke the maximum velocity of the gas is close to the piston velocity.

At 33.6 msec the manifold and exhaust valve are put back into the grid. Figure 12 shows the calculation at 36 msec, at the bottom of the expansion stroke. The inflow of gas through the valve and the small vortex in the cylinder chamber are caused by the fact that the exhaust valve opens 2.4 msec before the end of the expansion stroke, so air can be drawn in from the manifold. Figures 13-15 show the exhaust stroke. The distinctive feature of this flow is that it is relatively simple. The flow reaches its maximum velocity at 44

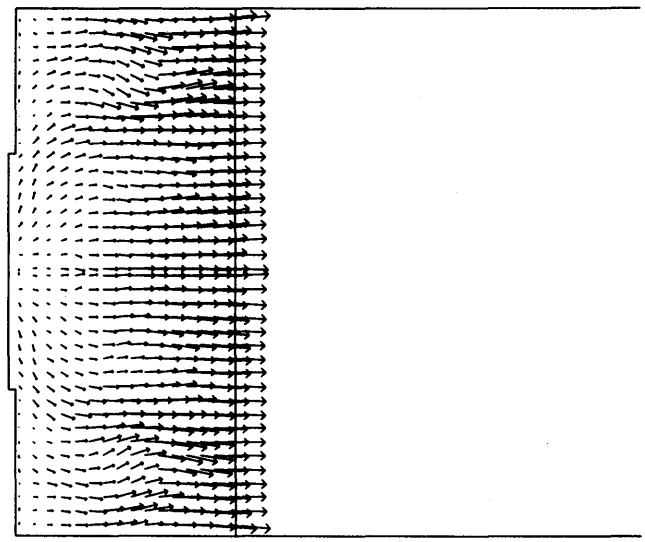

Figure 10—Time 28ms. Maximum velocity 12 m/s.

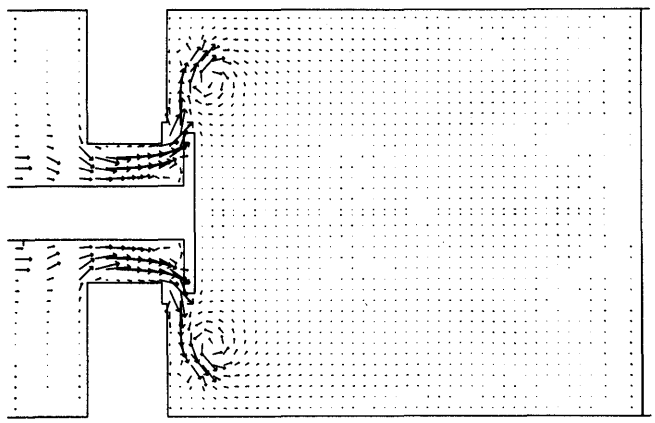

Figure 12—Time 36ms. Maximum velocity 48 m/s.

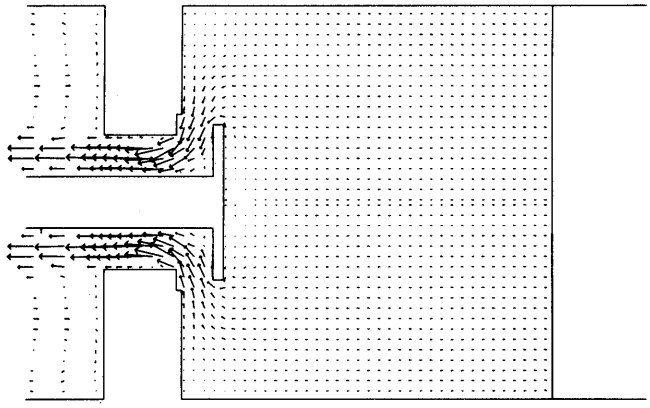

Figure 13—Time 40ms. Maximum velocity 113 m/s.

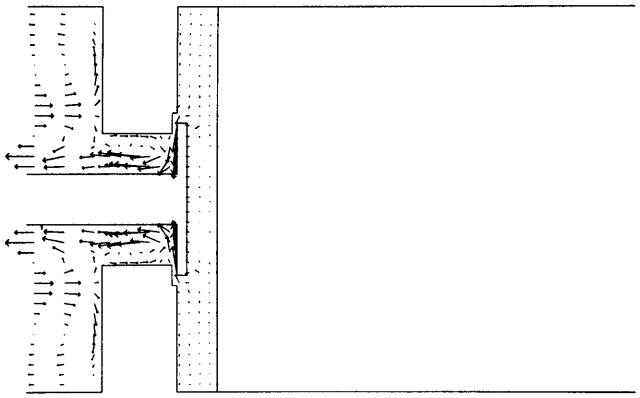

Figure 15—Time 48ms. Maximum velocity 46 m/s.

msec. The velocity at this time is two thirds the sound velocity.

These flow visualization calculations can consume significant amounts of computer time, particularly if a fine grid is needed to resolve the flow. Thus it is important in this kind of calculation to take maximum advantage of computer architecture and to have efficient algorithms for solving the equations. For example, the program used for the flow visualization calculation achieves a speed up of about a factor of two by using the parallel processing capabilities of the CDC-7600. Another factor of two was attained by using a more efficient algorithm for solving the equations. Thus a calculation which once took four hours of computer time can now be done in one hour.

In the examples presented of current research in computer modeling of automobile engine combustion, we have emphasized three major points. First, there are difficult theoretical problems which remain to be solved before many combustion problems can be effectively approached. For these problems, such as liquid atomization and turbulence, even the physical and mathematical formulations are not yet satisfactory. Major efforts are under way, directed towards solving some of these theoretical problems, and considerable progress can be anticipated in the next few years. Second, efficient numerical solution methods are needed in many cases where the mathematical model is satisfactory, but the computational methods are inadequate. Like in the case of chemical kinetics rate equations, where the development of stiff equation software made efficient solutions possible, problems remain which are primarily numerical in nature. One of the most prominent examples of this need is in the treatment of two-dimensional and three-dimensional geometrical problems involving spatial transport. At present, nearly all of the available solution algorithms for these problems are slow, unwieldy, and inaccurate, and a great deal of work needs to be done. The development of faster and larger computers, with new computer architectures, provides considerable promise in this area. Techniques which were not feasible on earlier computers may be attractive on vector pipeline or parallel processors. Finally, many additional limitations are placed on the productivity of computer combustion models by hardware limitations, particularly those of core size and computation speed. In this area as well, advanced computer development should be of great benefit to combustion research. The magnitude of the theoretical and computational tasks involved in modeling of automobile engine combustion makes it certain that this research will continue to require the most advanced computers and numerical techniques available. The automotive engine accounts for a significant part of current energy usage and an even larger share of the petroleum usage. Even small improvements in combustion properties can have a sizable impact in many areas, and computer modeling of automobile engine combustion has the capability to make significant contributions to improved combustion characteristics.

Computer modeling of automotive components and structures

by MOUNIR M. KAMAL and JOSEPH A. WOLF, JR.
General Motors Research Laboratories
Warren, Michigan

INTRODUCTION

After years of steady, predictable model changes, the American automobile industry is in the midst of the most intense product changeover in its history. By 1985, manufacturers must introduce new lines of vehicles which produce practically no pollutants, and which consume much less fuel. One obvious step in the solution is to resize the automobile, thereby producing a lighter, smaller vehicle, without sacrificing interior roominess and passenger safety. To accomplish the design of such a car, the structural engineer will need to use imaginative concepts and a variety of new materials. The computer is and has been an indispensable tool in carrying out these changes.

In the past, vehicle structural design was based on experience, extensive laboratory testing, and finally, proving ground evaluation and development. Analytic methods though available were extremely difficult, if not impossible to apply to the complex automobile structure (Figure 1). Emphasis, therefore, was on experimental determination of structural behavior and performance. However, the demands on the automobile designer increased and changed rapidly, first to meet new safety requirements and later to reduce weight in order to satisfy fuel economy requirements. Experience could not be extended to new vehicle sizes and performance data was not available on the new criteria. Mathematical modeling was therefore a logical avenue to explore. First, computer simulations of specific structural behavior were developed, especially in the area of automobile safety. Later the development of computer graphic packages allowed more accurate representation of automobile geometry with less engineering time required to generate the model. Most recently the finite element method, a computer dependent numerical technique, has opened up a whole new approach to vehicle structural design.[1]

The exponential increase in computerized analysis of automobile structures is reflected in the growing number of Society of Automobile Engineers (SAE) structural analysis papers presented in recent years. Over the last ten years, this increase has been at a compounded rate of 25 percent per year. A further sign of recent interest in finite elements and other structural analysis methods in the automotive industry can be found in the proceedings of two international conferences on Vehicle Structural Mechanics held in 1974 and 1977 by SAE.[2,3] The analytic methods discussed at these meetings made it possible to evaluate and optimize the automobile structural design.

Starting with the 1976 Cadillac Seville, all new General Motors automobiles have been evaluated and developed using the finite element method. Without these advanced computer aided analytic tools, it would not have been possible to make the progress that resulted in substantial weight reduction and still retain occupant safety, comfort and interior space requirements.

COMPUTER MODELS FOR VEHICLE SAFETY

In the early sixties, barrier impact testing was the only method available for evaluating the crashworthiness of a vehicle structure.[4] Later in that decade computer simulation techniques, based on test data, were used to help understand the dynamics of collision of both the vehicle[5] and the occupant.[6,7] In 1970 simulation was advanced to the point that the technique became a reliable design tool in the automotive industry. All these methods, however, required experimental inputs to represent the large plastic deformations in the structure. In particular, Kamal and Lin[5,8] represented the major vehicle structural components (such as the frame, sheet metal, drive line, fire wall etc.) as nonlinear resistances (Figure 2) whose force-displacement behavior are obtained from static crush tests. The body, engine, and transmission cross member are represented by lumped masses. The equations of motion are then solved in which the dynamic resistive forces of the crushing structures are each assumed to increase linearly with the instantaneous rate of deformation for that element of the structure. While these were important developments, there was still the need to solve the structural deformation problem analytically so that one could predictively assess the crashworthiness of a particular design. Given the irregular geometry of the automobile structure (Figure 1), the finite element method was a natural tool. Melosh and Kelly[9] outlined in 1967 the problems that would be encountered in applying the method to predict car crash

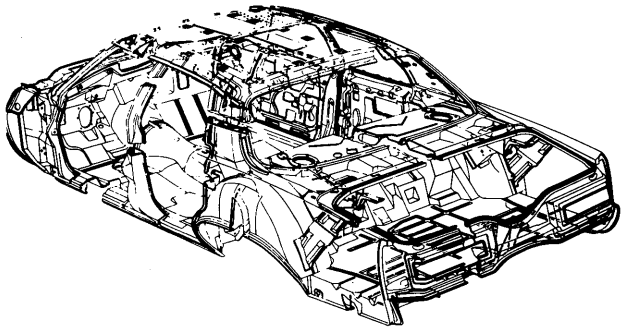

Figure 1—Typical automotive body structure

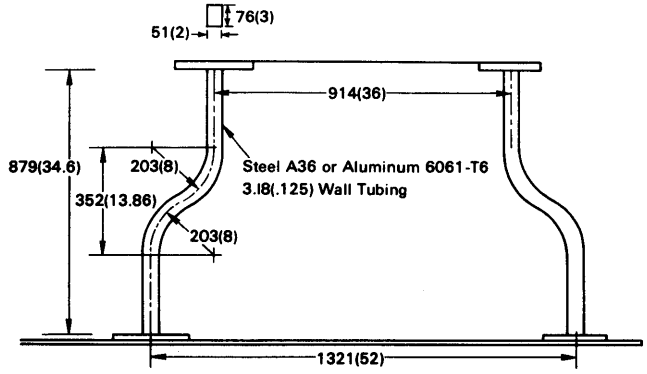

Figure 3—Dimension of curved box beam-column in mm (inches)

response. This, however, has yet to be accomplished for a full vehicle.

The structural problem to be solved is that of determining the dynamic forces and displacements for the automobile structure which is made up of shells, beams, corrugated panels, and irregular bars all subjected to large plastic deformations. Many of the components are made of thin-walled beams and columns whose sections collapse during these large high-rate deformations.

In the case of certain components or elements of an automobile structure, progress has been made. Ni[10] has modeled the impact response of a curved box beam-column using a finite element-finite difference technique. This type of structure (Figure 3) is used in the car frame and underbody structure. Good agreement with experimental measurements was obtained (Figure 4) for both aluminum and steel frames of various dimensions.

Chang[11] also discovered the importance of local deformation in his study of the automobile body structure. He presented an approximate technique for estimating the ultimate load-carrying capacity of the body structure without the need for experimental data (Figure 5). This procedure has been very useful in determining whether the body (or passenger compartment) will withstand the forces generated while the frontal structure crushes and decelerates the vehicle. It should be mentioned, however, that this is an ultimate load analysis quite different from what is needed in the frontal structure, namely the dynamic force-deformation function. Also metal panel deformations do not play as important a role in this problem as they do in frontal crush.

To summarize, computer simulation of vehicle impact is widely used to solve vehicle safety problems. Predictive analytic techniques are being developed, with progress being reported every year using numerical techniques heavily dependent on the digital computer.

VEHICLE MODELS FOR VIBRATION

Until the finite element method became available, dynamic modeling was on the basis of gross models with only a few degrees of freedom.[12] However, mathematical modeling using substructures or building blocks had been well understood for some time.[13] What was needed for implementation was the development of computers with large in-core storage capability to contain information on the large number of simultaneous equations or degrees of freedom required for a complete vehicle model. The final ingredient for success was the development of a "general purpose" structural computer code, which is user oriented, and has extensive documentation facilitating application by nonspe-

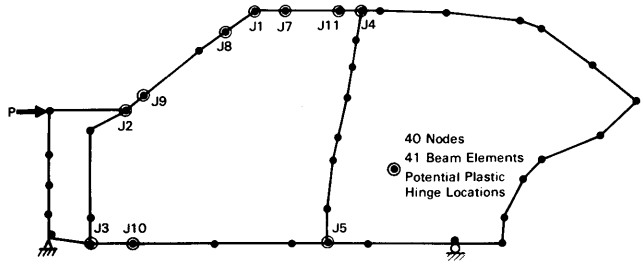

Figure 5—Finite element model of car body side structure

cialist design engineers. The NASA STRuctural ANalysis (NASTRAN) program is one such code.[14] A part of this user convenience has been the ease of model visualization and results interpretation arising from the choice of structural displacements as the unknowns in the formulation of the equations of motion.

Current methods

Within the last five years, complete vehicle structural models based on the finite element method have become a practical alternative to testing. More or less complete finite element models were described as early as 1970, by Selna and Salinas.[15] The method has been widely used both in the United States and overseas. This approach enables the analyst to generate a model based on structural blueprint dimensions and material properties, prior to any prototype build. Modeling is often done with enough detail so that the result may be used for examining local behavior as well as overall dynamic properties. The use of many thousand degrees of freedom (equations of motion) is not unusual. A typical model for a unit body car is shown in Figure 6. A typical beaming vibration mode shape resulting from computer finite element analysis of this car is shown in Figure 7.

The cost of performing a vibration analysis on a complete several thousand degree-of-freedom model can be prohibitively expensive even on a modern high-speed computer. Usually, dynamic degrees of freedom are needed only at points of significant mass and moment of inertia. Condensation techniques can be used in this case to reduce the unknowns to a more manageable number.[16]

Substructuring is also useful for cost and time savings.[13]

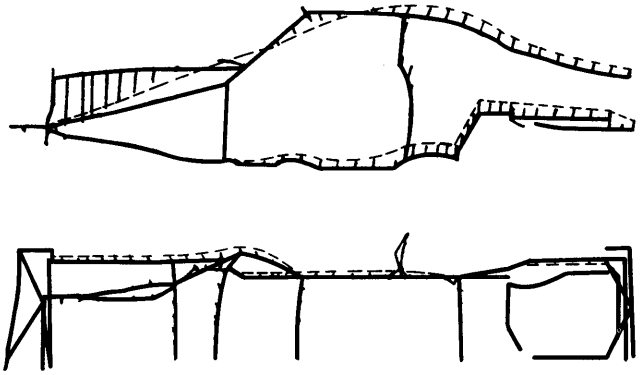

Figure 7—First beaming mode sprung mass model, 23.1 Hz

The key to success is the reduction in the total number of degrees of freedom (dof) as the model becomes more specific; that is, as we progress from a continuum (infinite dof), to a collection of finite elements (~2500 dof), to several substructures (~250 dof), to a structural system (~25 dof). This reduction procedure saves time and money in the computations without materially reducing our physical understanding. Substructuring is a good illustration of how one can extend the capabilities of the computer when the naive temptation is to represent more and more details in the hope of increasing the fidelity of the model.

Structural acoustics

Another area receiving considerable recent interest for modeling and computer solutions is low frequency vibrations (up to 200 Hz) of the interior volume of the passenger compartment. Finite element analysis is attractive for these systems of complicated geometry. Considering first the case of free vibrations, the passenger compartment air volume is subdivided into the usual finite element mesh, as shown in Figure 8. For low frequencies (less than 100 Hz), the sound pressure field has very little cross-body variation, and a two-dimensional model suffices.

The fluid mass and elasticity may be described relative to the finite element mesh as for a structural system. The calculations of natural frequencies and mode shapes then proceed in a straightforward manner.[17] The results are shown for four configurations of a station wagon in Figure

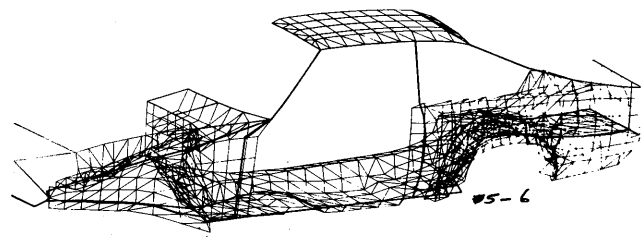

Figure 6—Model of unit body vehicle

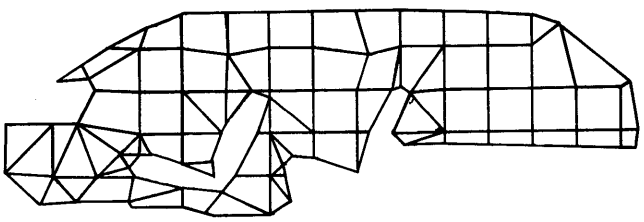

Figure 8—Finite element model of station wagon passenger compartment

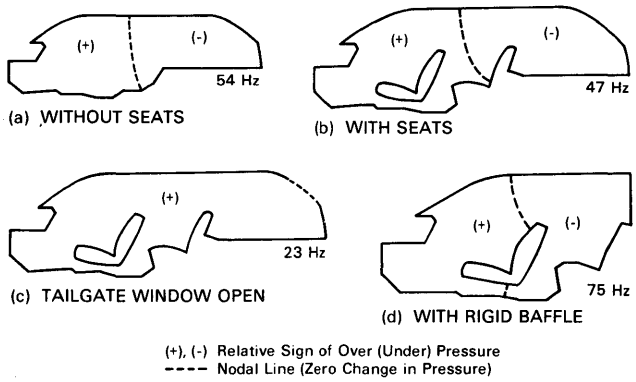

Figure 9—Acoustic mode shapes for four configurations of station wagon

9. The inclusion of flexible walls in the model is also easy to accomplish. Once the resonant properties of the compartment and surrounding structure are established, forced vibration analyses may be performed to predict the interior noise for various operating conditions.

Computer graphics

The magnitude of data input required for finite element models dictates the use of automated data generation and handling, usually using interactive computer graphics. At the General Motors Technical Center, the SMUG (Structural Modeling Using Graphics) Program[18] is based on earlier systems designed for recording and manipulating styling line data.[19] This program allows the analyst to generate a finite element model automatically from styling data during an interactive console session. The program output is a structural data file ready for input to NASTRAN. A typical plate model constructed using SMUG is shown in Figure 10.

Computer graphics is useful in several other areas, including checking finite element models for errors, and generating output plots of vehicle vibration modes. Graphics programs have also been developed for detecting interference among solids and surfaces, a prerequisite for allocating vehicle interior space efficiently.[20]

VEHICLE MODELS FOR RESIZING AND OPTIMIZATION

Resource and fuel savings are directly related to resizing and optimization of vehicle components. The availability of the computerized structural analyses discussed in previous sections of this paper led to the ability of automotive designers to resize production vehicles quickly without sacrificing interior roominess and passenger safety. For example, 1978 GM intermediate cars have been lightened by 310 kg (685 lb) on the average (Figure 11). The initial resizing resulted in a 68 kg (150 lb) savings. Subsequent compounding effects led to a total 15 percent mass reduction. These compounding effects result when weight reduction in one area permits reduction in another area. A good example is the bumper system. Clearly a narrower car needs a narrower bumper, saving 4 kg (9 lb) from resizing. Moreover, by reducing the total car mass through resizing of other components, the bumper requirements dropped, leading to an eventual overall savings of 30 kg (67 lb).

The next step in this process of design improvement might be to computerize the selection of a "best" design based on numerical criteria. This optimization process is an area of

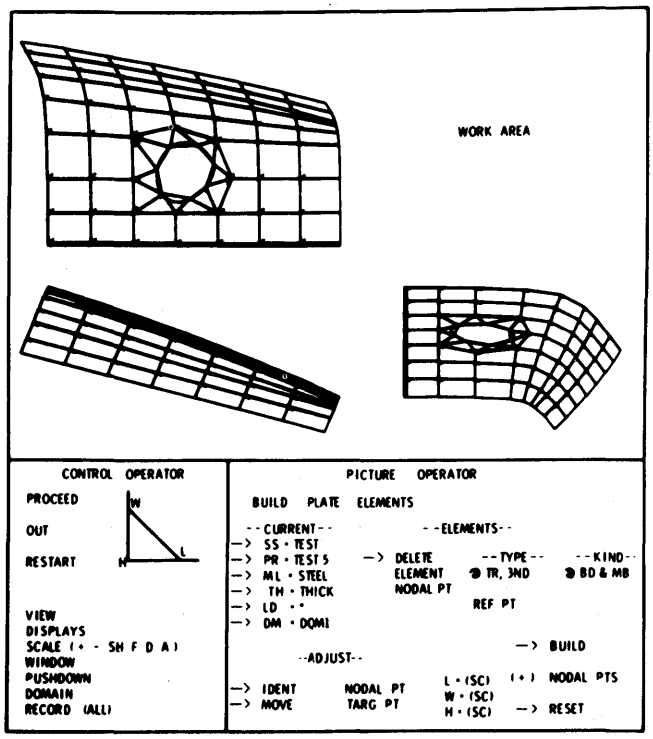

Figure 10—Display console screen image showing plate model

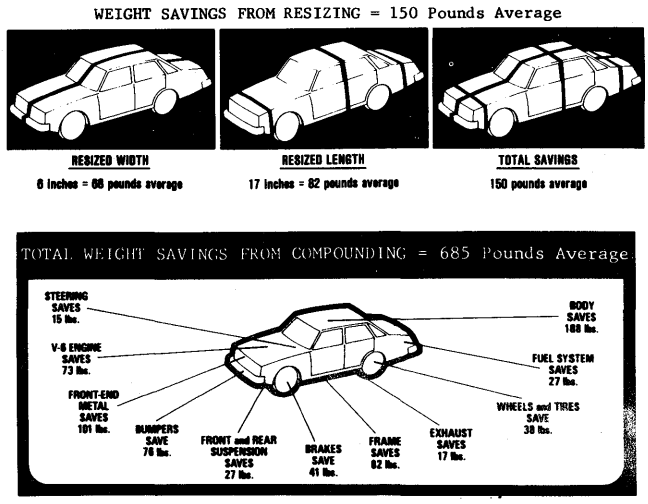

Figure 11—Weight savings from resizing

current research interest, and has resulted in recent papers on ride quality enhancement[21] and optimized vehicle crush resistance.[22] This concept of design through analysis has also been applied to the construction of an experimental automobile structure,[23,24] producing results of use in guiding production vehicle designers.

Material substitution studies

Another aspect of car design which can produce large mass and energy savings is that of material substitution. Using the technology of computer structural analysis and given explicit design criteria, the designer can quantify his engineering judgment regarding the benefit of a material substitution. For example, the effect on bending and torsion vibrations produced by a change in the mass of a "non-structural" hood panel of aluminum, or a change in the stiffness of a frame rail can be determined quickly using the computer. The various types of structural requirements to be considered in a material substitution study are discussed in a recent paper by Chang and Justusson.[25]

Computer stress analysis

In addition to the overall stiffness and dynamics computer models which have proved essential for vehicle resizing and material substitution studies, there has been considerable usage of finer mesh analysis models for computer stress analysis studies. Several papers representative of industry accomplishments in providing lighter, more efficient component designs appear in References 2 and 3. Problems dealt with include stress analysis of doors and other sheet metal parts, thermal stresses in brake drums, engine and transmission component design, stress analysis of a rear axle carrier, stress and deflection analyses of truck and tractor roll-over protection structures, calculation of gear stresses, stress and deflection analyses of (possibly nonlinear) suspension springs, and turbine and radial compressor component analysis.

FRICTION AND DRAG REDUCTION

Friction and drag reduction is another area of opportunity for the automotive engineer responsible for producing an energy and resource efficient vehicle. Because of the high degree of sophistication needed to model these phenomena, this area is one where the computer has already been of considerable use and has great future potential. This section will be divided into three parts, discussing aerodynamic drag, tires and lubrication.

Aerodynamic drag

Because of its timeliness and importance in fuel economy studies, this subject was the topic of a recent GM Research Laboratories symposium.[26] For current cars, the rolling resistance (due to the mechanical parts of the vehicle) and aerodynamic drag are about equal near 50 km/h (30 mph), but the aerodynamic losses are twice the mechanical losses at 90 km/h (55 mph).[27] As mechanical improvements occur, this trade-off speed will drop, emphasizing the aerodynamic losses more in the future.

The potential for energy savings is substantial. A 40 percent reduction in aerodynamic drag is felt to be feasible by aerodynamicists,[27] and might produce a 15 percent increase in fuel economy. Although the opportunities for energy savings are great in this area, direct computer assistance has been small to date due to the turbulent and usually unsteady nature of the three-dimensional flow field. Problems and prospects for analytical solutions in this area are discussed by Landahl[28] and by Hirt and Ramshaw.[29] At present, a finite difference technique has been applied to some problems, with finite element methods offering a second approach in the future.

Tires

Tire mechanics has been an active research area recently, and was the subject of a short course at the University of Akron in 1977. The variety of available numerical simulation techniques is discussed in one section of the course notes.[30] More specifically, because tire rolling losses are an important energy dissipator at all speeds, the relationship between tire rolling losses and fuel economy was the subject of a recent SAE-DOT research and development planning workshop. Discussion included the topics of numerical simulation of rolling tires and an analytical method for tire power loss calculations.[31]

Lubrication

The refinement of modern lubrication theory is of importance to the automotive engineer in reducing internal friction losses to the theoretical minimum. These losses occur not only in bearings, but also as friction between piston rings and cylinder wall (=25-50 percent of engine mechanical losses). Progress in this area has been impressive, in good measure due to the availability of large computers. Research on the film profiles which minimize the coefficient of friction and the total friction force for a given load in a slider bearing[32] are being extended to consider minimum friction loss in two-dimensional slider bearings, and in non-steady lubrication (i.e., piston rings sliding in an engine cylinder[33]).

Analysis of journal, thrust, and slider bearings has now been brought to the point of permitting a design engineer to correctly size such components interactively using computer aided design programs. For given geometry and material inputs, the computer immediately displays operating load, temperature, and power loss results. The designer can quickly refine the design to fit his needs.[34]

SUMMARY

Computer application in the automotive industry has had a rapid growth in the past 15 years. The world energy problem is but one of the challenges of recent times following safety and emissions. Computer models and methods are being used today to reduce weight, resize the automobile, reduce friction of moving parts, reduce aerodynamic drag, substitute materials, and assure product reliability and safety. This trend will continue and intensify in automotive engineering as progress is made in both computer hardware and the applied sciences.

The development and application of a mathematical model of enhanced oil recovery

by HARVEY S. PRICE

INTERCOMP Resource Development and Engineering, Inc.
Houston, Texas

INTRODUCTION

A great deal of attention has recently been focused upon "enhanced oil recovery"; that is, the application of recently developed processes for recovering oil that would normally remain in a reservoir following depletion by conventional techniques. Since this heretofore unrecoverable remaining oil amounts to about 300 billion barrels in the U.S. alone (see Figure 1), one can see why enhanced recovery is getting so much attention.

Among the broad class of enhanced oil recovery processes are processes called chemical flooding. These chemical flooding processes are extremely complex and really not completely understood. For example, a chemist in the laboratory can design a process which will recover 80 to 100 percent of the oil-in-place from a representative piece of reservoir rock; however, when these same systems are applied in the field, recoveries have ranged from 15 to 65 percent. This implies that there are interactions which sometimes occur in the reservoir that are sufficiently off design relative to laboratory work, to result in near or total process failure. To this technical uncertainty, add the problems of selecting a specific process for a given reservoir and the tremendous economic uncertainties that still exist; we see why chemical flooding is not projected to recover substantial amounts of oil for this country by the year 1985.

One way to accelerate the amount of oil recovery from chemical flooding is to obtain a better understanding of what takes place in a chemical flooding project. This understanding can be achieved through the interaction between mathematical models, laboratory results and actual field experiments. Much work is going on in the laboratory, and much work is going on in the field. However, until very recently there did not exist a mathematical model which could be used to better evaluate and understand the complex physics involved in all these processes and be used to scale the laboratory results to the field. INTERCOMP has developed such a chemical flooding model, and the development and application of this model is the subject of this paper.

The term "chemical flooding" used here is only one of many names used by the oil industry to describe similar oil recovery processes. Other names include micellar-polymer flooding, low tension waterflooding and soluble oil flooding, as well as several trademarked names for processes developed by specific companies. These have in common the injection of a chemical, normally a surfactant (or soap) to reduce the forces that trap oil in the rock in the presence of water. With these forces reduced, the oil can be mobilized and driven to a production well. Although the process is simple in concept, the specific interactions of the fluids involved are quite complex.

In order to model the behavior of chemical flooding, a number of primitive unknowns need to be identified and the complex partial differential equations which describe mass balances on these unknowns need to be solved in one, two and three dimensions. This, however, is not all of the problem. Because of the important physical processes which are taking place, the mathematical solution of these equations needs to be far more accurate in some instances than in any other petroleum recovery technique which is currently being routinely modeled. This paper presents results of some approximations which have been successfully used by INTERCOMP to generate solutions with acceptable accuracy.

This model is currently being used in an application to help engineer a micellar-polymer flood in the Bell Creek field for Gary Operating Company. The model has been effectively used to characterize two quite different chemical flooding processes and has aided Gary in selecting the process which will be used in the field. A discussion of the selection process and some preliminary engineering results which should enhance the performance of Gary's field pilot are also presented. While the discussion of the Bell Creek Project is very preliminary, we believe that this is the beginning of an understanding which will ultimately lead to much better agreement between project design and field performance. If this goal is achieved, we will be well on our way to knowing how many of the 300 billion barrels of now unrecoverable oil can be recovered economically.

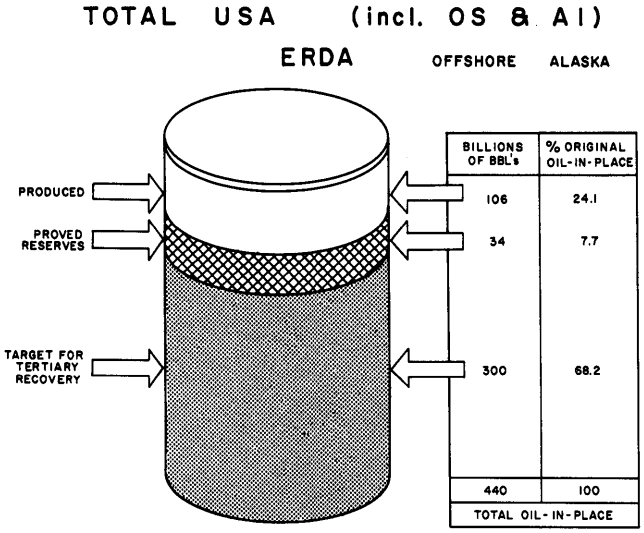

Figure 1

SPECIFIC TREATMENT

Chemical flooding is the name we shall use to denote these reservoir processes characterized by the injection of an agent to reduce the surface tension between oil and water and, hence, allow the displacement and recovery of oil that is normally trapped by capillary forces as a waterflood residual. The process is known alternatively throughout the industry as miscible-type waterflooding,[1] micellar flooding,[2,3] low tension waterflooding,[4] surfactant flooding,[5–7] and soluble oil flooding.[8]

Although chemical flooding could be applied for secondary as well as a tertiary oil recovery, the typical chemical flooding candidate is currently a watered-out oil zone; the in situ water being a normal oil field brine, high in total dissolved solids and divalent cations. The chemical flooding process thus consists of (1) a brine preflush to condition the formation and provide a controlled fluid environment that will allow optimum activity of the following surfactant system; (2) a small slug of a surfactant fluid, generally consisting of a dilute concentration of petroleum sulfonate in brine, with the possible additions of cosurfactants, polymers and other chemicals to stabilize the system, enhance the surfactant activity, reduce adsorption losses and control slug mobility; (3) a mobility control slug consisting of a dilute solution of polymer in brine, used to protect against backside dilution or overrunning of the surfactant slug by drivewater and to enhance areal and vertical sweep efficiency; and (4) a waterdrive to sweep the displaced oil, water and injected fluids to the producers.

As pointed out by Knight et al.,[15] use of a brine preflush is not universal and certainly there are nuances that are unique to each company's process. However, the above description appears to be the generally accepted characterization of the chemical flooding process.

The fluid characteristics and transport mechanisms important to the chemical flooding process have been studied extensively throughout the industry. A few of these studies are described in References 1-14 and we have included in our model the mechanisms and fluid properties indicated to be significant.

The chemical flooding system can be represented by six species or components flowing in a maximum of two phases. We may think of species one through six as water, oil, polymer, surfactant, salt and divalent ions, and denote the phases as aqueous and hydrocarbon. However, if we write the conservation equations for species three through six as to allow for (a) partitioning between aqueous and hydrocarbon phases, (b) adsorption on the reservoir rock, and (c) bulk transport and dispersion in both phases, other systems may be examined as well. In fact, the formulation used should allow the study of all of the mechanisms which have been indicated by the literature to be important.

Model formulation

The chemical flooding model solves for six components (or species) in two fluid phases. All six components may partition amongst the aqueous and hydrocarbon phases. Four components may disperse by both molecular diffusion and mechanical dispersion in both the longitudinal and transverse direction and in both phases. The same four components may adsorb on the reservoir rock, satisfying equilibrium sorption isotherms.

The primitive unknowns to be solved for by the simulator are:

- WA1 Mass fraction of water in the aqueous phase
- WH2 Mass fraction of oil in the hydrocarbon phase
- WA3 Mass fraction of component three (normally polymer) in the aqueous phase
- WA4 Mass fraction of component four (normally surfactant) in the aqueous phase
- WA5 Mass fraction of component five (normally monovalent salt) in the aqueous phase
- WA6 Mass fraction of component six (normally divalent salt) in the phase saturation
- SA Aqueous phase saturation
- p Aqueous phase pressure

The equations to be solved by the simulator are:

Component 1 (Water)

$$\frac{\partial}{\partial t}(\phi S_a \rho_a WA1 + \phi S_h \rho_h SH1) + \nabla\cdot(\rho_a WA1 \tilde{U}_a + \rho_h WH1 \tilde{U}_h) - \tilde{q}_1 = 0 \quad (1)$$

Component 2 (Oil)

$$\frac{\partial}{\partial t}(\phi S_a \rho_a WA2 + \phi S_h \rho_h WH2) + \nabla\cdot(\rho_a WA2 \tilde{U}_a + \rho_h WH2 \tilde{U}_h) - \tilde{q}_2 = 0 \quad (2)$$

Component 3 (Polymer)

$$\frac{\partial}{\partial t}(\phi_p S_a \rho_a WA3 + \phi_p S_h \rho_h WH3 + \phi \rho_{r3}) + \nabla\cdot(\rho_a WA3 \tilde{U}_a + \rho_h WH3 \tilde{U}_h) - \nabla\cdot(\phi_p S_a \rho_a \underline{\underline{K}}_{a3} \nabla WA3 + \phi_p S_h \rho_h \underline{\underline{K}}_{h3} \nabla WH3) - \tilde{q}_3 = 0 \quad (3)$$

Components 4 (surfactant), 5 (monovalent salt) and 6 (divalent salt) equations are the same as that for Component 3, except that ϕ_p is replaced by ϕ.

There are three constraint equations for the system. The first requires the sum of saturations be equal to one. This equation is satisfied by setting $S_h=1-S_a$ in a six component balance equations. The other two constraint equations require that the sum of the mass fractions in each phase equal one. These equations are left explicitly in the formation as Equations (7) and (8). By ordering the unknowns as shown on the list of primitive unknowns, Equations (7) and (8) eventually become the "saturation" and "pressure" equations.

Assuming an isothermal system with compositions independent of pressure, we have the following equilibrium relationships for partitioning of species one through six between the aqueous and hydrocarbon phases and for adsorption of species three through six on the reservoir rock:

$$WHi=f_i(WAj)_{j=1-6} \quad \text{for i=1 through 6} \tag{9}$$

$$\rho_{Ri}=f_{Ri}(WAj)_{j=1-6} \quad \text{for i=3 through 6} \tag{10}$$

For equations of state, we have

$$\rho_a=\rho_a(WAi,p_a)_{i=1-6} \tag{11}$$

$$\rho_h=\rho_h(WHi,p_h)_{i=1-6} \tag{12}$$

$$\tilde{U}_a=-\frac{k_a}{\mu_a}(\nabla p_a-\rho_{ae}g\nabla D) \tag{13}$$

$$\tilde{U}_h=-\frac{k_h}{\mu_h}(\nabla p_h-\rho_{he}g\nabla D) \tag{14}$$

where

$$k_a=k_a(S_a,WAi)_{i=1-6} \tag{15}$$

$$k_h=k_h(S_a,WAi,\tilde{U}_a)_{i=1-6} \tag{16}$$

$$\mu_a=\mu_a(WAi,S_a,\tilde{U}_a)_{i=1-6} \tag{17}$$

$$\mu_h=\mu_h(WAi,S_a)_{i=1-6} \tag{18}$$

Assuming that the capillary pressure is a function of both saturation and composition, we have finally

$$p_h=p_a+P_c(S_a,WAi)_{i=1-6} \tag{19}$$

MODEL SOLUTION

As if developing numerical solutions to Equations (1) through (19) is not complex enough, the numerical solution needs to be extremely accurate in order to be able to model the phenomena of dispersion and fingering. If it weren't for these special problems, the numerical solution to Equations (1) through (19) could follow any normal finite difference or finite element type approximation, and for this reason will not be addressed in this paper. We will, however, address our attention at the specific problems of dispersion and fingering since these are truly important physical phenomena to be modeled and help to make some of the interesting points of this paper.

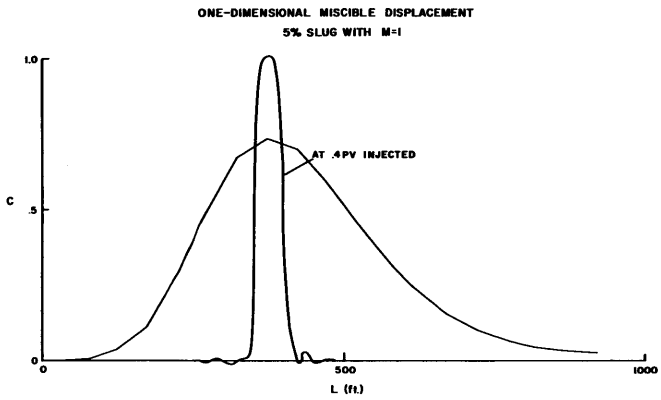

Figure 2

Figure 2 is included here to illustrate the effects of numerical dispersion. This figure displays the results of a simple, one-dimensional calculation. If the solution were infinitely accurate, the high spike shown on this figure would result from the effects of actual physical dispersion on the solution. As you can also see on Figure 2, the very smeared curve displays the effects of large numerical truncation error which has the exact same effect as a large physical dispersion. Figure 3 is an illustration depicting the phenomenon of viscous fingering. This occurs whenever a more mobile fluid is injected into a less mobile fluid; the more mobile fluid wants to finger through the less mobile fluid to the producing well providing a thief zone for the injected fluid. This phenomenon results in cycling of the injected fluid without really displacing the fluid in place. In chemical flooding, because the costs of the chemicals injected are so extremely high, all of the processes are designed around putting in as little chemical in the ground as is absolutely necessary.

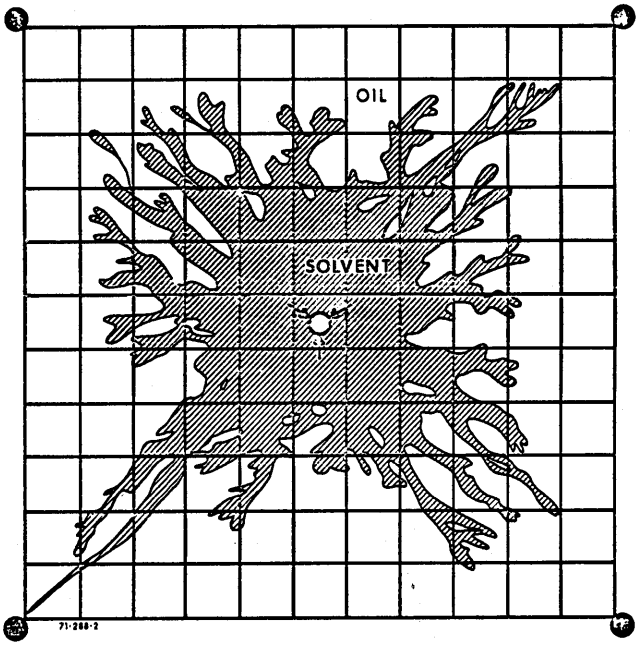

Figure 3

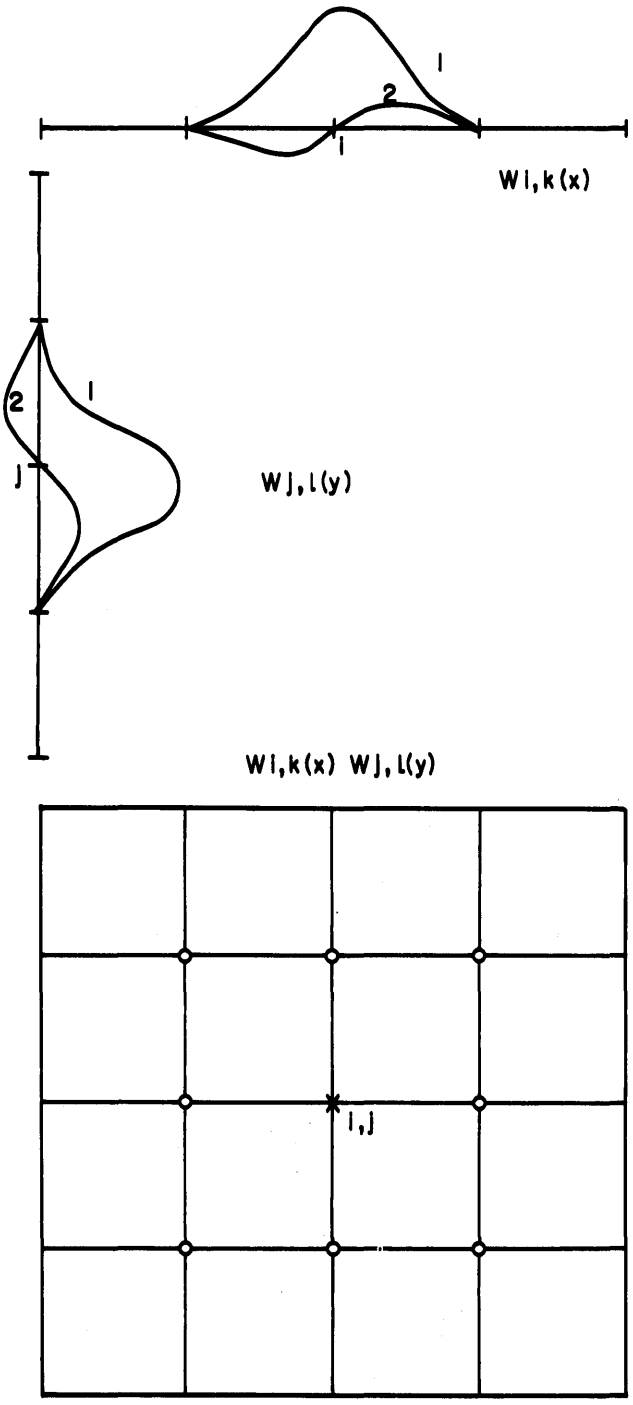


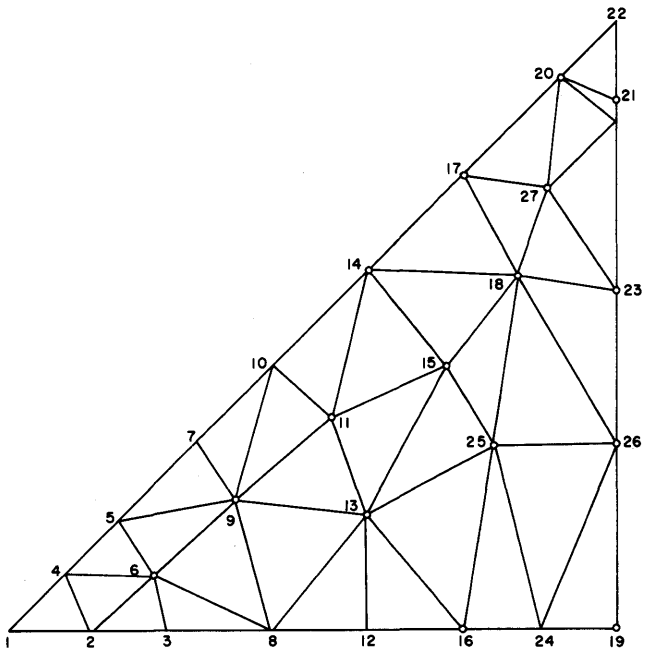
HERMITE PIECEWISE CUBIC ELEMENTS

Figure 4

Because of this, the effects of both physical dispersion and viscous fingering are extremely important in the field and need to be modeled accurately if realistic results are to be obtained.

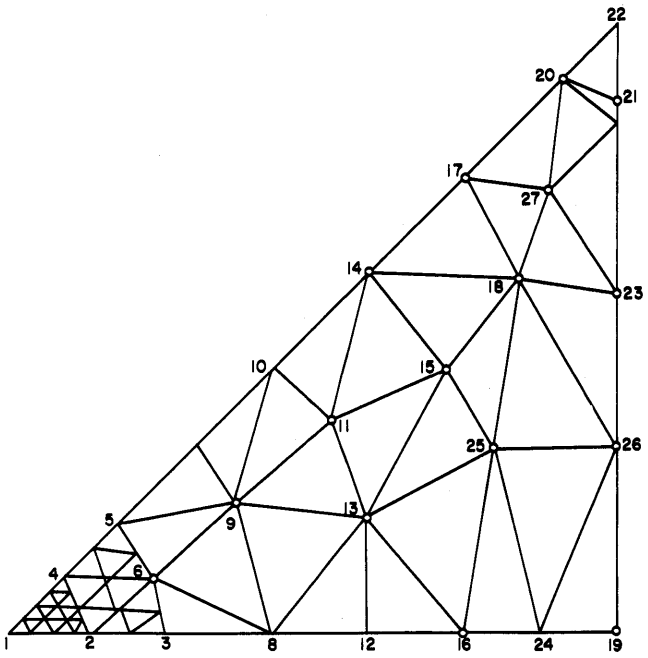
There are two approaches to solving partial differential equations describing the chemical flooding process and still be able to achieve the kind of accuracies required in order to model dispersion and fingering. The first approach is to use high order finite element approximations and the second approach is to use some local grid modification such that the accuracy can be concentrated in the areas where it is required and coarse grids can be used elsewhere. The high order finite element approximations are depicted by Figure 4 where I have illustrated here third order, cubic Hermite polynomials which can very effectively be used to generate fourth order accurate approximations. Figures 5, 6 and 7 illustrate a specific type of local grid refinement. Here we have an original triangle grid in Figure 5 and two levels of refinement shown right at the injection well which is in the lower left-hand corner of Figure 6. Figure 7 illustrates a later point in time when this refinement has moved in somewhat away from the injection well in order to accurately describe a front which is moving away from the injection well. This is a local refinement that needs to be time varying and move along with the front.

To illustrate the importance of these phenomena, I've shown on Figure 8 the effects of dispersion on recovery. You will note that as the physical dispersion is reduced, the peak concentration of the injected slug is increased and, therefore, the amount of oil recovered by continuous displacement of the injected fluid is significantly increased. Figure 9 is an illustration of a computer plot which shows a first order approximation to the injection of a slug of displacing fluid at a one-to-one mobility ratio. You will note how dispersed this particular slug is relative to Figure 10, which represents a fourth order correct solution to this problem. You will note also Figure 11 where the use of local grid refinement has been used how much sharper and higher the



MACRO TRIANGULATION

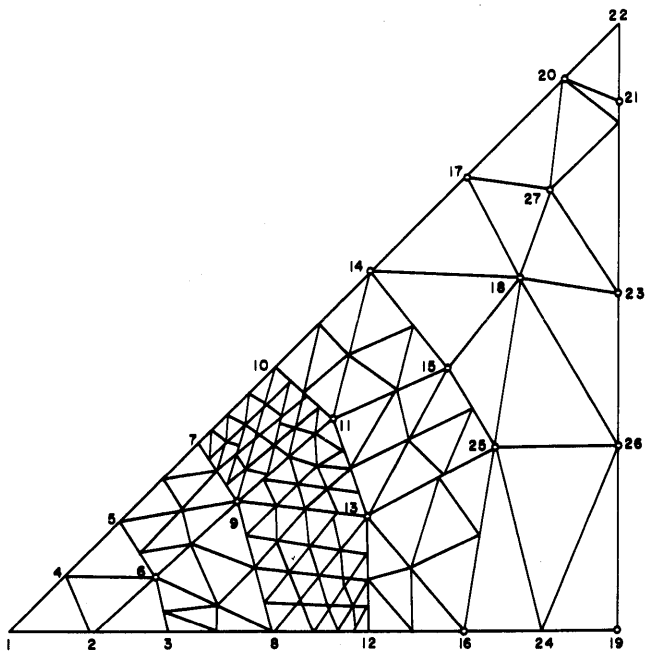
Figure 5



MACRO TRIANGULATION

LOCAL REFINEMENT

Figure 6



MACRO TRIANGULATION

LOCAL REFINEMENT

Figure 7

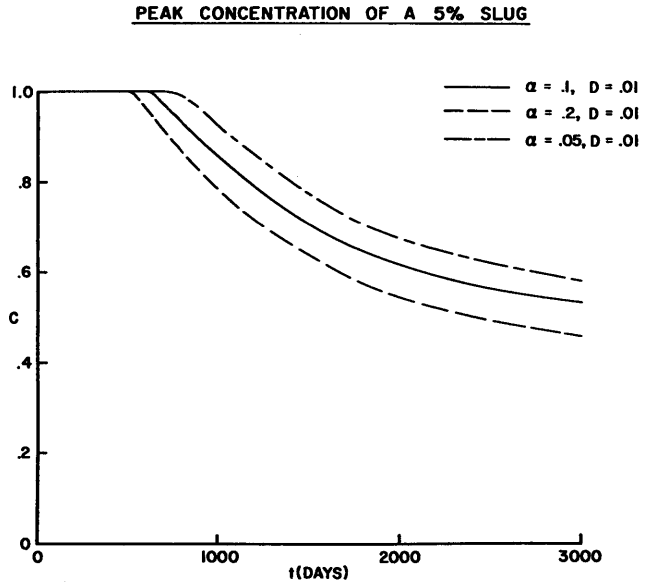


Figure 8

peak slug concentrations are than in Figure 9. Figure 12 is an illustration of a fourth order finite element approximation's ability to actually model viscous fingering in an unfavorable mobility ratio displacement and Figure 13 is an illustration of how the model is able to accurately predict recoveries at low dispersion levels for unfavorable mobility ratio displacements by introducing nominal heterogeneities into the system to propagate viscous fingers.

One further phenomenon which results when finite difference approximations are used to model unfavorable mobility ratio displacements is that of grid orientation. Figure 14

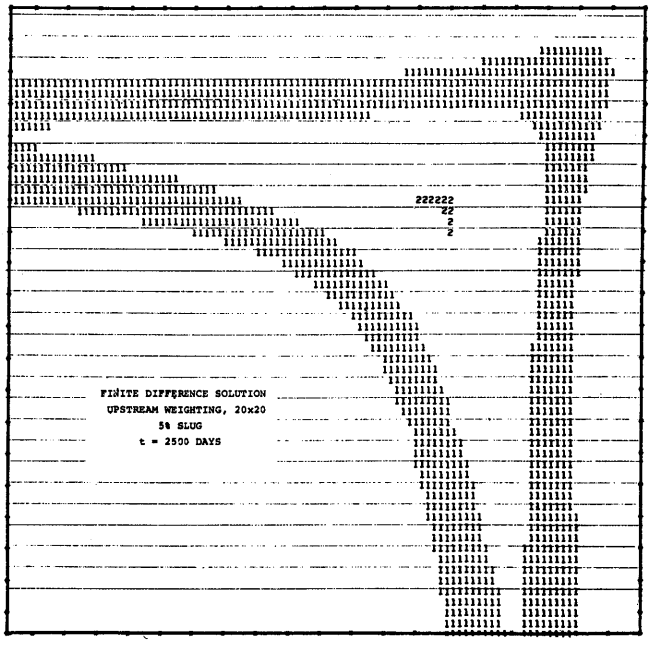

Figure 9

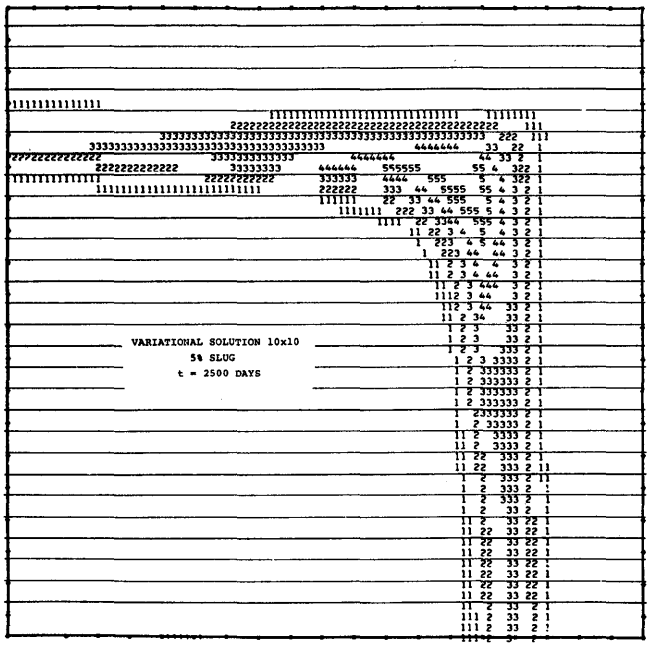

Figure 10

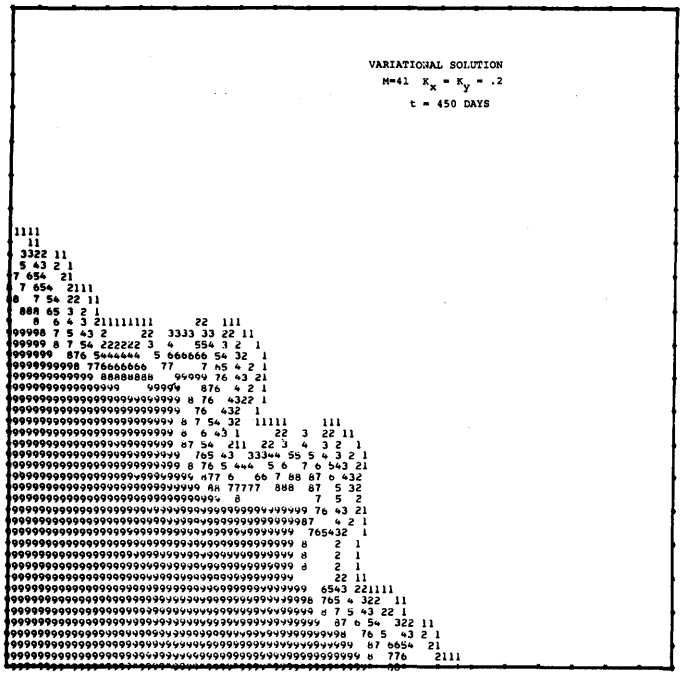

Figure 12

shows a repeated five-spot pattern and illustrates the two different grids that could be used to represent the flow of fluids in a five-spot. You will note that if the regions are totally homogeneous and if all the injection wells have the same rates and all the producing wells have the same rates, each of these repeated patterns should perform identical to

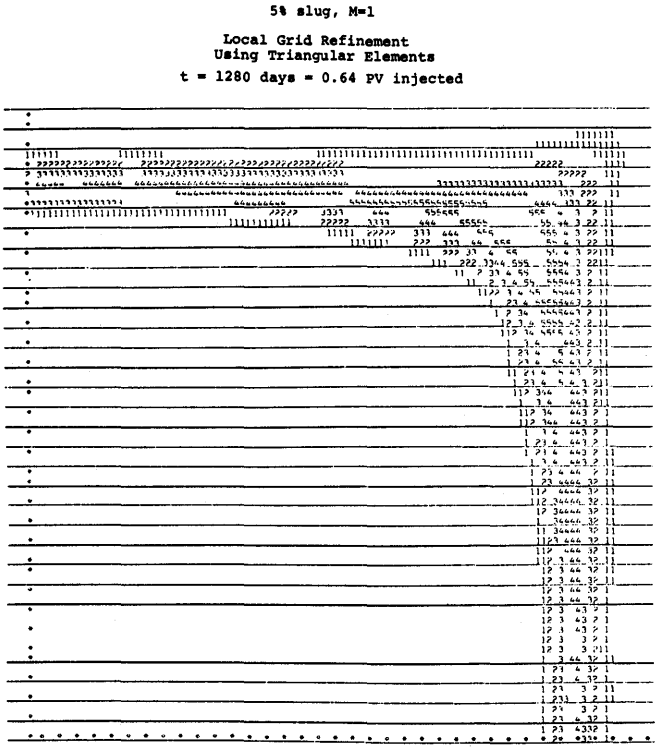

Figure 11

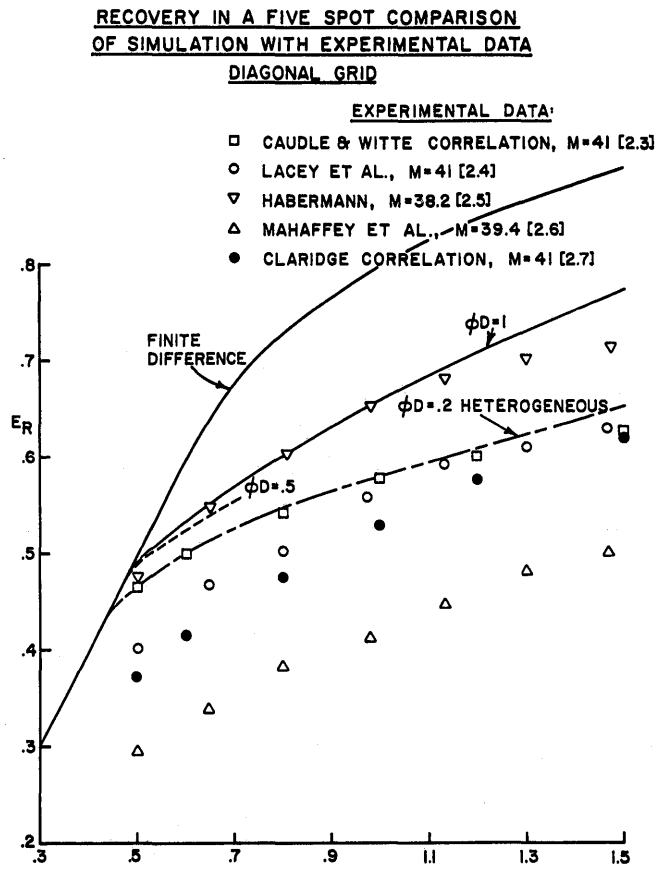

Figure 13

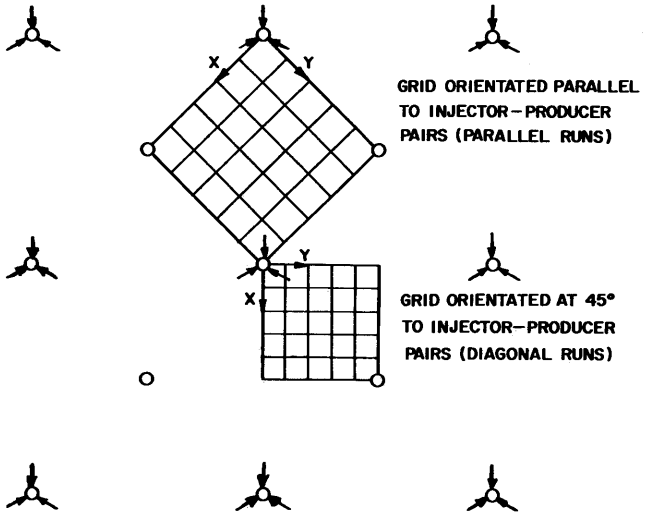

GRID ORIENTATION FOR SIMULATION OF DISPLACEMENTS IN FIVE-SPOT SYMMETRY ELEMENTS

Figure 14

every other repeated pattern. You will note from this figure that one of the grids is parallel to the coordinate axes while the other grid is running at an angle of 45° to the coordinate axes. These two grids are called parallel and diagonal for the sake of discussion. You will note in Figure 15 how the recovery performance for a very simple displacement process can vary depending on whether one uses the parallel or the diagonal grid. As mentioned before, these results should be identical and yet there is as much as a 20 percent difference in the recovery of oil after one pore volume of fluid injected. This is clearly an intolerable error and needs to be eliminated. It can also be seen on this same curve that high order finite element approximations do not exhibit this grid orientation phenomenon. In fact, none of the finite element approximations exhibit grid orientation effects which plague finite difference schemes.

We have illustrated in this section how the problem of describing a physical process such as chemical flooding requires numerical approximations which not only solve complex partial differential equation with complex nonlinearities, but which also must describe the important physics of the problem. Finite element approximations are definitely recommended when high order accuracy to model effects such as physical dispersion and/or viscous fingering are required.

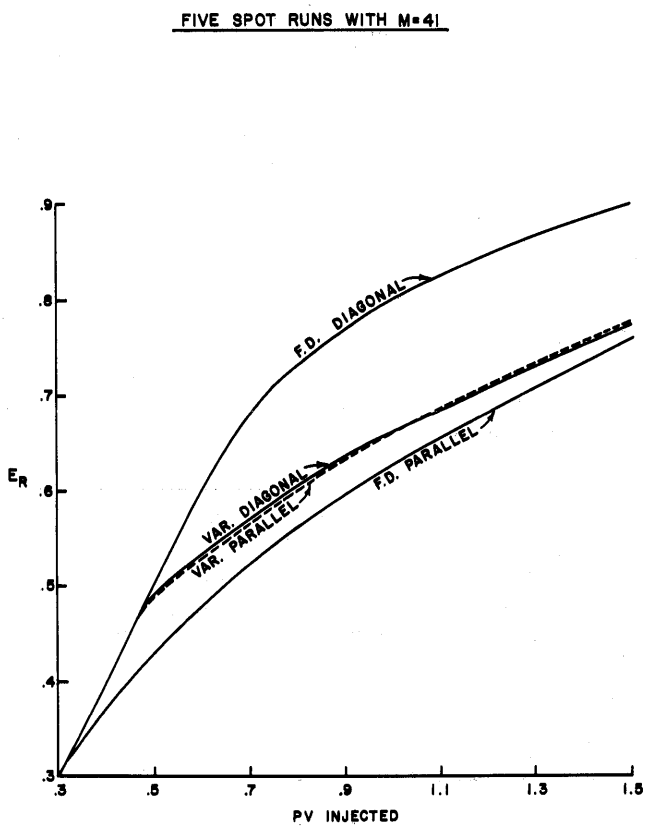

Figure 15

MODEL APPLICATION

Once a complex physical model, such as the one described by Equations (1) through (19), has been coded and debugged and running smoothly on a large-scale digital computer, one of the first things that needs to be done is to validate the model against actual physical processes in order to determine that the model does in fact describe the complex physics that it was intended to describe. This is really the stage of model development in which INTERCOMP is currently engaged; however, we have modeled two complex chemical flooding schemes and will illustrate here how the model was utilized in these particular instances.

The actual study that was performed was to model two competing design philosophies and to utilize the model to determine which of these should be implemented in Gary Operating Company's Bell Creek micellar-polymer pilot. The two chemical design philosophies which were modeled were (1) a small slug high concentration "soluble oil" system, and (2) a large slug dilute concentration, "optimal salinity" design.

A number of laboratory experiments were run in order to obtain basic data for the model as well as to test the design philosophies in displacing oil from the Brea core. While a large number of experiments were actually modeled, I have chosen just two here to illustrate the actual capabilities of the chemical flood program. You will note from Figure 16 how good an actual match was obtained for a .09 pore volume slug using the high water content "HWC" process and from Figure 17 we have illustrated the match for the soluble oil process using a .03 pore volume slug. The interesting features about these history matches were that both

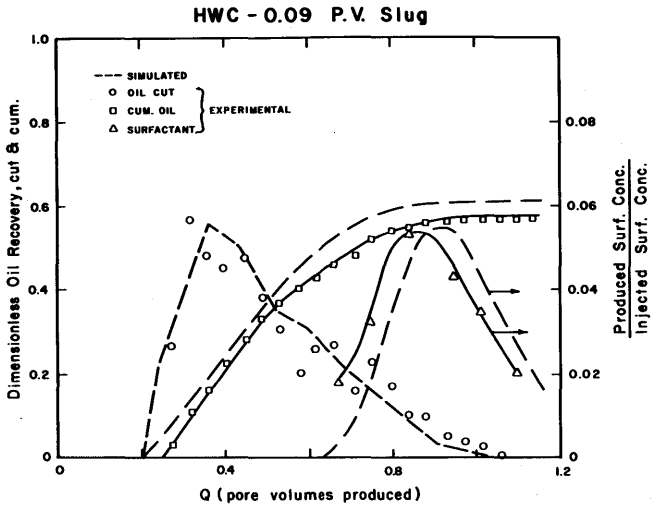

Figure 16

model runs utilized basically the same data and that only the different description of the physics resulted in the different model predictions. While these history matches are not perfect, they could easily have been further adjusted and fine tuned. However, it was not felt that this was necessary since the purpose here was really to demonstrate the model's capability to describe the physics of the two completely different systems. Once the history match was obtained then the model was used to predict the ultimate recovery from the cores using various weight percent surfactant concentrations. You see from Figure 18 that here again the model did an excellent job of reproducing laboratory experiments and that clearly the soluble oil system, at least in the core, was significantly better than the high water content process.

Once this history match was obtained the model was then utilized to make both areal and vertical cross section runs to see how these processes might deteriorate in the field. It

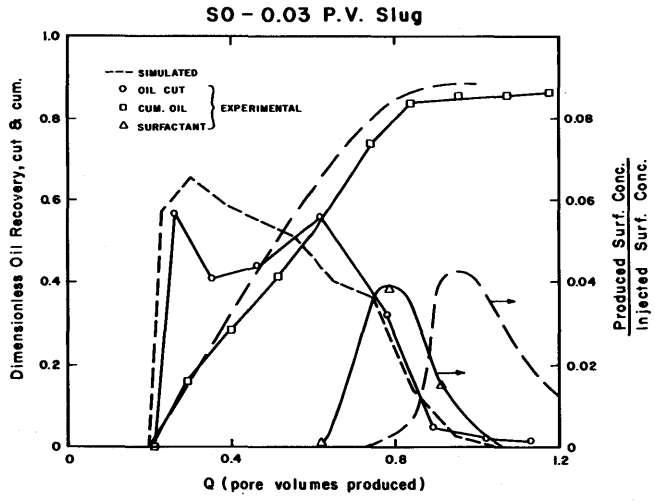

Figure 17

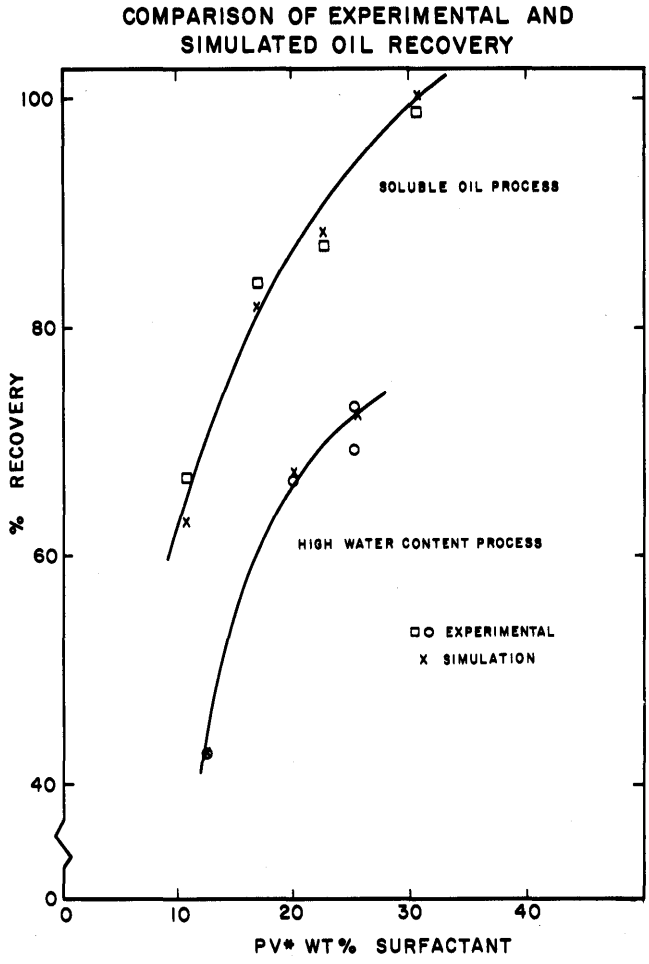

Figure 18

is interesting to note that once we made these runs and combined the areal and the vertical runs to estimate what would be recovered from the pilot that the model predicted a 55 percent recovery with a soluble oil process and only a 35 percent recovery with a high water content process. These results are still preliminary since we did not at this point look at any degradation due to layering for these systems. However, it is very interesting to note that a process which recovers almost 90 percent of the oil in a core would be predicted to recover only 55 percent of the oil in an idealized pattern. This is far more like what is actually being observed in the field and is extremely encouraging that we have now reached the point where mathematical models can be used to predict oil recovery by chemical flooding.

Again while this work is still very preliminary, I would like to point out one other very interesting thing that has been learned to date from this particular study. The field pilot has been designed as a five-spot with this expanded to the full field originally if the pilot is successful. However one of the interesting things that was noted in this work is that because of the diverging nature of the flow in a five-spot as the slug moves away from the injection well very

little oil is displaced around the edges of the pattern. In fact, almost no oil is being mobilized around the edges and most of the oil being recovered from the pilot is coming right out of the stream tubes that run between the injector and the producer. This gives the strong indication that line drives or patterns other than five-spots might be considerably better for recovering oil via chemical flooding. This work will be expanded upon and may in fact even result in some design modification for this very exciting and interesting pilot project.

CONCLUSIONS

In this paper we have presented some of the interesting aspects in the development and application of a chemical flood model. This clearly illustrates how computers and mathematical models can play an extremely important role in aiding the oil industry in recovering additional oil. The complex model which was developed is now being utilized to better understand laboratory work which will in turn enable us to scale the very important laboratory experiments to actual field scale projects and hopefully enable us to obtain a better understanding why some processes seem to work and other processes seem to fail. Once a process is characterized and the reservoir is characterized we feel that a mathematical model of this sort is an excellent predictive tool and should go a long way toward enabling the oil industry to recover a substantial fraction of this 300 billion barrels of oil which is left in the ground and currently called unrecoverable.

Geophysical DP requirements could exceed the world's GP capacity by 1985

by CARL H. SAVIT

Western Geophysical Company of America
Houston, Texas

INTRODUCTION

The reflection seismic method of underground mapping is today the only practicable means of selecting a place to drill a new oil or gas well. As a consequence, the free world spends about two billion dollars a year for reflection seismic exploration.

All of this activity consists of data gathering, data reduction, and data analysis. In 1977 the industry recorded between 10^{14} and 10^{15} bits of primary data in digital form. All of these data was processed at least once. Indeed, it is probable that the geophysics industry processes more primary digital data than does any other activity. Worldwide, the industry dedicates computer power equivalent to a few dozen IBM 370/168's to processing seismic reflection data.

During 1977 new field techniques were introduced to improve the resolution of the entire process. These new techniques begin by recording about 20 times as much data per unit of survey as are being recorded in conventional, present-day practice. A further increase to about 50 times the present data rates will be needed to make the horizontal resolution of the system reasonably consistent with the vertical. Ultimately, algorithms that take full advantage of the increased recording density will require 1000 or more additional computation steps per input point. Consequently, we perceive a need for a 50-fold increase in internal memory and a 50,000-fold increase in arithmetic speed. In terms of "power" (where power is defined as the product of internal memory size and the number of operations per unit time), these requirements translate to a 3×10^6-fold increase.

It has been the experience of the past three decades that available computer power (as we have defined it) increases about one order of magnitude every 2.7 years. If, as seems reasonable today, this trend continues until 1985, our computers will then be about 10^3 times as powerful as they were in 1977. Also, as seems reasonable today, reflection seismologists will by 1985 be ready for the 3×10^6-fold increase we have projected. To accomplish the same number of units of survey in 1985 as were done in 1977, we could be facing a requirement for 3000 times as many 1985 model computers as the number of 1977 model machines we used in 1977. It would, in addition, be reasonable to expect the market for surveys to have doubled in the next seven years so that we may need to increase our demand by an additional factor of two. (Figure 1)

DATA AND ALGORITHMS

To understand the nature of the geophysical computation requirement, an overview of the basic physics of reflection seismology will be of some help.

In reflection seismology a mechanical excitation is applied at or near the surface of the earth. Pick-ups also on or near the surface and relatively near the point of excitation detect the response of the earth to the excitation. From the complex pattern of energy returned to the surface, the exploration geophysicist attempts to select the longitudinal elastic waves (i.e., the sound waves) that have returned to the surface by reflection from underground interfaces between different rock layers. In the current state of the art, energy of all other kinds is rejected or suppressed as unwanted "noise."

Nearly all processing methods in general use into the first few years of this decade were based on the concepts of geometrical optics. In other words, sound waves were assumed to travel along rays and to be reflected or refracted at the point of intersection of each ray with an interface or discontinuity. (Figure 2)

As a consequence of these assumptions, deriving a representation of the configuration of underground layering from the received acoustic signals involves the use of little more than the algebraic and trigonometric equations of analytic geometry. One major intermediate problem, that of deriving the velocity of sound as a function of depth from the surface, appears to require the solution of an integral equation. Instead, however, of attempting an analytic solution in the face of noisy and incomplete data, the exploration seismologist has opted for the method of exhaustive search. He solves the forward problem of determining a suite of likely reflection times for selected parts of the data over an anticipated range of assumed velocities. The algebra required is primarily the Pythogorean equation followed by a vast number of correlation calculations to determine the degree to which reflection times derived from the searched velocities fit the observed signals.

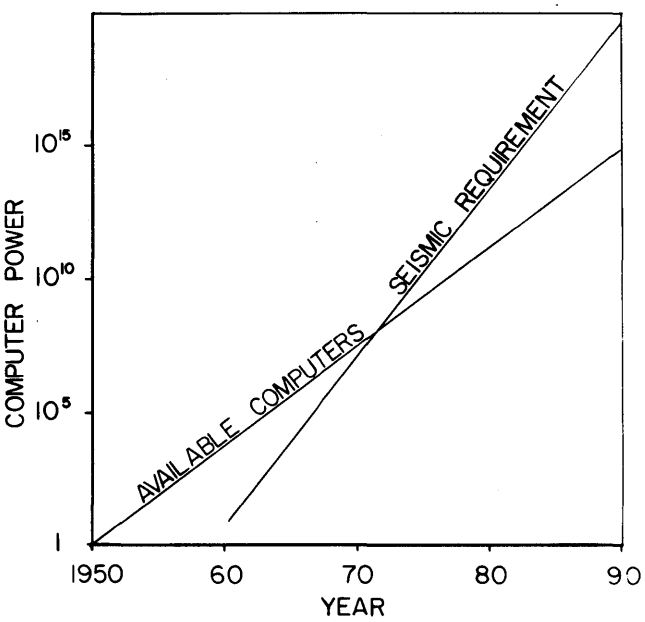

Figure 1—The power of typical commercially available computers has been growing about one order of magnitude every 2.7 years and should continue to do so through the 1980's. Requirements of the seismic exploration industry have been growing and should continue to grow at a substantially faster rate.

The necessary ray-path calculations are quite simple and so produce a relatively small computational load. Most of the computation time is devoted to the extraction of good acoustic "signals" from noisy data. The two approaches used to improve signal-to-noise ratios are the averaging of redundant data and filtering by means of a battery of sophisticated techniques.

By far the largest computing load stems directly from the high redundancy of data being taken. A typical field record of the response of the earth to one mechanical input consists of 3000 data values taken simultaneously at each of 48 equally spaced surface locations. Each input thus produces about 150,000 floating-point numbers. Floating point is required because the signal immediately after the instant of input can be four orders of magnitude larger than the signal six seconds later when the recording is finished.

Typically one signal input is applied every 30 to 60 meters along a line of survey so that a seismic survey produces

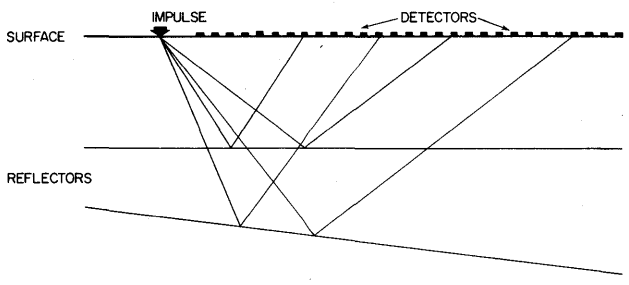

Figure 2—The geometric-optic model of reflection seismology postulates a unique raypath connecting an impulse, a given reflection, and an individual detector; and the angle of incidence is equal to the angle of reflection.

some 2.5×10^6 to 5.0×10^6 floating-point data values per kilometer.

Such surveys produce data redundancies ranging from 12 to 24 or 48. When more redundancy is required to achieve useful anti-noise discrimination, more data are taken per kilometer of survey. Redundancies of 96 are not uncommon in special situations.

In nearly half of all surveys on land, the input consists of a swept-frequency (chirp) signal of substantial duration. Systems using this form of input require the recording of thirty times more data values per kilometer. Simple computation in the field compresses these data about 16-fold, but the result of this compression must be further processed before it reaches the computational level of unprocessed impulse data.

Before redundant data can be combined or averaged, several distinct data processing steps must be applied. Those redundant data that apply to, or represent, the same subsurface point are gathered from diverse input and pick-up points. The different sound waves reflected from the same subsurface point have travelled paths of different length and have encountered different inhomogeneities in their paths. Field recordings are, of necessity, made in real time so that data from different pick-ups must be recorded in time-multiplexed order.

Normally, the first computational step is to demultiplex the data into time-sequential value sets for each pick-up. Next, data are normalized both as to amplitude and time scale to approximate values that would have been produced by horizontal plane waves. The necessary transformations are non-linear but have simple geometric bases.

In most cases the first of several filtering steps is applied to the data after the amplitude normalization and before application of the time-scale normalization. Almost always the filter is in the nature of a deconvolution; that is, an attempt is made to undo the various spread functions that characterize the effective shape of the input signal. That the input function has substantial duration is the result both of the imperfect nature of the mechanical impulse itself and of the reverberatory character of the earth materials near the input source.

Designing the filter operators to be applied to the data to convert the input signal to a band-limited, simple impulse function represents a substantial computation load. While it is a relatively simple matter to use the Wiener-Levinson algorithm to invert a known (i.e., recorded-in-the-field) mechanical impulse shape to a desired simple impulse, it is somewhat more burdensome to derive the analogous operator to compensate for an unknown reverberation function. The usual method is to derive the amplitude spectrum of the reverberation function from autocorrelations of the unfiltered data and to assume (on physical grounds) that the function is minimum-phase. Other more complex schemes are in use to various extents.

All of the steps described to this point are necessarily applied to essentially all of the field-recorded data and, hence, represent the great bulk of the computation load. In those cases in which the velocity of seismic waves varies rapidly along the line of survey, the intermediate step of

velocity determination, described earlier, can dominate the computation requirement.

In the last computer pass of these preliminary computation steps, the data are combined or averaged to produce the compacted, signal-enhanced data set for final processing. Essentially all of the redundancy has now been removed so that data volume is reduced by the original redundancy factor of 12 to 96. Furthermore, the dynamic range of the data has been sufficiently reduced that results may validly be written as 16-bit, fixed-point numbers.

Until quite recently, virtually all seismic reflection data were subjected to at most one or two additional filtering steps and were amplitude-conditioned in one of two alternative modes and formatted for presentation in graphical form as hard copy.

Such additional calculations as have been made within the geometric-optics framework have ranged from simple smoothing operations to elaborate ray-tracing routines but in the aggregate have had negligible impact on computer requirements.

ACOUSTIC WAVE EQUATION

We in the exploration-geophysics community have long been aware that the geometric-optics model of the seismic reflection process is, at best, a first approximation to reality. Even the fundamental assumption of the geometrical optics model—that the longest wavelengths involved are small compared to the dimensions of interacting elements in the medium—is at best weakly valid. Some of the wavelengths we use are indeed substantially greater than the dimensions of subsurface features of interest.

The simplest model that enables us to relax the dimensional assumption required in geometric optics is acoustical. In the acoustical model it is assumed that the propagation of seismic energy can be described by the acoustic wave equation

$$\frac{\partial^2 \varphi}{\partial t^2} = c^2 \nabla^2 \varphi.$$

That equation is the mathematical expression of a physical model in which energy is propagated in a lossless medium solely by means of variations of pressure.

It is well established that many of the defects of the ray propagation assumption of the geometric-optic model are mitigated or effectively eliminated by use of the wave-equation model. Unfortunately, these advantages are gained at the cost of orders of magnitude increases in the required computations.

This increase in computational load is inherent in the difference in the physical models. In the geometric-optic model, the reflection from a point on an interface obeys the specular rule—the angle of incidence is equal to the angle of reflection. Thus, an impulse from a particular surface point of origin can reflect at a given point on the reflector to only one receiver point on the surface. To process the information relevant to one subsurface point, it is only necessary to treat a number of data values equal to the design redundancy of the system. (Figure 2)

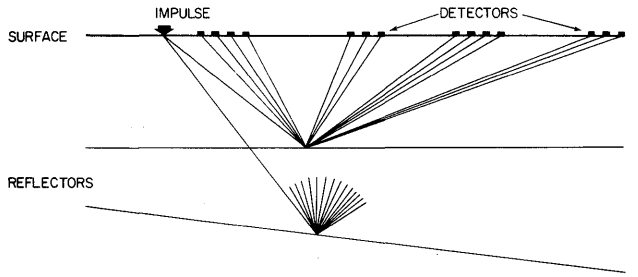

Figure 3—The acoustic model of reflection seismology postulates that energy is radiated in all directions from every point on a reflecting surface. Accordingly, *every* detector receives some energy from each reflecting point in response to a given impulse.

In the acoustic model, however, the reflection point is a new source and retransmits energy in all directions. Hence, every receiver records energy "reflected" from every point on the reflector in response to an impulse. Conceptually, we should use all data from the entire survey to determine the characteristics of each reflection point. While the details differ, operationally the process is analogous to the creation of an image corresponding to a hologram. (Figure 3)

Obviously, an immediate and complete shift from the ray-theory to the wave-equation approach would have required more computer power than is available in the entire world. In any event, the necessary analytical foundations for such a change have not yet been developed.

What has happened is that a working mix of the two models has been evolving. In its earliest manifestation the mix consisted of ray-path processing until a final compressed, enhanced data set is produced, following by a single-application of a limited-parameter version of the Kirchhoff-integral solution to the wave equation. The number crunching required for this process when applied to 48-fold-compressed data was of the same order of magnitude as that needed for all the preceding steps.

In today's world, a battery of programming techniques and analytical simplifications have made the wave-equation approach more economical and the need for better data has made funding increasingly available.

In the most sophisticated approach known to me to be in commercial use, the data are processed at least part way in the geometric-optic manner to derive model parameters which are then used for extensive acoustic-wave processing. The result of that processing is then further modified by a technique derived from geometric optics to compensate for an inadequacy in the wave-equation formulations available today. (Figure 4)

Another few years should see a fully mature acoustic-wave technique to carry the entire processing sequence, but it will almost certainly require ray-path processing as a preliminary step to determine initializing or first-approximation parameters. Much of the processing may be iterative.

For those who are inclined to worry about a possible static future, I would point out that the introduction of attenuation into the equations should suffice to keep everyone busy for some years beyond these projections. After that we could profitably spend a generation or two applying

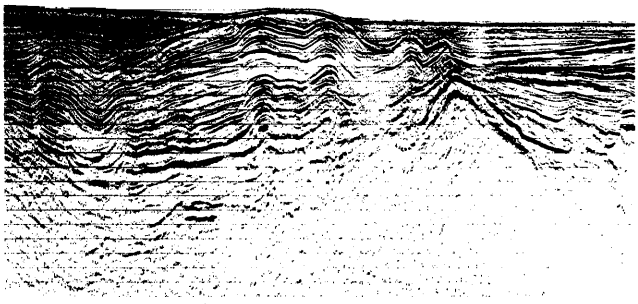

Figure 4—This cross section from offshore California represents a horizontal distance of about 26 kilometers and a total vertical dimension of 2.7 kilometers. About 3×10^9 bits of data were recorded at sea. Processing through the compaction stage was performed in accordance with the raypath model. The compacted data were treated by acoustic wave methods, and the results were then further modified by another ray-theory-derived process. Processing costs were something over $6000.

the tensor equations that describe the elastic behavior of real solids.

HARDWARE REQUIREMENTS

Since the seismic reflection industry went digital in the mid 60's, it has been pressing hard at the frontiers of computer technology. The first group to undertake regular computer processing of seismic data designed and built a special purpose system because of the limitations of the then-available GP systems. Seismic industry requirements soon stimulated the development by computer manufacturers of specialized hardware to cut computing costs for some heavily used algorithms and thus bring overall costs to an acceptable level. In the initial years, correlation and convolution operations were the pacing items making up computer costs. For that reason the first hardware specialties were a fast multiply-add instruction, followed within a matter of months by hardwired correlators. In 1966 IBM announced the 2938 array processor and made its first installation at the beginning of 1968.

The 2938, designed in collaboration with Western Geophysical, had an instruction set of about 12 instructions with data arrays as operands. Pipelining and other hardware innovations resulted in great speed improvements. Geophysical processing could, as a consequence, proceed for almost a decade without serious hardware constraints by taking advantage of normal GP computer developments to complement the array processor.

Today's array processors come in a bewildering variety of styles and capabilities. Married to a mini, one of today's better array processors will, on seismic data, outperform a GP computer and do it at less than 25 percent of the cost of the GP machine.

Seismic reflection data today, and for some time to come, consist of observations arrayed in a three-dimensional matrix. One dimension of the matrix, the one along the line of survey, is essentially unlimited but, as a practical matter, is limited to a few thousand values. The vertical (or time) dimension of the matrix is usually about 3000 data values; and the third dimension, representing the simultaneous observations for each input pulse, is in the process of growing from a present typical value of 50 to about 500 or 1000 in the next few years. For some applications in which an area is surveyed in detail (so called 3-D surveys), a fourth dimension of a few tens or hundreds of values is appended.

It is becoming more common to use extended inputs such as coded or pseudo-random pulse sequences—a process which greatly increases raw data volumes.

The only way all of these data will ever be processed is by extending the technology of specialized devices exemplified by the array processor.

I visualize the processor of 1985 built around a gigabyte high-speed memory with multiple access modes. Only a handful of algorithms will have to be applied to the data. The processor will have hundreds or perhaps thousands of identical single-chip microprocessors to execute each of the required algorithms. The micros will be used in a combination of parallel and pipeline modes so that all are operating simultaneously. All of this activity will be under control of a relatively small CPU which can handle traffic control and the calculation of processing parameters.

In operation all or a sizable chunk of the raw-data matrix will be read into main memory from the compact storage medium on which they were recorded in the field. A succession of operators will be passed through the matrix in various directions and various orders by directing sequences of data from memory through the micros.

Technology visible today can make the whole project feasible; and as Jules Verne has so aptly said, "What one man can imagine another man can do."

Seismic modeling with minicomputers

by R. L. SELZLER, R. M. ALFORD, K. R. KELLY, N. D. WHITMORE, and H. M. WILLIAMS

Amoco Production Company
Tulsa, Oklahoma

INTRODUCTION

The energy crisis has created increased interest in petroleum exploration. Discoveries of major deposits are increasingly rare and difficult to locate. The geophysicist requires more accurate knowledge to assist him in locating deeper and smaller hydrocarbon deposits. While gravity, magnetic, and electrical methods are also used, the predominant exploration tool is the seismic method and provides a wealth of subsurface information. Geophysicists continue to increase their seismic proficiency by using such things as modeling.

The concern of this paper is the ability to model the seismic response of a known subsurface. The practicality and usefulness of a modeling technique is determined by how accurately, routinely, and economically it may be used to simulate realistic cases. Modeling techniques, such as numerical solutions to the wave equation and ray tracing, are possible and offer distinct advantages and disadvantages. The method presented in this paper is a numerical solution to the wave equation obtained by finite difference techniques.

A brief background in seismic methods and theory is presented. The numerical modeling technique is described, and a typical example is given. Also discussed is a minicomputer system which makes the method economically feasible for routine use.

GEOPHYSICAL SEISMIC METHOD

The typical method of gathering seismic data is depicted in Figure 1. At the site of interest, seismic wave transducers, or seismometers, are coupled to the surface of the earth along a line typically 10,000 feet in length. Individual seismometers (actually arrays) are generally spaced about 100 feet apart and are monitored by a central recording station. A seismic source, often an explosive charge buried beneath the surface, generates seismic waves which travel through the subsurface according to the principles of elastic wave propagation. The direct wave and the many reflections from the subsurface interfaces are digitally recorded at the surface for several seconds. These records contain complex multiple reflections and ambient noise; they are later subjected to digital processing in an attempt to remove these effects.

The records are often plotted as a seismogram as shown in Figure 2. Here the abscissa represents the horizontal position of the semismometers and the ordinate represents time. Time increases downward and is equal to zero at source initiation. The contribution to the plot from a single seismometer is highlighted. It is informative to notice the reason for this orientation of the display. It is a first attempt at inferring the geological structure from the recorded time response. A sense of horizontal position is somewhat preserved while the time ordinate is related to the geological depth.

Ideally, one would like to directly generate a picture of the subsurface geology from the recorded surface data. This would be referred to as the inverse problem. Unfortunately at this time it is only possible to deduce the structure, indirectly, after an involved sequence of digital processing, followed by extensive human interpretation. Mathematical modeling can be extremely helpful during the interpretation and processing steps.

While the microscopic composition and porosity of the rocks is important, we are concerned only with their macroscopic effects upon seismic wave propagation. The earth's subsurface, for our purposes, may be divided into homogeneous regions characterized by constant velocity and density values. This defines the subsurface in terms of the parameters in the wave equation. The variation of these parameters at the interfaces between regions gives rise to reflections, refractions, and other wave phenomena.

FINITE DIFFERENCE METHOD

Given a governing equation for seismic wave propagation, it is possible to numerically approximate its solution by finite difference techniques. Although the elastic wave equation governs seismic wave propagation, the simpler acoustic wave equation provides useful and practical results and will be considered here. The same approach has been applied to the elastic equation.[1]

The two-dimensional acoustic wave equation to be considered is

$$\rho v^2 \left[\frac{\partial}{\partial x}\left(\frac{1}{\partial}\frac{\partial}{\partial x} U\right) + \frac{\partial}{\partial z}\left(\frac{1}{\rho}\frac{\partial}{\partial z} U\right)\right] = \frac{\partial^2}{\partial t^2} U, \qquad (1)$$

where $v(x,z)$ is velocity, $\rho(x,z)$ is density, U is the acoustic pressure, t is time, and x and z are horizontal and vertical

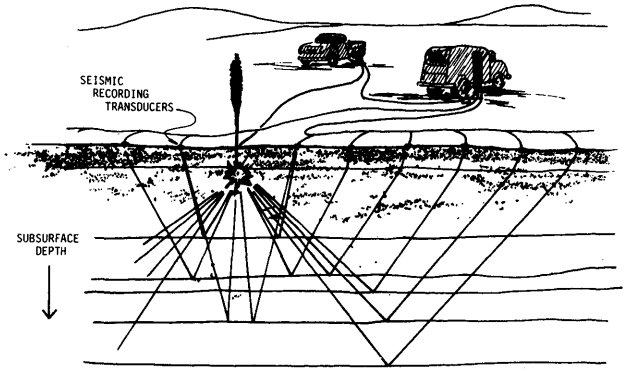

Figure 1—Seismic exploration method

position, respectively. Interfaces are automatically accounted for since velocity and density variations are included in the equation.

The majority of the calculations occur in regions with constant density, where equation (1) simplifies to

$$v^2\left[\frac{\partial^2}{\partial x^2}U+\frac{\partial^2}{\partial z^2}U\right]=\frac{\partial^2}{\partial t^2}U. \tag{2}$$

For simplicity, attention will be limited to equation (2).

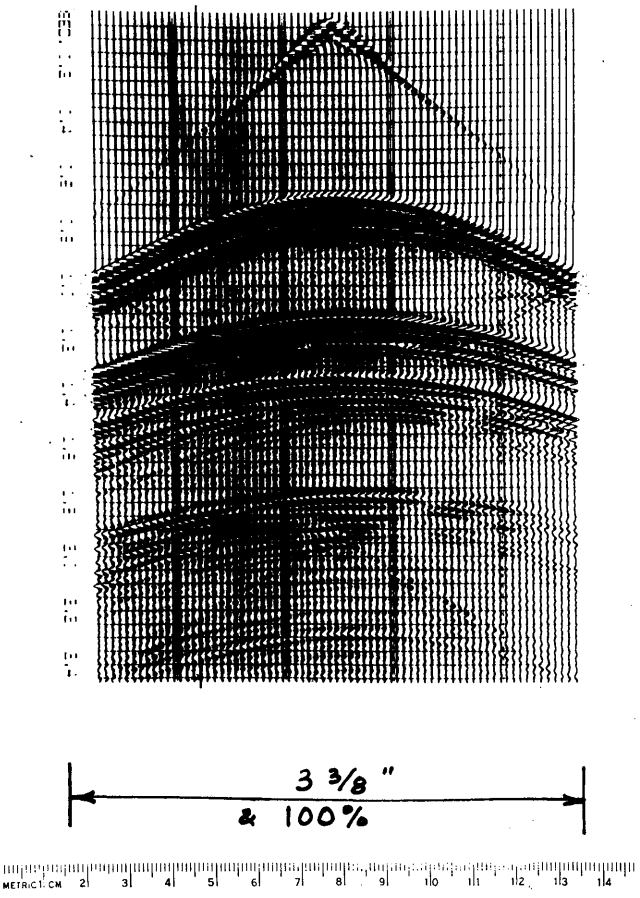

Figure 2—Synthetic seismogram

Using standard finite difference methods,[2] equation (2) may be approximated by

$$\begin{aligned}U(x,z,t+\Delta t)=&(1-2p^2)U(x,z,t)\\&+p^2\{U(x+h,z,t)+U(x-h,z,t)\\&+U(x,z+h,t)+U(x,z-h,t)\}\\&-U(x,z,t-\Delta t),\end{aligned} \tag{3}$$

where $$p(x,z)=\frac{v(x,z)\Delta t}{h},$$

where Δt is the time increment and h is the spatial grid interval.

This finite difference scheme is one of many possible approximations. Notice that it provides an explicit solution for the acoustic pressure at a future time, $t+\Delta t$, in terms of the pressure at the current time, t, the previous time, $t-\Delta t$, and the geological paramters.

The geology to be modeled is represented by two-dimensional arrays of velocity and density as shown in Figure 3 ($h=\Delta x=\Delta z$). A uniform square grid is superimposed on the model, and at each discrete grid point, values for the velocity and density are assigned. The creation of these discrete arrays describing complex geological structures is well suited for interactive graphics programs.

Consider the "molecule" of data required for the calculation of the pressure field at a single point. The velocity and density parameters do not vary as a function of time, whereas the field value does. The algorithm may be visualized as a single matrix of geological parameters superimposed on many multiple time planes of field values. Fortunately for storage conservation, the algorithm requires that only two successive time planes ever be present, since the future value can replace the previous value in storage.

The accuracy of the algorithm is a function of the coarseness of the grid. For our purposes, a minimum of ten grid points per wavelength is usually sufficient.[3] There is also an upper limit imposed upon the time step to maintain the stability of the algorithm.

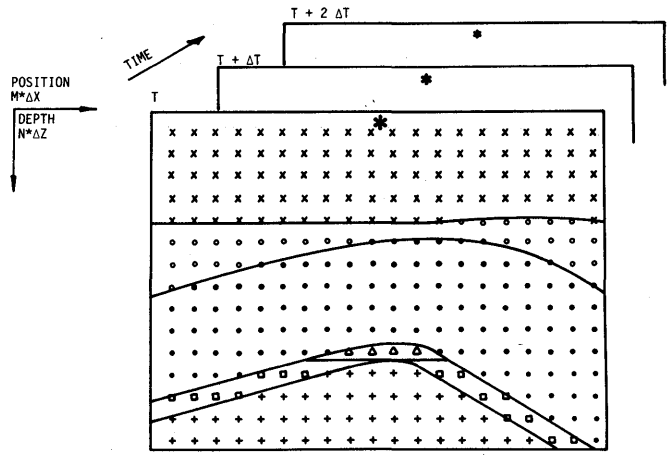

Figure 3—Geological parameters in discrete space superimposed upon multiple time planes of the wave field

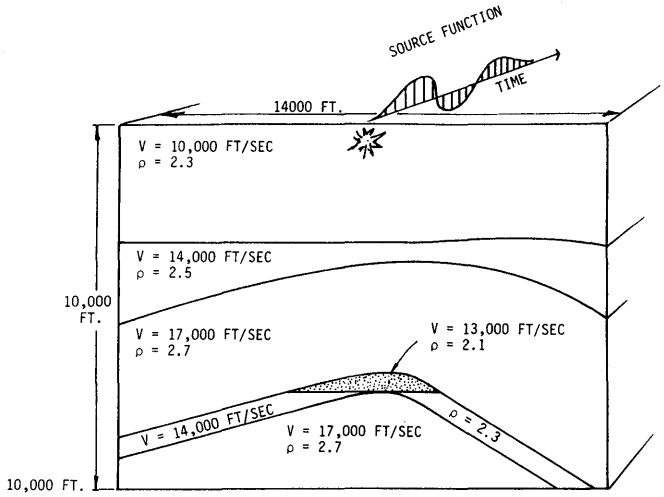

Figure 4—Geological model

MODELING APPLICATION

Figure 4 depicts the two-dimensional geological cross section of a model. The small semicircular shaped region near the center represents a gas reservoir. A synthetic seismic response is desired in order to better understand how such a deposit would be observed in the presence of the other geology.

The model extends 14,000 feet horizontally and 10,000 feet vertically, which for a grid point spacing of 25 ft, results in 560 grid points horizontally and 400 grid points vertically. The response is generated for 2500 milliseconds to assure that reflections from the depth of interest are obtained. This requires about 2000 time steps. The time variation of the source is represented by the second derivative of a Gaussian,[3] with an upper-half-power frequency of 30 Hz, which is similar to that generated by an explosive charge in the field.

Figure 2 is a plot of the synthetic time section obtained by recording the numerical values at the surface of the model. This corresponds to what the seismometers would record in the field. The first event to arrive at the surface is the direct wave from the source. Next is the reflection from the first interface, followed by many additional primary and multiple reflections. Although the geological model is relatively simple, the time section is complex and contains many refraction, reflection, and diffraction events. In practice, the responses for a large number of source locations are combined through an involved processing sequence, to create a more easily interpretable seismic section. An example of such a process, applied to a collection of synthetic seismograms for differing source locations, is shown in Figure 5. This synthetic section now more closely resembles the model geometry, and the lower boundary of the gas reservoir is readily identifiable as indicated on the display. Processing and interpretation of synthetic data sets simulating the actual

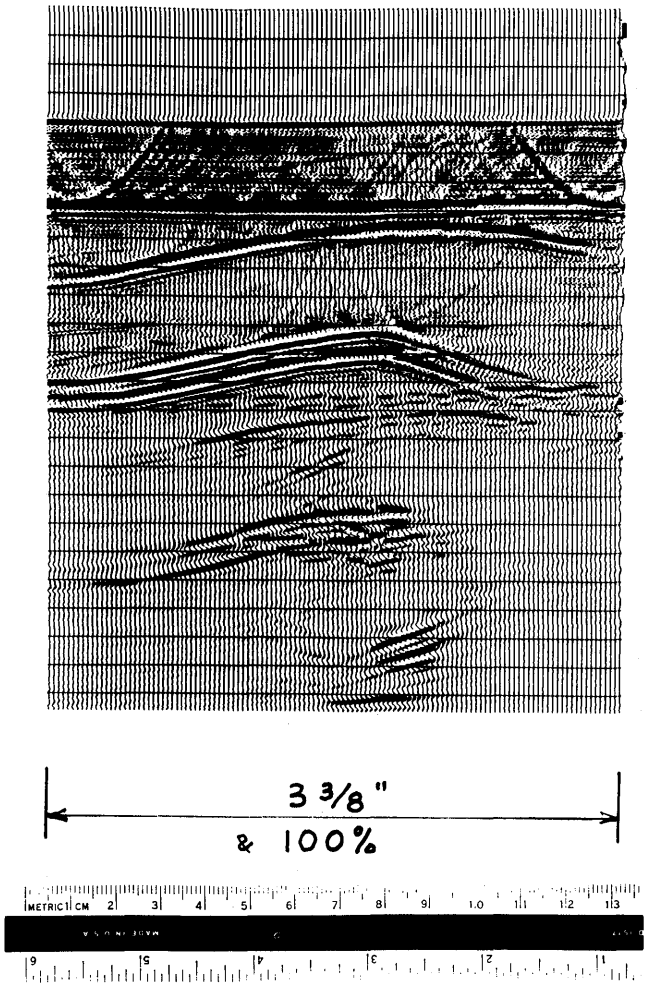

Figure 5—Composite of multiple seismograms after processing

field procedure provides an opportunity to develop and test ideas in a controlled, known, noise-free environment.

An added bonus of this modeling method is "snapshots," shown in Figure 6. A snapshot is a plot of the entire wave field at a single time plane. The geological structure has been superimposed on the display to assist the interpretation. The snapshots are resampled by four to one to conserve storage, thus causing the structure to appear coarse.

Snapshots can improve our understanding of seismic wave phenomena, since individual waves can be followed as they propagate through the media. A movie of seismic wave propagation has been produced using closely spaced snapshot sequences.

The finite differences technique is a very useful and flexible method for seismic modeling. Models of arbitrary geological complexity require no unusual considerations and seismograms may be generated routinely. The synthetic response provides realistic waveforms with accurate arrival times and amplitudes. The response includes diffraction events and, if desired, the method can be applied to the

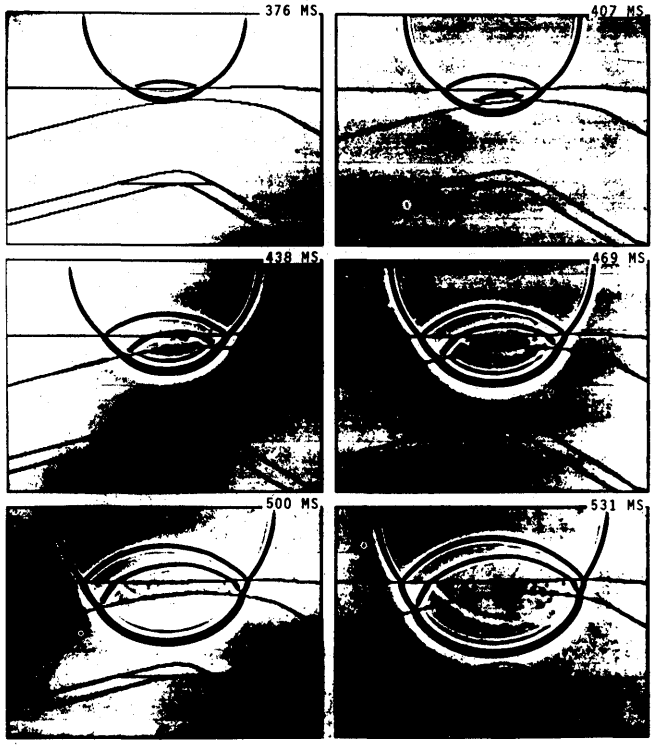

Figure 6—Snapshot sequence with structure superimposed

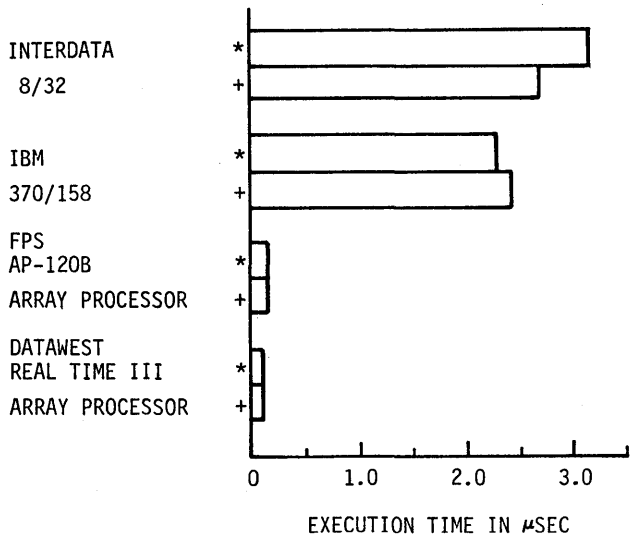

Figure 7—Multiple (*) and add (+) execution time for various floating point processors

elastic case to study shear wave events and other elastic phenomena. The flexibility of the method allows source and receiver locations to be easily varied, permitting complex arrays and non-standard acquisition techniques to be simulated.

DEDICATED MINICOMPUTER SYSTEM

The computational burden imposed by this modeling method is tremendous. Seismic models ranging in size from 400 to 800 grid points horizontally and vertically are desirable. This results in 160,000 to 640,000 grid points per model. Each geological point modeled requires from 10 to 20 bytes of computer storage. Typically the solution at 1500 to 3000 time planes must be computed. Even though a maximum of two successive time planes are needed, this requires large quantities of storage. If sufficient local memory is not available, computations may be performed on model segments rolled in and out from mass storage peripherals.

Early finite difference modeling was performed on large general purpose computers using standard FORTRAN programs. It was considered economically impractical to routinely submit models larger than 100 by 100 grid points on such a system. Minicomputers were considered as an alternative processing system.

The dominant factor in the computational speed is the large number of wave field calculations required. Calculations are performed in single precision floating point arithmetic. Figure 7 compares the floating point multiply and add speed for memory to register instructions for a variety of processors. The processors may be divided into three categories: large general purpose computers, minicomputers, and array processors. The array processors considered here are programmable devices that have their own local memory. They require a host computer and, therefore, are considered high speed computation extensions of the host.

A dedicated minicomputer system, with minimal memory and peripheral devices, may achieve real time performance comparable to a large general purpose computer for applications which are CPU bound, such as the one under consideration. In view of the comparatively modest hardware cost, the minicomputer system thus becomes economically attractive for installations where high and continued usage of the program is anticipated. The preceding modeling example required approximately eight hours of minicomputer CPU time (without an array processor) to create the synthetic seismogram for a single shot location. This would have been impractical on a large computer.

An Interdata 8/32 minicomputer was selected: it can service any subordinate function required and is capable of hosting an array processor, making available their powerful resources. The hardware configuration used is shown in Figure 8. The minicomputer has 32 bit architecture and hardware implemented floating point instructions. It supports up to one megabyte of memory with a bandwidth greater than six megabytes. Multiple selector channels allow the peripherals high speed DMA (*D*irect-*M*emory-*A*ccess) capabilities. This is important since high speed mass storage discs are an integral part of our implementation. The optional array processor also utilizes DMA extensively. A multiplexor bus is available for other low-speed peripherals.

The speed of the main calculation loop is paramount to overall performance. While the bulk of the program may be written in FORTRAN, this loop must be carefully optimized in assembly language. This is especially important with some

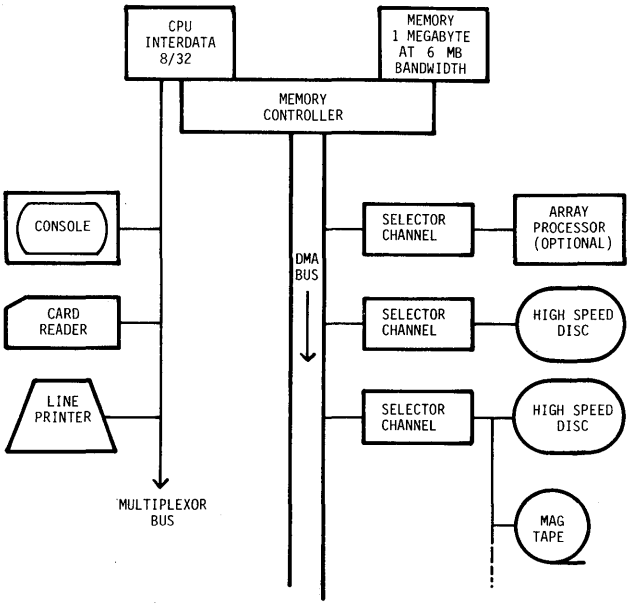

Figure 8—Minicomputer hardware configuration

minicomputer FORTRAN compilers, which may not produce very efficient execution code. This relatively simple improvement has yielded a 4-fold speed improvement. The same idea applies if an array processor is used; it is more efficient to program the algorithm directly on the array processor, than to use standard vector multiply and add sequences. Not only may direct programming improve speed, but it can also conserve expensive array processor local memory.

The continuous flow of model segments from storage, to memory, and back to storage again, is an integral part of the processing. One must be acutely aware of operating system overhead and I/O requirements for optimum performance. The hardware configuration has two high speed mass storage discs, each with an independent DMA selector channel. An unbuffered disc file access method provides the most efficient I/O. This allows input, output, and calculation of model segments to proceed concurrently. This is considerably faster and more efficient in real time than if each occurred serially. The ability to do simultaneous I/O and calculations emphasizes how the user may closely coordinate software and hardware. By carefully controlling the disc random accesses, the calculations may be synchronized to the point of transferring model segments on successive fractional rotations of a high speed disc.

CONCLUSIONS

Seismic modeling using finite difference methods provides the exploration geophysicist accurate synthetic results for complicated geological structures. Modeling provides a means of comparing synthetic results with field data. It provides a fast, flexible, and economical laboratory for investigating new procedures and confirming old ideas. The finite difference approach used here is but one of many numerical variations possible, all of which merit further consideration. This technique is not limited to geophysical applications, but is applicable to other areas of wave propagation research.

Programs demanding heavy CPU computations for long periods of time may not be justifiable on large general purpose computers. Large time shared computers are designed to obtain high usage levels through simultaneously and efficiently managing multiple tasks. Demanding programs, such as finite difference modeling, utilize the CPU for long periods of time which eliminates the need for sophisticated multiple user management. Dedicated minicomputer systems may be more economical because the memory and peripheral devices can be tailored to the specific application.

Present and future applications of computer technology to petroleum exploration

by R. A. TERNUS and A. S. HOFFMAN
Chevron Oil Field Research Program
La Habra, California

INTRODUCTION

In this paper we will summarize the steps involved in exploring for oil and gas, review the role that computers play today in exploration and discuss some of the roles that computers may play in the future.

PETROLEUM EXPLORATION

The ultimate way in which oil and gas are discovered is to drill into the ground. The objective of all prior steps in the exploration process[1] is to identify where to drill to minimize the risk of drilling "dry" holes.

Generally exploration (Figure 1) begins with a regional geologic survey. This is done to locate geologic basins containing sedimentary rocks, and to extract information from surface geologic features and rock samples about the types of sedimentary rocks and their depositional environments. Such information can suggest where oil and gas may have been generated and is trapped in reservoirs.

The second step may consist of gravity and magnetic surveys. These determine the regional variations in the thickness of the sedimentary rocks and locate subsurface structures such as faults and salt domes, which often help to form traps for hydrocarbons.

Gravity prospecting involves measuring local fluctuations in the earth's gravity field, then correcting these for latitude, elevation, topography, and earth tides. The resulting gravity maps can be useful in determining subsurface geological features marked by changing rock density.

Magnetic prospecting, which measures local fluctuations in the earth's field, is more complex and erratic than gravity measurements. However, the magnetic measurements are simpler and cheaper to make, require only minimal corrections, and are more diagnostic of mineral distribution.

The third step consists of reflection seismic surveys, some of which may be long regional lines used to better define the sedimentary basin. Others are laid out on more finely-spaced grids—to obtain detailed information in specific areas. From these one can determine the specific locations of possible hydrocarbon traps and, in some cases, the actual presence of hydrocarbons.

The basic principles (Figure 2) of the seismic reflection method[2] are rather straightforward. A controlled source of

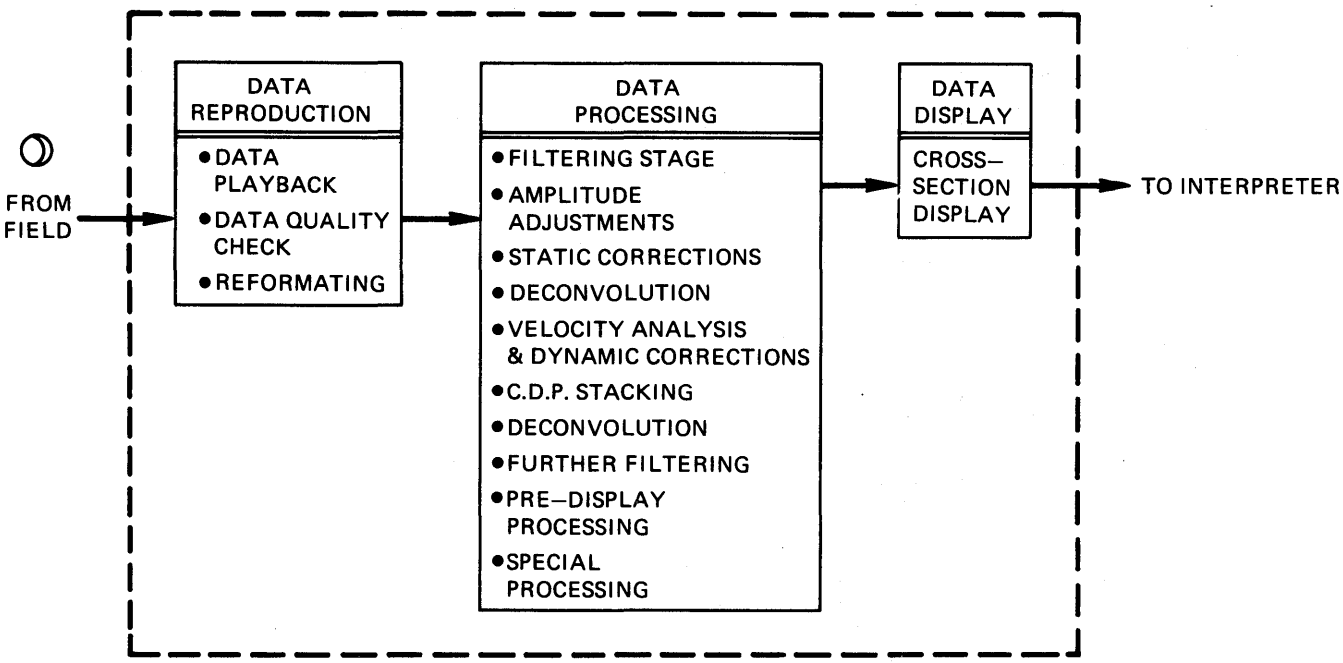

Figure 8—Typical processing flow

acoustic energy at or near the earth's surface propagates energy into the subsurface. The reflected energy from geologic strata is sensed by arrays of seismic detectors at the earth's surface (or in the sea, slightly below the surface).

Correlating the resulting subsurface reflectivity maps with a knowledge of geologic structure and rock properties allows the interpreter to delineate a three-dimensional geologic model of the subsurface. The basic acquisition objective of the seismic technique is to maximize the contribution from compressional waves reflected from the depths of interest and to minimize that from surface waves and ambient noise.

CURRENT USE OF COMPUTERS

Computers are used extensively today in all phases of exploration, with the possible exception of the initial regional geologic surveys. They are used to filter the gravity and magnetic data, make various geometric-type corrections, and assist in interpreting the data (Figures 3 and 4). The latter is often accomplished by constructing mathematical models that describe the shapes, densities, and/or magnetic susceptibilities of various parts of the subsurface. The implied gravity and magnetic fields for these models are calculated and compared to measured fields. The mathematical models are then adjusted to obtain suitable matches between implied and actual fields. The final model (Figure 5) provides an interpretation of the data.

However, the most widespread use of computers in exploration is in the seismic reflection method. There is a ubiquitous presence of various types of data-processing systems, including data acquisition in the field, "number-crunching" data processing and reduction, and the often-interactive interpretive phase (Figure 6).

The data acquisition stage (Figure 7) involves several thousand individual detectors connected in 100 or so separate recording channels. Each channel is sampled at up to 1000 times per second, usually over the 4-6 seconds of useful reflection time for a single seismic source event. Depending on whether the acoustic source is below or on the surface, from about a hundred to several thousand such events can be initiated each day and either recorded or partly "stacked" in the field and then recorded.

The objective in the processing stage[3,4] is to enhance the desired signal at the expense of the noise, to make geometric corrections to the data as well as to extract desired parameter values. A typical processing flow (Figure 8) might be as follows: magnetic tapes containing the field data are played back in the processing center, and the data is sorted and properly formatted for processing. Traces, having either excessive noise or neither noise nor data (i.e., dead traces) are edited out or flagged so that they do not interfere with future processing.

Next, the data may be filtered to remove noisy parts of the frequency spectrum that contain little or no signal. Static adjustments (time shifts) are calculated and applied to each

Figure 10—Common depth point stacking

trace, to compensate for variations in shot and receiver elevation and in the thicknesses of shallow, low-velocity sediments. The velocities in the subsurface are estimated by examining the different arrival times of reflections associated with different shot-receiver offset distances (Figuare 9) but the same reflection point in the subsurface. Deconvolution—a filtering type of operation that serves to "whiten" the remaining part of the spectrum—is normally applied. This improves the resolution between closely spaced events. Finally, all traces having the same common depth point (Figure 10) may be summed to create a final stacked section. At various points in this processing stream, special techniques may be employed to enhance the coherent signals and to reduce multiple reflections.

Computers are also used to interpret seismic data in a manner analogous to that described previously for gravity and magnetics data.

As the data is collected and interpreted, maps and seismic cross sections are constructed (Figures 11 and 12) showing the configurations of the sedimentary rock layers (beds) and possible locations for trapped hydrocarbons. Interactive graphics terminals are often used so the interpreter can work with the computer in the construction of these maps.

After these initial steps a well (or wells) may be drilled. Whether or not hydrocarbons are found in the drilling, data about the rocks and their pore fluids are incorporated with the previously obtained data, to refine the interpretations and maps and identify additional drilling locations.

FUTURE USE OF COMPUTERS

In the future the use of computers will continue to expand in the roles of processing and interpretation. Processing algorithms often are built around simplifying approximations, made to hold down computer processing time. As

Figure 11—Typical exploration prospects

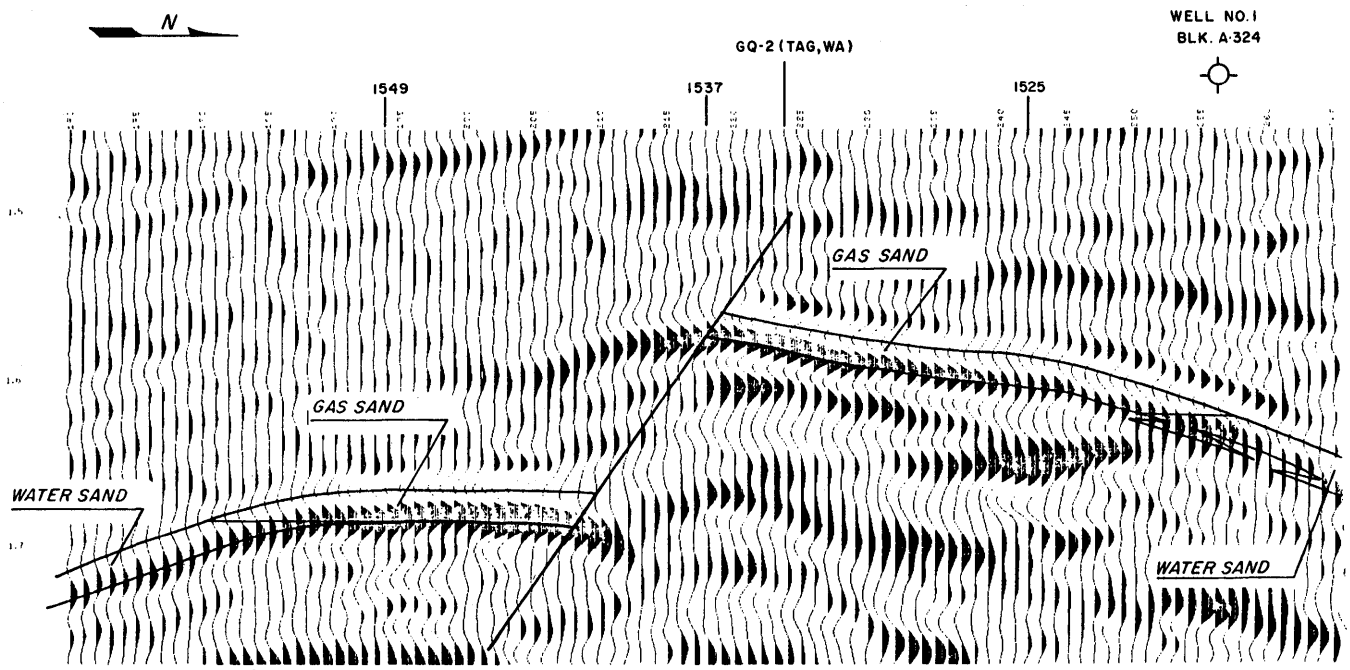

Figure 12—Seismic section showing possible oil traps

computers become more powerful, some of the approximations can be eliminated, so we can improve our processing capabilities and thereby extract useful information from data which now yield little or none. In addition, we will be more finely sampling the seismic data. This will improve resolution, accuracy, and sensitivity in our interpretations of the subsurface by increasing the bandwidth of the data.

While much of this processing is done on large general-purpose computers, we have, over the last few years, begun to make more use of special-purpose computers, such as programmable array processors, and this trend is certain to continue. The use of interactive graphics is still in its infancy, and we will see considerable growth in the use of this type of computer aid. Consider, for example, the problem of reordering seismic data. Some of the processes mentioned above operate on one trace at a time. Others need all of the traces originating from a single shot. Still others need all of the traces having a common depth point; that is, those having the same midpoint between their respective shots and receivers. As we work with more traces, because of the need for higher redundancy, we will need a "black box" that can rapidly reorder the data prior to the individual processing steps.

Preprocessing during data collection will also require more special-purpose systems. Consider the current limitations of some of our data collection procedures. In a normal seismic survey, multiple (10-100) sensors, i.e., geophones or hydrophones, are connected to collect the data for a single trace. This increases the signal-to-noise ratio at the output of the sensor group over that available from the individual sensors and reduces (by spatial filtering) the effect of unwanted energy propagating along the surface. However, this type of configuration has limitations, particularly in recording higher frequency seismic data. In the last few years, we have been going in the direction of recording more groups, so that the length of each can be reduced.

Ultimately we may record each sensor individually. However, this leads to the collection of large volumes of data that must be transported back to the processing center and put through on the computer. This method may be limited to areas requiring the highest data quality obtainable.

In the next five years one can project data acquisition rates up to 40 MBits/sec, requiring a storage capacity per record (i.e., a single seismic event for a deep source, or twenty or so coherent events for a surface source) of 350-500 MBits. For normal crew operations, this would require a storage capacity of from 10-350 GBits/day's operation. Obviously we will need either a mass storage mechanism in the field, or more processing before recording, or possibly both.

In order to obtain many of the benefits of recording each sensor individually, we will probably go in the direction of preprocessing at the group level in the field (Figure 13) rather than in the processing center. The rapid growth of the computer hardware technology is well-known, particularly the increasing capabilities of micro-processors and the increased density of memory chips. It is reasonable to expect that within the next few years we will develop the hardware and software algorithms necessary to perform differential dynamic corrections, differential static corrections, and

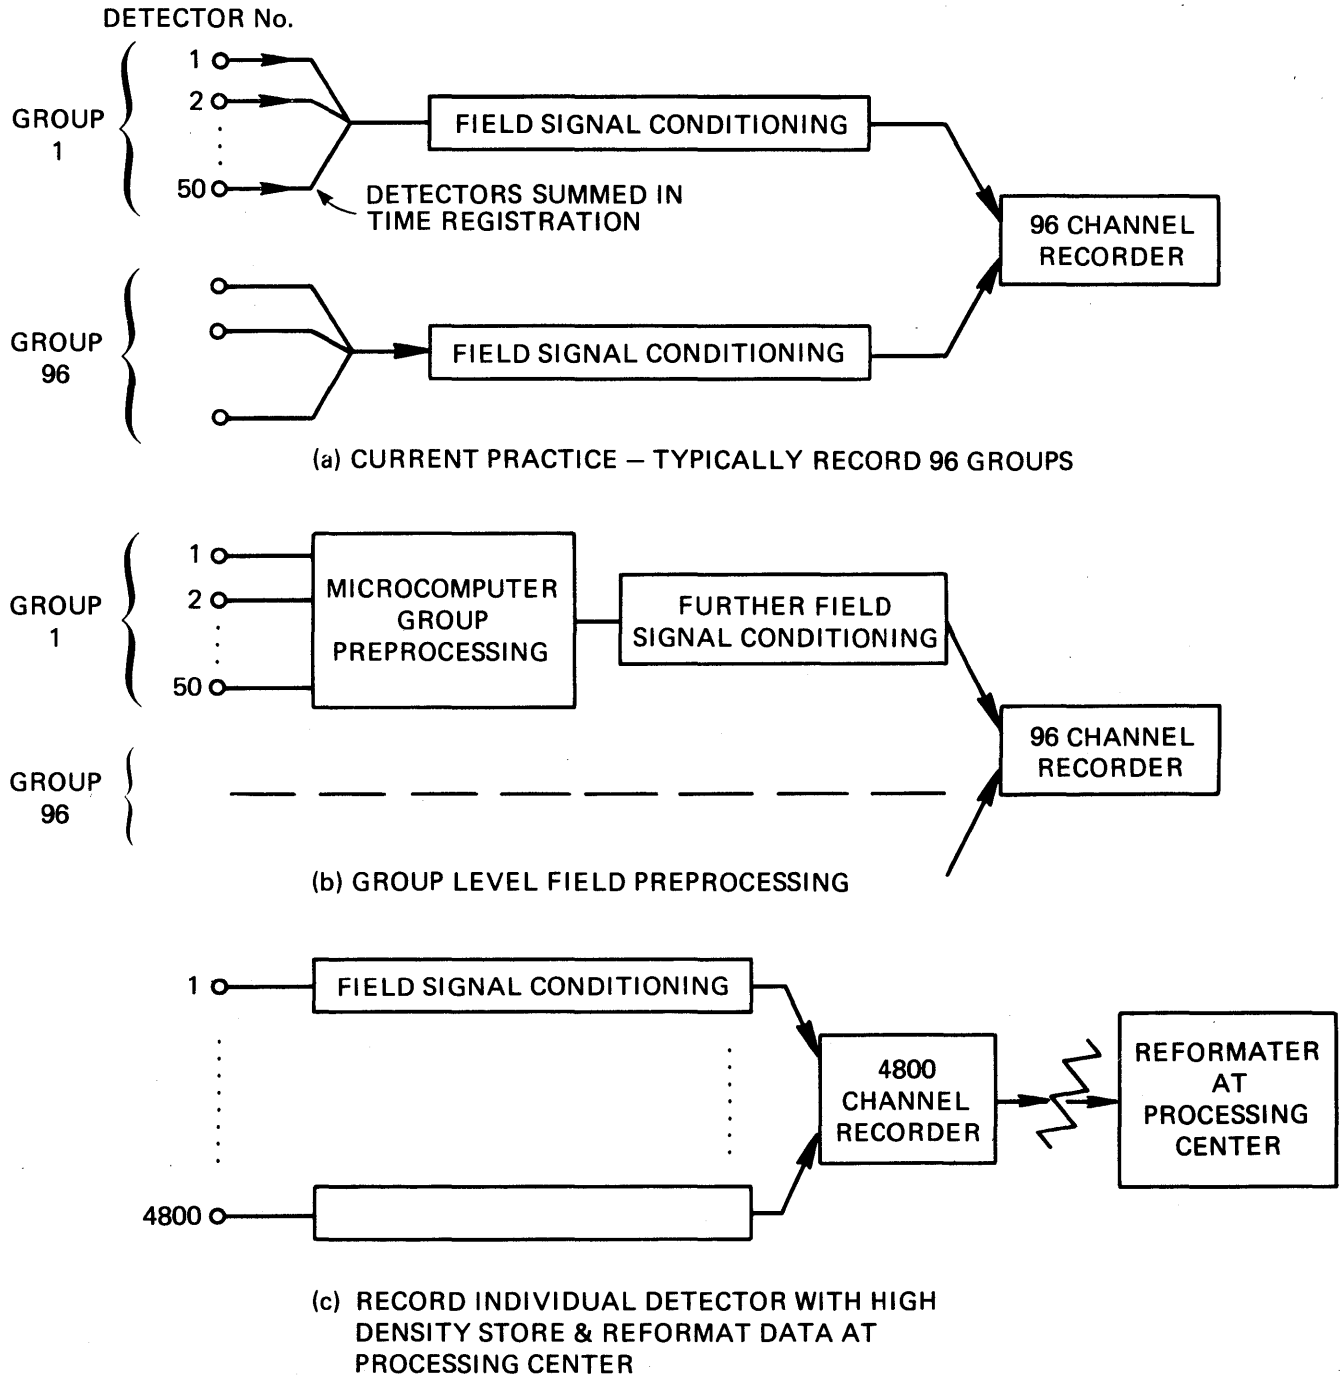

Figure 13—Group level preprocessing

waveform variation adjustments on the output signals from the individual sensors. We can then sum these signals in the field to obtain the equivalent of today's sensor group output.

In summary, computers are used extensively to assist in the exploration for oil and gas. Future processing and interpretation requirements will put greater demands on our use of computer technology, and we will have to use innovative approaches in order to solve these problems.

Remote sensing and image processing in earth resources

THE EARTH RESOURCES SITUATION

Population growth and demands for higher standards of living are creating pressures which affect all aspects of our society. The global population, currently near 3900 million, is growing at a rate of 75-80 million/year.

Coupled with population growth, and magnifying the effect, are rising demands for a more equitable sharing of the products and benefits of technology. The products and benefits derive from the consumption of natural resources. As societies develop and technological advancement begins, individual demands increase resulting in a more rapid rate of consumption of resources. Information is necessary to enable prudent decisions regarding the management of resources. But understanding alone will not lead to solutions on a long-term basis. Knowledge must be current, necessitating continuing inputs of fresh information. The most practical and economical manner of acquiring repetitive global, Earth Resources information is by means of a satellite-based remote sensing system.

Key to the utilization of the data is the ability to register the data to the ground, to previous images, and to data derived from other sources, and then to perform analysis. These together comprise the area of image processing.

IMAGE PROCESSING

The area as a whole will be covered by four sessions. They will be planned to lead persons not knowledgeable in image processing into the subject, with primary emphasis on image processing for remote sensing of the Earth. This area of application is selected because of its growing importance in the maintenance of our quality of life and the growing need for monitoring of the Earth's resources. The four sessions taken together will have some aspects of a short-short course, in that they will briefly introduce the remote sensing problem and the characteristics of images (Session I), discuss image-specialized computer techniques and programming considerations (Session II), then considerations of image processing system design and digital image based information systems (Session III). Session

IV is planned to be a panel, with presentations of future satellite and data plans and data characteristics. This is planned as a panel to allow rebuttals and discussions of these future plans and their implications to the computer world.

This format has been selected to provide cohesive treatment of the subject, with the thought that many computer people who have not been involved in it will become involved in the future as the popularity of digital image processing and analysis grows. This growth is expected based on the widespread use of the digital data to date, far beyond the early NASA expectations, and the NASA plans to provide much improved digital data in the future.

Applications have been discussed in other contexts extensively. The discussions here will lay the groundwork, but then concentrate on the implications to the computer world. These implications will include data timeliness, effects of various processes such as the necessary geometric registration on the utility of the data as seen during the subsequent analyses, and the user needs for interaction and data display.

In the applications world, images are getting larger, for example, up to 6000×6000 multiband elements for future Landsat. Data storage, dissemination, and processing are all going to be a problem, especially to the small or medium user. At the same time, the analyses being attempted are becoming more sophisticated. There is a need for image descriptive and image processing languages which will provide improved tools for the analyst. They must be flexible, efficient, and easy to use. New data dependent adaptive techniques are being devised.

The required image analysis cannot exist in a vacuum. Efficient systems must be provided. Three types are needed: (1) Large pipe-line systems for handling large quantities of data routinely and quickly; (2) Flexible, modular systems for research and/or interactive analysis; (3) Geographically oriented systems for use with/as geocoded data bases. These all have features in common: need for efficiency, need to retrieve and handle large multiple data sets (the images), possible need for interactive analysis and refreshed image displays. The latter two also have the need to be easily modularly expanded and updated. The geocoded systems must be able to input and output data in tabular and polygon form as well as imagery, and be able to use all together.

Information requirements for natural resource inventories

by WILLIAM J. BONNER
Bureau of Land Management
Denver, Colorado

INTRODUCTION

Background

The Bureau of Land Management (BLM) administers the natural resources on 191 million hectares of public lands in eleven* contiguous western states and Alaska. In addition BLM has management responsibility for 25 million hectares of publicly owned mineral resources on privately owned lands. Added to this is the management responsibility on approximately 500 million hectares of Outer Counter Shelf (OCS) lands.

The basic task of BLM is to manage all resources found on these lands to provide maximum public benefit and full consideration for good conservation practices. This includes the dedication to carrying out whatever programs are required to insure that the stewardship of the public lands and their resources leads to the optimum planned use for the long range public good. These programs include activities in domestic livestock grazing, fish and wildlife ecology and habitat development, outdoor recreation, timber production, watershed protection, wilderness preservation, minerals development, environment protection, river basin planning, and general land use classification under the concept of multiple use. Resource management and development activities are supported by various programs which provide for roads, trails, and physical improvements such as recreational facilities; and by an active program to protect the public lands and their resources from wild fires and from all forms of public and private misuse.

To carry out these programs BLM must collect and handle large quantities of resource inventory information. Further the fiscal and manpower resources which must be committed to gathering this information is staggering. This is due to (1) the increasing public awareness of the importance of wildlands as a national resource, and (2) the increasing need for documentation of the bases of management actions, including baseline resource conditions, trends, plans, and environmental analysis of proposed actions. For example, a large fraction of the vital energy resources (coal, oil, oil shale) of the nation underlie the public lands; the development of these resources in a manner consistent with national interests requires timely, accurate, and comprehensive resource inventory information.

In October 1976, the 94th Congress passed Public Law 94-579. The purpose of this Act is to establish public land policy; to establish guidelines for its administration; and to provide for the management protection, and enhancement of the public lands. In addition this Act which is known as the "Federal Land Policy and Management Act of 1976" charges the Secretary of the Interior with the following responsibility.*

> "The Secretary shall prepare and maintain on a continuing basis an inventory of all public lands and their resource and other values (including but not limited to, outdoor recreation and scenic values), giving priority to areas of critical environmental concern. This inventory shall be kept current so as to reflect changes in conditions and to identify new and emerging resource and other values. The preparation and maintenance of such inventory or the identification of such areas shall not of itself, change or prevent change of the management or use of public lands."

Thus Public Law 94-579 coupled with existing requirements causes BLM to reassess its traditional methodologies for the collection of resource inventory information.

Remote sensing in resource management

BLM is involved in a program with the National Aeronautics and Space Administration (NASA) and EROS Data Center (EDC) to evaluate remote sensing technology. The purpose of this evaluation is to determine the feasibility of performing resource inventory via remote sensing on an operational basis.

Management of the public lands under the concept of multiple use requires consideration of several resources. The BLM system identifies these resources as: range, forestry, wildlife, recreation, watershed, minerals, and lands. The common denominator of these resources is vegetation

* Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, Washington and Wyoming

* Public Law 94-579, Title II Section 201(a), 43 USC 1711, October 21, 1976

and for that reason BLM has selected the broad area of Wildland Vegetation as the theme for this program. The overall program objective is to test and implement a remote sensing based inventory system for wildland vegetation resources on an operational basis within BLM. It is planned to operationally implement the techniques developed during this project.

Agency roles

The Wildland Vegetation Resource Inventory Project is a joint effort between the three previously mentioned organizations. The BLM has overall management authority in the program and works closely with NASA and EROS to insure that project schedules and milestones are met and that program activities are successfully accomplished. In addition to this management function the BLM assumes the following responsibilities:

(1) Coordinate and document user activities within BLM.
(2) Perform cost analysis studies.
(3) Acquire large scale photography.
(4) Specify and evaluate output products.
(5) Implement training programs in remote sensing for BLM personnel.

NASA, working in cooperation with BLM, is providing the technical capability for the initial year of the program through a contract with a commercial remote sensing firm. As part of this contract NASA is obtaining data analysis, documentation, and specialized training for BLM personnel. In addition NASA is providing small and medium scale photography to be used as supporting data in the digital analysis processes.

EROS through EDC provides specialized facilities and equipment as well as technical support for key project activities. In addition EDC is collaborating with BLM on development and implementation of a BLM wide remote sensing training program.

The overall concept of NASA and EROS involvement is to transfer remote sensing technology to BLM. To achieve this goal a plan has been developed in which BLM rapidly assimilates the technology in house and assumes prime responsibility for performance of the project tasks. At the end of the program BLM will have an operational program in remote sensing and be independently capable of performing all activities required for wildland vegetation resource inventory.

TEST SITES

In selecting test sites for this program a number of factors were considered. It was desired to have test sites with a variety of vegetation. In addition test sites were to be representative of the public lands which BLM administers. The size of the test site was scoped at approximately one million hectares; a size judged sufficient to constitute a legitimate test of the technology but not so large as to require more than one project year to complete. The final criterion for test site selection was the presence of timber in sufficient volume to conduct a meaningful test of multistage sampling technology. Using these guidelines the BLM selected test sites in Alaska, Arizona and Idaho.

Alaska test site

The Alaska test site is located in the interior of Alaska and encompasses approximately one million hectares. The northern boundary of the site is roughly the foothills of the Alaska range. The southern boundary is defined by an east-west line passing through the confluence of the Maclaren and Susitna Rivers. The test site extends from the town of Paxson on the east to Cantwell on the west. The Denali Highway which is 135 miles in length transects the site. The range of vegetation in the test site includes all vegetation associations normally found in interior Alaska. Typical vegetation units are black spruce, alder, willow, and dwarf birch. Tundra units include many varieties of lichens, moss and grass. The test site is in an area which is known as the "Denali," the Athabascan Indian name for Mt. McKinley, meaning "The Big One." The Alaskan Test Site is typical of the northern spruce-tundra biome.

Arizona test site

The Arizona test site is located in the extreme northwest corner of the state of Arizona in the BLM Arizona Strip District. The test site is approximately one million hectares in size. It is bordered on the west and north by the states of Nevada and Utah respectively. Its eastern boundary is range line 6W and 7W and the Colorado River forms its southern terminus. The test site is approximately 88 km southeast of the town of St. George, Utah. The test site characterizes the southwest desert community and includes vegetation types common to that unit; such as, creosote, big sage, and blackbrush. In addition significant stands of pinyon-juniper and ponderosa pine are found in the higher elevations.

Idaho test site

The Idaho test site is in the southwest corner of the state of Idaho and is also comprised of approximately one million hectares. It is bordered on the north by the Snake River, on the east by the Boise Meridian, on the west by the state of Oregon and on the south by the state of Nevada. The test site typifies the extensive sagebrush-grassland communities of the inter mountain basins. Vegetation in the test site is primarily grass and sage with some douglas fir and pinyon-juniper stands in the higher elevations.

RESOURCE INVENTORY REQUIREMENTS

Landsat data processing

BLM is utilizing an interactive digital image analysis system for processing of Landsat data. This system is capable of processing digitized multispectral scanner (MSS) data and has a "stand alone" image processing capability which provides a wide range of digital image processing techniques. The system is configured to utilize a minicomputer and is user interactive, with an interactive color display. The system uses a maximum likelihood algorithm for Landsat classification. The hardware and software configurations are readily expandable for maintaining the system at the state-of-the-art and for meeting unique data requirements.

Preprocessing

BLM applies the following radiometric corrections to the Landsat data. These corrections are applied as appropriate depending upon the task to be accomplished. These radiometric corrections are: line drop, banding removal, noise filtering, atmospheric path radiance, and sun angle.

In addition to the previously mentioned radiometric corrections, the following geometric corrections are applied: mirror scan velocity profile, detector sampling delay, panoramic distortion, scan skew, earth rotation, spacecraft velocity, perspective geometry, attitude, altitude, map projection, and adjustment to ground control. These corrections are applied to obtain an accuracy consistent with the base map.

Classification for vegetation

A maximum likelihood algorithm is preferred for the classification process. BLM uses unsupervised, supervised and controlled clustering techniques for classification. Generally speaking controlled clustering is the approach most commonly used in BLM, due to the spectral variability which is found in wildland environments. Once the digital data has been classified (in this case a final product is referred to) it is desirable to apply a "smoothing" or "cleaning" algorithm to reduce the "salt and pepper" effect of pixel by pixel classification. In addition BLM has a requirement to "generalize" the classified data to provide representation of cover types for each map scale required. The classified data must also be quantified in terms of acreages for combinations of vegetative communities and their characteristics. These acreages must be compiled and tabulated for each class by total area and/or jurisdictional unit.

Data must be environmentally stratified for such parameters as topography, elevation, precipitation, and ecotypes. In addition administrative boundaries must be overlain on the Landsat data to the accuracy of the base maps used in the process. When appropriate BLM performs multidate processing to obtain additional information and accuracy from the classification process. Change detection is utilized to map physical changes resulting from wildfire, mining operations, and the like. It is also necessary to digitally mosaic adjacent Landsat scenes in order to produce a composite image of a study area.

Accuracy determination

In the past the evaluation of the viability of in place vegetation type maps produced through discriminant analysis of digital data image processing technicians have been inhibited by a lack of "a posteriori" verification. Verification provides an index with respect to the utility of the product. This verification must be a statistically valid evaluation of the accuracy of the classification and should be accomplished through a systematic or random selection of pixels from each class on the Landsat product. Pixels can be compared to classifications based on photo interpreted plots and ground samples to determine percent misclassified. Areas to be examined in the verification process must be chosen independently of the areas used in the classification process. The sampling design for verification must account for spatial errors due to pixel misregistration and the realities of collecting photography and ground data for the verification. The following items are acquired by BLM in verifying their classification products:

(1) A percentage accuracy of classification for each cover type class, with a corresponding statistical confidence statement for each percentage.
(2) A numerical summary for each cover type indicating the kinds of classification errors (omission and commission).
(3) A narrative indicating probable causes of misclassification; e.g., spectral similarity, spatial resolution, and phenological phenomena, etc.
(4) A definition of class names for cover types encountered in the classification process through species composition determination.
(5) A statistical confidence statement for each area by cover class determination.

Enhancement for geology

BLM uses both standard and enhanced Landsat products for the purpose of geologic interpretation. Enhanced products are produced using a variety of digital image processing techniques; such as ratioing, contrast stretching, truncation, fourier filtering, etc. Both environmental and geomorphologic data are required. Examples of the parameters of significance from our program in Alaska are as follows:

A. Environmental—structural geology
   1. Active volcanoes
   2. Geothermal hot spring areas
   3. Active glaciers, with aerial extent and whether advancing or retreating
   4. Active landslide areas and potential hazard areas

5. Large active snowslide areas
6. Severe erosion areas—classify genetically
7. Lineaments interpreted to be of geologic, tectonic significance
8. Geologic structures

B. Geomorphologic
1. Morainal features, classified as lateral or terminal
2. Outwash plains, classified as well-drained or poorly drained
3. Eskers
4. Alluvium, classified as silt and clay, gravel, or unsorted
5. Beach deposits
6. Igneous features, which produce a significant landform such as dikes, intrusive igneous structures with a topographic expression, volcanic cones, calderas, lava flows, etc.
7. Karst topography
8. Permafrost and nonpermafrost areas
9. Active strip mining areas
10. Bedrock geology—identify and map those remote sensing units which coincide with conventional geologic mapping units, i.e., formations, members.

Multistage sampling

Statistical sampling schemes, using multistage variable probability sampling for areal estimate of timber volume and rangeland productivity, are being used in this program in Arizona and Idaho. A Landsat digital classification is used as the stratification and small, medium, and large scale photography are used as necessary with supplemental ground work. The BLM program attempts to address rangelands, forest lands, and woodlands.

Rangelands

For each Landsat classified rangeland vegetation type the following parameters are estimated: ground cover, species composition, vegetation condition, forage production, and grazing carrying capacity. Statistics are aggregated by pastures and allotment.

Forest lands and woodlands

For each forest stand identified in the stratification process the following parameters are estimated: size and age class, areal extent, volume, mortality. Statistics are aggregated for each stand.* These same parameters are estimated for woodlands but since the concept of a stand for woodlands is not well defined, aggregation is by allotment.

* A stand is an aggregation of trees or other growth occupying a specific area and sufficiently uniform in species composition, age, arrangement, and condition as to be distinguishable from the forest or other growth on adjacent areas.

Figure 1—Example of provisional classification framework for Alaskan vegetation

Classification Framework and Platforms

For this project BLM has developed classification frameworks for use with remote sensor data. The classification system developed is suitable for use with data from both satellite and aircraft. Figures 1 and 2 are examples of the Provisional Classification framework for Alaska and Arizona respectively. Using Anderson (1976) the multilevel classification system indicates the fact that different sensors provide data at a range of resolutions dependent upon altitude and scale. In general, the following relations are reasonable: Level I—Landsat, Level II—High altitude aircraft, Level III—Medium altitude aircraft, Level IV—Low altitude aircraft. It is the goal of BLM to develop guidelines, based upon the foregoing, which indicate the scales and levels of data suitable for given management requirements. BLM is also attempting to push the different levels of data, such as Landsat, to its maximum extent hoping to obtain good evaluations of the satellite as a mixed level II, III, and IV sensor. Figure 3 illustrates vegetation classification level versus scale and source of data.

Level I	Level II	Level III	Level IV
Woodland/Brushland	Woodland	Juniper - Pinyon	Juniper
			Pinyon
			Juniper - Pinyon
			Pinyon - Juniper

OUTPUT PRODUCT REQUIREMENTS

A requirement exists for a variety of output products. Color coded classified maps adjusted to a Universal Transverse Mercator (UTM) projection are required. These maps are to a scale of 1:250,000 and are aggregated in eight or 32 hectare units as required. Polygon maps showing vegetation as sets of closed polygons are also used. Polygon maps are typically aggregated in eight hectare units. Another product which BLM has found to be beneficial is the line printer map which is typically at a scale of 1:24,000. In this product the aggregations are dependent upon print character size. Other products which are obtained from Landsat data are: geologic maps showing environmental, structural and geomorphological data; surface water maps showing clear and sediment laden water; fire hazard maps showing vegetation types and spread rates.

SUMMARY

BLM is responsible for the multiple use management of the public lands. Public Law requires that a continuing and current inventory be maintained on the public lands and their resource values. In order to meet the requirements of law, as well as to insure that the stewardship of the public lands and their resources leads to the optimum planned use consistent with the long range public good, BLM is evaluating remote sensing as an operational tool for resource inventory.

The remote sensing program and its attendant activities described in this paper attempt to define methodologies to acquire quality resource inventory data. Vegetation units are mapped, acreages are compiled. Multistage sampling techniques are used to estimate timber volume and standing forage. Change detection methodology is used to map physical change from wildfire and mining activities. Geologic maps are produced from sophisticated image processing techniques. All of the resultant data are verified using statistically valid processes. Products are evaluated and interpreted by qualified resource specialists who have also received intensive training in remote sensing. The result is the development within BLM of information requirement guidelines defining platform levels (satellite; high, medium, or low altitude aircraft) suitable for selected resource inventory tasks.

Digital image analysis techniques required for natural resource inventories*

by WAYNE G. ROHDE
EROS Data Center
Sioux Falls, South Dakota

INTRODUCTION

Landsats-1 and -2 have provided Earth resource scientists the opportunity to acquire multispectral data repetitively over large regions. These data are being used to monitor change in Earth resources, map resources over extensive regions, and inventory specific resource parameters. Application of these data to resource management problems necessitates development of interpretive methodologies that allow quick, consistent, and accurate extraction of pertinent information. In the 1960's, considerable effort was placed on developing digital and analog multispectral processing capabilities. Most of the capabilities were developed through research with aircraft multispectral scanner data. Many initial image processing capabilities were developed on systems that provided little flexibility to the analyst, were difficult to use, and required considerable computer time to complete an analysis. However, these capabilities and the availability of Landsat data has provided the impetus for engineering and development of new, improved, low-cost image analysis systems.[1–8] The trend has been toward more interactive systems that provide users greater flexibility in analyzing multispectral data more rapidly than previously possible.

Evaluation of digital image analysis of Landsat multispectral scanner (MSS) data for mapping and inventorying natural resources have been made.[9–15] These studies and others have led to the development of image analysis techniques that are useful in resource inventory and mapping programs. The purpose of this paper is to discuss analysis techniques that are commonly required for successful application of Landsat MSS data to natural resource inventories.

IMAGE PROCESSING

Radiometric corrections

Landsat MSS data are characterized by several types of radiometric anomalies including bad data lines and points, radiometric striping, and atmospheric scattering effects. Corrections or normalization procedures must be used prior to image classification to minimize the effect of these anomalies on the interpretation and analysis of Landsat data.

Bad data lines, line segments or pixel dropouts are often referred to as intermittent striping problems. Two techniques are commonly used to insert new data in place of bad data. One technique is to replace the bad data line with the preceding line. A second technique is to replace the bad data by interpolating between the brightness values from the pixels in the line before and after the bad data line (Table I). Although the difference between the two techniques seem slight, the latter tends to provide a more accurate representation of the correct brightness value.

Radiometric striping is characterized by variations in film density that should be uniform but often appear as systematic light or dark lines across an image (Figure 1). Radiometric striping introduces anomalous variations in the spectral signatures of resource cover types and will influence classification performance because of, (1) high variances, or (2) lack of adequate training data to characterize signatures of picture elements occurring in lines with striping. This striping is caused by unequal response of the detectors in the MSS to incident electromagnetic energy.

The Landsat MSS consists of six detectors for each of four spectral bands, a total of 24 detectors. Each of these detectors has a slightly different response to the incident electromagnetic radiation (EMR) falling upon it, thus, for the same intensity of EMR, a slightly different output voltage. Specifically, the detectors have different gains and offsets (Figure 2). To provide a uniform response, the six detectors of each band must be calibrated to a known source and corrections applied so that the output of each detector is the same for the same value of incident EMR over the entire useful range of the detectors. Removal of residual differences after calibration constants have been applied is called "destriping."

Several techniques are available to minimize effects of striping. One technique, histogram normalization, calculates the mean brightness value for each detector in each band (Figure 3). A normalization factor is calculated by ratioing the maximum mean to the mean of each detector. The normalization factor for each detector is then multiplied by the

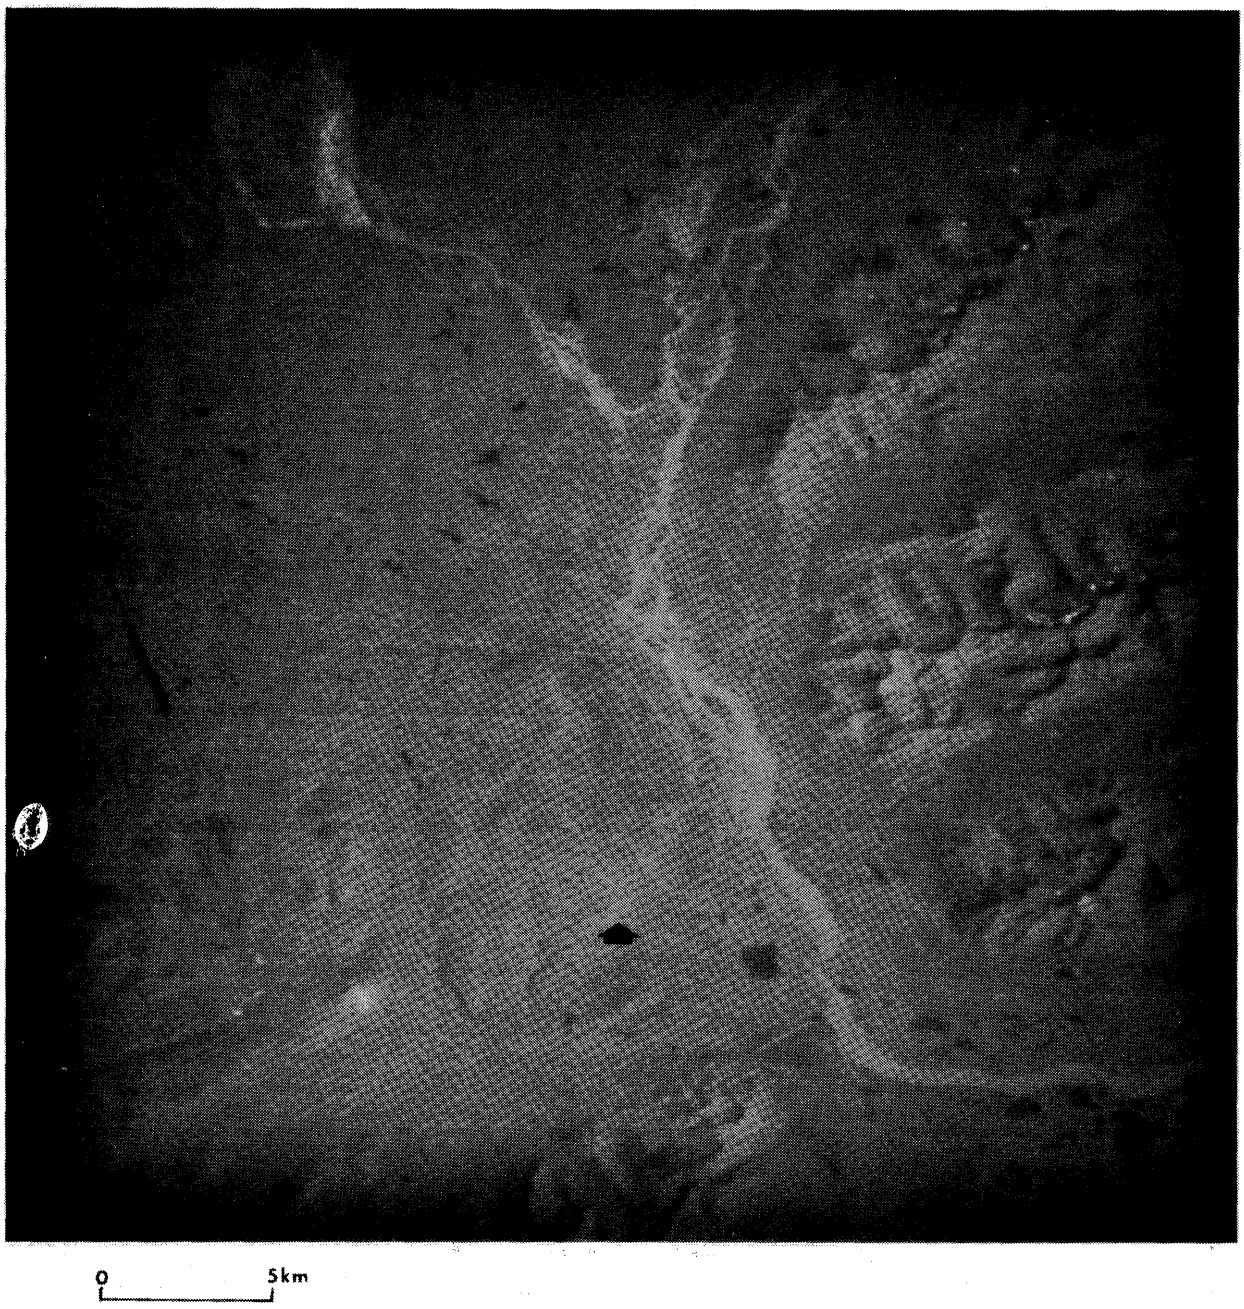

Figure 1—Part of a Landsat color composite from scene 5470-19560 acquired on August 1, 1976 over Cantwell, Alaska. Radiometric striping is characterized by horizontal lines across the image (see arrow). This image has not been geometrically corrected.

brightness value of each pixel recorded by the detector and the pixel is assigned a new brightness value. Figure 4 shows the same image as Figure 1 after destriping has been performed. Although this technique minimizes striping, residual striping, caused by localized radiometric anomalies, are sometimes found in the data. Other approaches to minimize striping effects in Landsat data are described in Reference 16.

Geometric rectification

Landsat digital data have inherent geometric errors that must be corrected if the data are to be correctly displayed on film, map overlays, or registered to some geographic reference system. The geometric errors can be either systematic and predictable or variable and measurable.[7] Geometric errors that are systematic and predictable can be

TABLE I.—Brightness values for each of 12 pixels in 15 consecutive scan lines. Line 8, typical of a bad data line, has pixels with brightness values considerably higher than pixels from adjacent scan lines. The bad data line can be corrected by replacing the data with values from corresponding pixels in the preceding line or by interpolating between brightness values from the pixels in the line before and after the bad data line.

Figure 2—Causes of radiometric striping in Landsat data

modeled and corrections applied to the data.[7,17] However, errors caused by variations in spacecraft attitude and altitude are not systematic or predictable. In natural resource inventories, accurate location of sample plots or specific resource features are required, thus, the non-systematic errors must also be corrected.

When variable errors are in the data, the effect of the errors can be determined by measuring the apparent displacements of ground control points. Ground control points are features that can be located in an image and whose geographic positions are known.

Once the displacement of control points is known, correction functions or mapping transformations are derived and used to calculate coordinates and map pixels into their correct spatial location on the corrected image. The corrected location of a pixel seldom coincides with a pixel in the distorted image, thus the distorted image must be resampled to determine the brightness value of the pixel in the corrected image. Three commonly used resampling techniques are nearest neighbor, bi-linear interpolation, and cubic convolution. In nearest neighbor resampling, a pixel in the corrected image is assigned the brightness value of the nearest pixel in the uncorrected image.

In bi-linear interpolation resampling, the brightness value of a pixel in the corrected image is determined by interpolating between brightness values of the four nearest pixels in the uncorrected image. In cubic convolution resampling, the brightness value of a pixel in the corrected image is determined by interpolating between the brightness values of 16 nearest pixels in the uncorrected image. More detailed discussions of geometric correction and resampling techniques are discussed in References 8 and 17 through 21.

In most natural resource inventory projects, that have utilized Landsat data, correction functions were calculated prior to classification, but the actual corrections were applied to the classification results. This procedure has been used largely because it is less expensive to correct one band of classification results than to correct four bands of multispectral scanner data.

In addition to correcting Landsat MSS data or classification results to a geographic reference system, geometric correction functions can be used to register one Landsat scene to another, register any graphic or map data to Landsat data, or compute the location of sample units for resource inventory applications. These capabilities are useful in subsequent analysis tasks to perform image stratification, calculate training statistics, refine image classification, allocate sample units, and estimate the geographic coordinates of sample units.

DIGITAL IMAGE CLASSIFICATION

Basically, the purpose of digital image classification is to group a large number of pixels into a number of meaningful categories that can be related to resource features. This grouping is normally done by a classification decision rule (e.g., minimum distance to the mean, parallelepiped, maxi-

mum likelihood). In resource inventory projects, Landsat digital data are commonly analyzed using interactive analysis procedures and a multispectral classification algorithm. Most classification algorithms require the analyst to specify training statistics for the desired resource classes.

Developing training statistics

Fleming, Berkebile, and Hoffer[22] describe three approaches used to derive training set statistics for use with a classification algorithm. These three approaches can be referred to as supervised, unsupervised, and modified or controlled clustering. When developing training statistics, the analyst must ensure that the training statistics represent the variation in spectral characteristics of all cover types found in the project area.

In supervised classification, the analyst selects areas that are spectrally homogeneous for each resource category. Because of variations in spectral characteristics of resource cover types, there often is more than one training area selected for each category. Training statistics, including the mean brightness value within the training area, variance about the mean, and the covariance between data channels are calculated for each training area. Adaptations of this approach use a clustering technique to identify a unique number of spectral classes within each training area. In either case, the analyst assigns a resource cover type to each training area prior to deriving the training statistics.

Unsupervised development of training statistics uses a clustering algorithm to group pixels selected for training into a number of relatively homogeneous spectral classes. The analyst can usually specify certain parameters to the clustering program including the maximum number of classes,

Figure 3—Mean brightness values for each detector in each spectral bank were calculated based on the data from the image shown in Figure 1. Normalization factors (K) are determined by ratioing the mean of each detector and the maximum mean for each band. After data are multiplied by the normalization factor, the normalized means indicate less variability between detector means, thus minimizing the effect of striping.

Figure 4—Part of a Landsat color composite from scene 5470-19560 acquired on August 1, 1976 near Cantwell, Alaska. The data have been destriped using a histogram normalization technique (compare with Figure 1). This image has not been geometrically corrected.

maximum standard deviation within a class, and the minimum number of pixels within a class. In addition to the clustering parameters, the analyst must also specify the pixels to be used in developing the training statistics. He may specify all pixels in the project area or randomly select sample areas of some specified size. Clustering of all pixels in a project area into a small number of spectral clusters or classes is sometimes referred to as unsupervised classification. After unsupervised classification, it is necessary to identify the resource category represented by each cluster. An image showing the distribution of the resource categories is made by combining all clusters of the same resource category into one class.

When classifying wildland vegetation, it is often difficult to identify spectrally homogeneous training areas for each resource category. In such situations, clustering of pixels within randomly selected training areas is often a useful approach for developing training statistics. This approach

was used to develop training statistics for classifying wildland vegetation and other land cover types on a 118,000 ha (293,000 ac) area near Cantwell, Alaska.

The area shown in Figure 4 was gridded into 4,096 eight-pixel-by-eight-pixel cells. Ten percent of the cells were randomly chosen and processed with a clustering algorithm to identify a unique number of spectral clusters in the data. Fifty-six spectral clusters were identified in the sample data. Using this approach to derive training statistics, it was assumed that the sample data represented all of the cover types in the area. Further, it was assumed that each cover type would be represented by at least one spectral cluster and that each spectral cluster would represent only one cover type.

A mean brightness value and its variance for each spectral band and a covariance matrix was calculated for each spectral cluster. These statistics were used in a maximum likelihood algorithm to classify each picture element into one of the 56 cluster classes. Color infrared photographs and field data collected in July 1976, were used to assign each cluster class to one of nine land cover classes. The data were color encoded and recorded on film with a film recording device (Figure 5).

Controlled clustering is another approach to developing training statistics. Using this approach, the analyst selects, either randomly or purposively, polygonal shaped training areas that usually include several resource cover types. Pixels within the training areas are clustered into a number of spectral clusters as in the unsupervised approach. The spectral clusters are printed onto paper or displayed on a color monitor. Using aerial photographs, ground data, and other supporting data, the analyst identifies the resource cover type associated with each spectral cluster prior to performing the maximum likelihood classification.[22]

Controlled clustering was used to develop training statistics to classify the extent of flooded agricultural land in an area near Fargo, North Dakota. Five training areas, each approximately 2,200 ha, were located on color infrared photographs. Areas were selected which represented the range of flood conditions and land cover types throughout the area. The training areas were located on the Landsat data and brightness values of all pixels within the training areas were clustered into a large number of spectral clusters. A line printer map of each training area was compared with a color infrared photographs and each spectral cluster was assigned to one of the ground cover classes shown in Table II. The statistics for all spectral clusters were used to calculate a statistical measure of the separability between spectral clusters in multidimensional space. The separability statistic and the interpreted cover class for each spectral cluster were used to determine which spectral clusters could be combined. The final statistics file contained 21 spectral clusters.

The training area statistics and the Landsat data were put in a maximum likelihood classifier. Evaluation of initial results indicated confusion between older residential areas and agricultural land which had been partly inundated. Fallow fields and fields recently plowed and planted were also misclassified as inundated (Figure 6).

TABLE II.—Land cover classification scheme used in mapping the extent of flooding near Fargo, N. Dak. in July 1975.

Cover type
1. Urban
2. Agricultural land not affected by flood
3. Partially inundated—agricultural land partially affected by flood condition
4. Completely inundated—agricultural land where effects of flooding were apparent over entire field
5. Standing water
6. Wooded (both dry and flooded)

The Landsat digital data were stratified into three strata to minimize the variation in land cover and inundated agricultural land within each stratum. A Landsat color composite was enlarged to a scale of 1:250,000. The general area affected by flooding was delineated on the enlarged Landsat image and plotted onto U.S. Geological Survey 1:250,000-scale maps and digitized. All urban areas greater than approximately 65 ha were plotted on U.S. Geological Survey 1:24,000-scale maps, and digitized. The digitized strata boundaries were registered to the Landsat image with a mean residual error of less than 0.5 pixel.

The strata boundaries were used to extract the image data associated with each strata. The original training statistics were modified to reduce the number of training classes and minimize the likelihood of misclassification noted in the initial results. A separate training statistics file was created for each stratum. The training statistics file and appropriate Landsat data for each stratum were input to a maximum likelihood classification algorithm to classify all picture elements. After classification, the three strata were added to reconstruct the original image. The final classification results are shown in Figure 7. Stratification of Landsat data prior to classification significantly reduced misclassification error.

Summarizing classification results

Image classification results show the areal extent of resource cover types. Because the data are in digital format, the area within each cover class can be easily tabulated (Table III). In most inventory projects, statistical summaries are desired by ownership, administrative units within an ownership, or political boundaries. If these boundaries are plotted onto maps and digitized, the boundaries can be registered to Landsat (Figure 8). The area of each cover type can then be summarized within each defined boundary. This technique has been used in several forest and range resource inventories.[13,23–25] Krebs and Hoffer (1976) have also reported on the use of digitized topographic data to summarize the area of cover types by elevation, slope, and aspect.

SAMPLING FOR ACCURACY ASSESSMENT AND RESOURCE INVENTORY

Although areas of cover classes can be tabulated for any polygonal area within the Landsat data, there is no indica-

Figure 5—Landsat classification of land cover types near Cantwell, Alaska. Barren lands are shown in black. Clear water and sediment-laden rivers are shown in dark blue and light blue, respectively. Tundra is shown in dark green, low shrub is shown in light green, and tall shrub is shown in red. Open conifer-tall shrub is shown in light red, open conifer-low shrub is shown in violet, and dense conifer is shown in purple.

tion of classification accuracy nor can a confidence statement be placed on the tabulated figures. In resource inventories, the parameter of interest may not be measured precisely on Landsat imagery; thus, sampling procedures are needed to derive estimates of the parameter of interest and to evaluate classification accuracy.

Investigators have shown that when remote sensing imagery at several scales is available, it is often most efficient to first make a large number of fast, inexpensive measurements of a parameter (X_i), on small scale, low resolution imagery, and then correlate this parameter with the parameter of interest (Y_i).[12,13,26,27] A second phase involves selecting a small number of sample units on which the parameter of interest (Y_i) is measured precisely on larger scale, higher resolution images. Statistical methods are then used to estimate the parameter of interest from the measurement made on each image type and to estimate the variability about the estimated total.

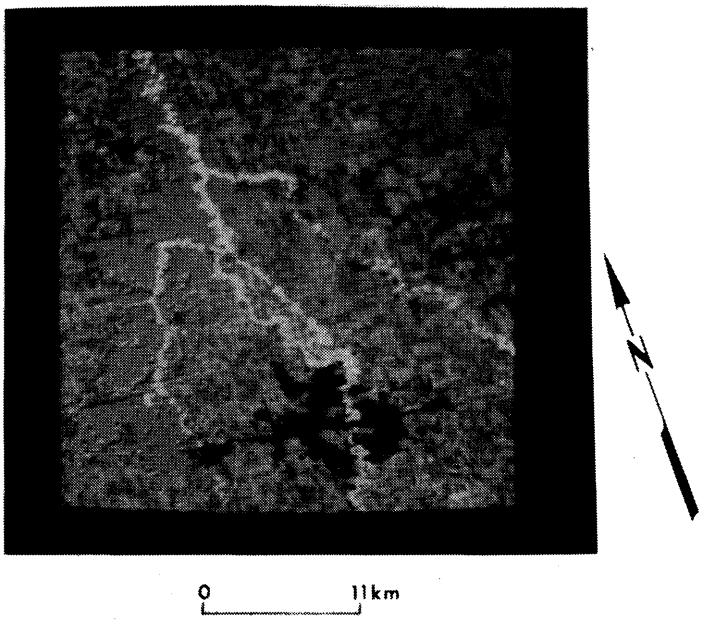

Figure 6.—Landsat classification results showing agricultural land affected by flooding near Fargo, N.D. Wooded areas are shown in light green. Urban areas are shown in red, and cropland not affected by flooding in dark green. Land where complete inundation occurred is shown in dark blue (standing water) and dark brown (land where there was no standing water on July 14, 1975). Land which was partly affected by flooding is shown in yellow. Initial results indicated confusion between older residential areas and agricultural land which had been partly inundated (see arrows).

Verification of classification accuracy

Evaluation of classification accuracy necessitates sampling each of the cover classes. One approach that can be used is a clustered-stratified random sampling technique. This technique will provide the user an estimate of the accuracy of cover types displayed on classification map overlays. This procedure allows evaluating accuracy on a pixel-by-pixel basis and also takes advantage of the efficiency in cluster sampling. To estimate the classification accuracy for the area shown in Figure 5 with an allowable error of ± 5 percent at the .95 probability level, 2,050 individual pixels would have to be sampled. The procedure for estimating sample size is presented by Rohde and others.[28] Because a large number of pixels were to be sampled, cluster sampling was used to reduce the amount of time required to locate plots and interpret specific pixels. Analysis techniques are used to superimpose a sample unit grid on the classification results, randomly select sample units, and tally the results within the selected sample units.

The classified image was gridded into five pixel-by five-line grid cells with each grid cell containing 25 pixels (Figure 9). Each grid cell constitutes a cluster. Sixty-two clusters were randomly selected and plotted on aerial photographs (Figure 10). Each photo was subdivided into 25 subplots (each subplot is equivalent to a pixel).

The predominant cover type at each subplot was interpreted from the aerial photographs. After the photo interpretation was completed, the computer classification of each sample unit was tallied and the classification of each subplot was compared to the photo interpreted cover type. The overall classification accuracy was estimated to be 84.5 percent ± 4.2 percent at the .95 probability level. An accuracy statement was calculated for each cover class using statistics described in Rohde and others.[28]

TABLE III.—Area Classified into Each Cover Class in the Cantwell, Alaska Area Shown in Figure 5.

Cover Type	Hectares	Acres
Clear water	1240	3063
Sediment laden water	2575	6364
Barren land	20508	50672
Tall shrub	7671	18955
Low shrub	26769	66144
Tundra	45524	112488
Open conifer/low shrub	3034	7497
Open conifer/tall shrub	8130	20089
Dense conifer	3159	7805
	118610	293077

Sampling procedures for area estimates

Multispectral classification techniques were used to classify the area of agricultural land near Fargo, North Dakota that was affected by flooding (Figure 7). Although the area could be easily tallied, a sampling procedure was required to place a confidence interval around the estimate.

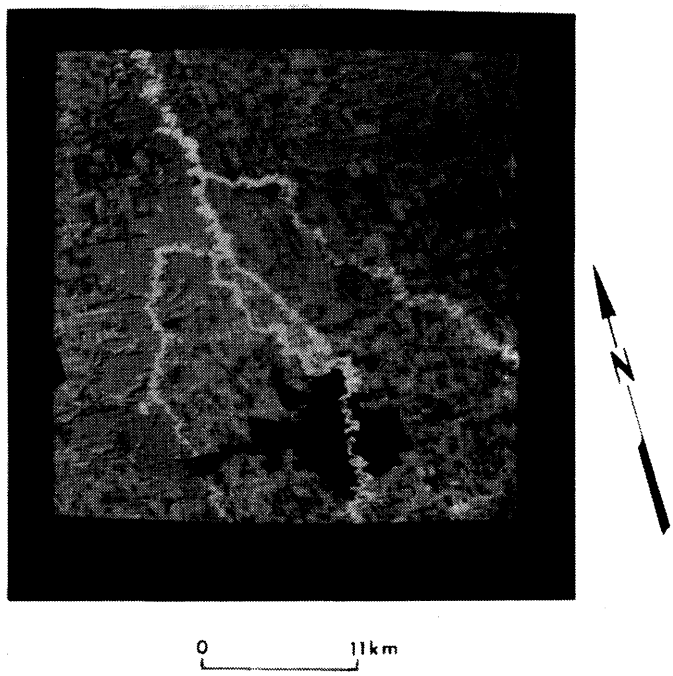

Figure 7.—Landsat classification results showing agricultural land affected by flooding near Fargo, N.D. Image stratification prior to classification reduced the misclassification between residential areas and agricultural land which had been partly inundated (compare with figure 6).

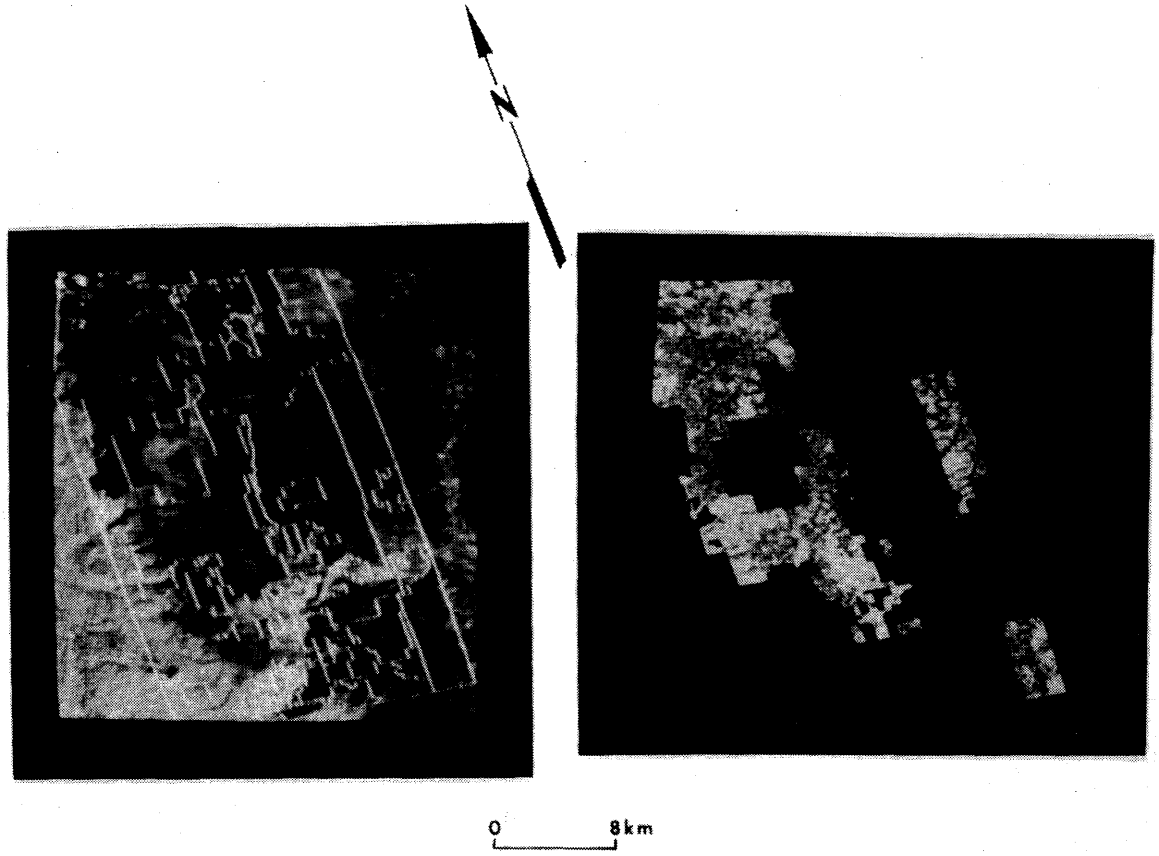

Figure 8.—Part of a Landsat color composite image from scene 2195-17520 acquired on August 5, 1975 (left). Land ownership boundaries were digitized and registered to the Landsat image. The Landsat data were classified into three broad volume classes (low, moderate, high) and summarized by ownership. Classification results for U.S. Forest Service land is shown on the right. Low volume is shown in white, moderate volume in red, and high volume is shown in green.

A two-phase sampling scheme was used. In two-phase sampling, sample units are the same size in each phase. The Landsat classification results provided the quick estimates in the first phase. A subsample of the first-phase sample units was selected for more precise measurements in the second phase. A least squares regression of estimates from the second phase on estimates from the first phase was used to adjust estimates made from the first phase.

Assuming a sample unit size of 1,600 pixels, the number of sample units required for measurement at each phase was estimated, based on an expected correlation between measurements made at each phase, the cost ratio of obtaining measurements at each phase, and the desired accuracy level. To achieve an estimate with an accuracy of ± 10 percent at the .95 probability level, it was estimated that 200 first-phase samples and 30 second-phase samples would have to be measured.[29] A forty-pixel-by-forty-line grid was placed over the classification results and two hundred sample units, 1,600 pixels in size, were randomly selected. The Landsat classification results in each selected sample unit were tabulated to provide the first-phase estimates. Thirty second-phase sample units were randomly selected from the 200 first-phase sample units. The latitude and longitude coordinates were computed for the four corner points of each second-phase sample unit. Each second-phase sample unit was plotted onto U.S. Geological Survey 1:24,000 scaled maps and transferred to color infrared photographs. The area of cropland affected by flooding in each second-phase sample unit was estimated with a dot grid. The area estimates made on the second-phase sample units were used to develop regression coefficients to adjust estimates made in the first phase from the Landsat classification.

Using two-phase sampling statistics, 379,165 ha of agricultural land were estimated to be affected by flood conditions. It was also estimated the 148,020 ha were partially affected and 236,835 ha were completely flooded. The area estimates and associated sampling errors are shown in Table IV.

The ability to overlay a sample unit grid of varying size on Landsat data, tabulate classification results within sample units, and calculate geographic coordinates of sample units, provide data that resource specialists can use to define sampling schemes or allocate sampling efforts to derive resource estimates. Landsat data, multi-phase and multi-stage sampling techniques have been used in numerous resource inventory projects.[28]

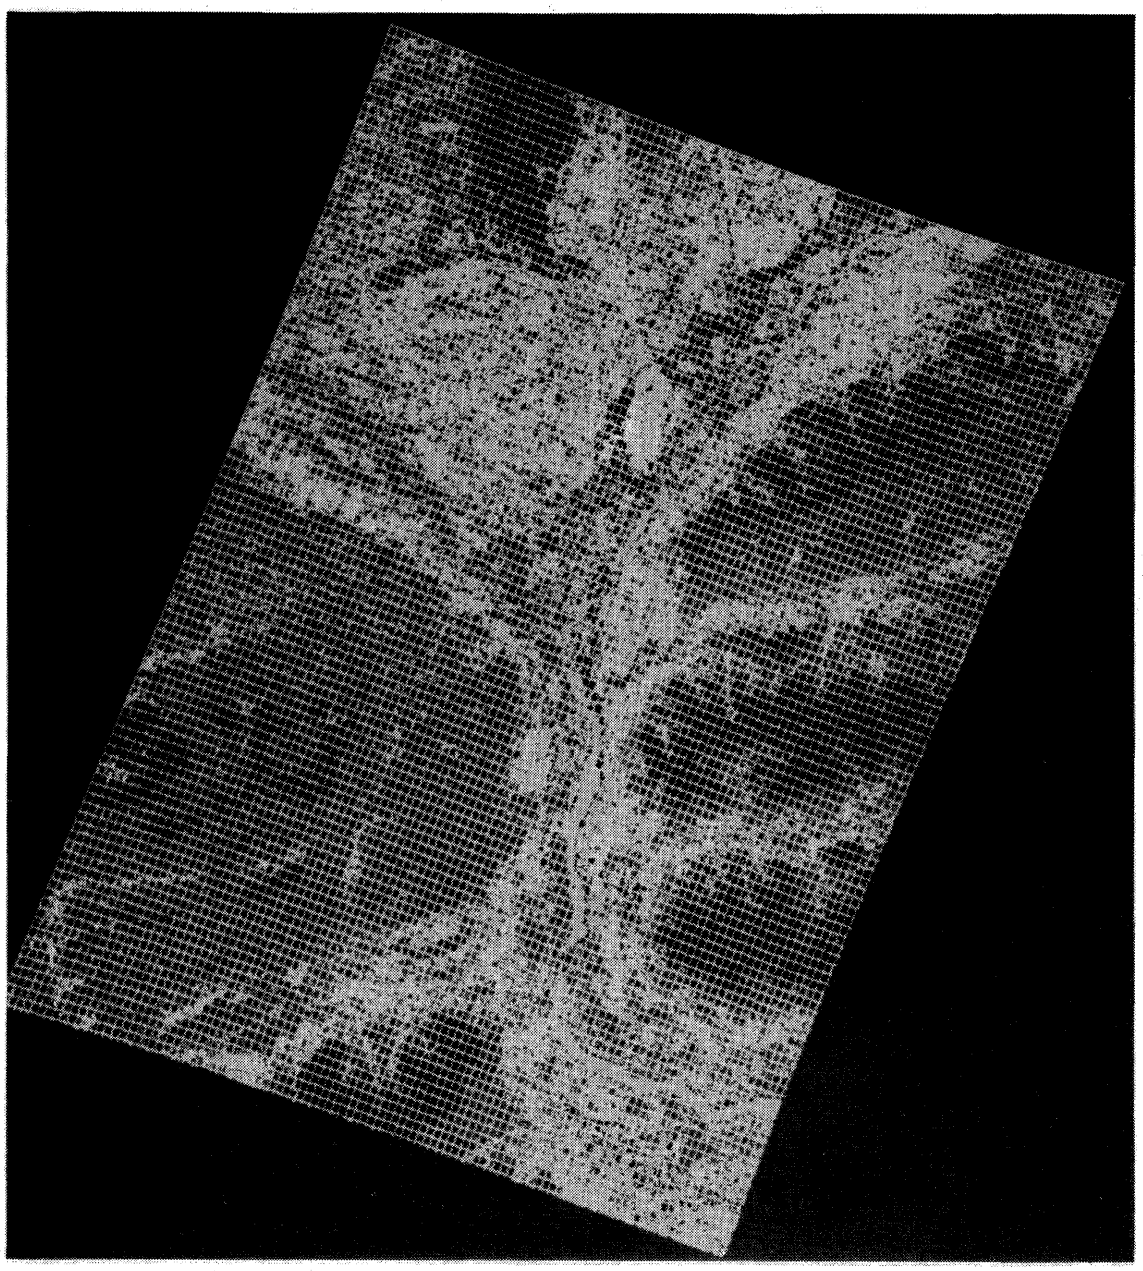

Figure 9.—Five pixel by five line sample unit grid superimposed on Landsat classification of land cover types near Cantwell, Alaska. The color scheme is listed in figure 2. Sixty-two sample units were randomly selected with equal probability for interpretation on aerial photographs to estimate the classification accuracy.

OUTPUT PRODUCTS

Resource managers often need map overlays that show the areal extent of resources being inventoried or mapped. Common requirements include color encoded map overlays or line map overlays at various scales from 1:24,000 to 1:250,000. Digital classification results provide great flexibility in displaying data in various formats and map scales. The data can be easily aggregated for display at various levels of generalization or at a given level of detail to simulate various minimum mapping units.

In most multispectral classification techniques, each individual picture element (0.40 ha or 1.1 ac) is assigned to one class. This often results in a "salt-and-pepper" appearance on map overlays. Spatial smoothing programs can be used to simulate a minimum mapping unit and to reduce the "salt-and-pepper" appearance. The image in Figure 11 was processed with a smoothing algorithm to simulate an approximate 4 ha (10 ac) minimum mapping unit. A three pixel by three line cell was passed through the data one pixel at a time. The first and last lines and the first and last pixels in each line were not changed. All other pixels were reas-

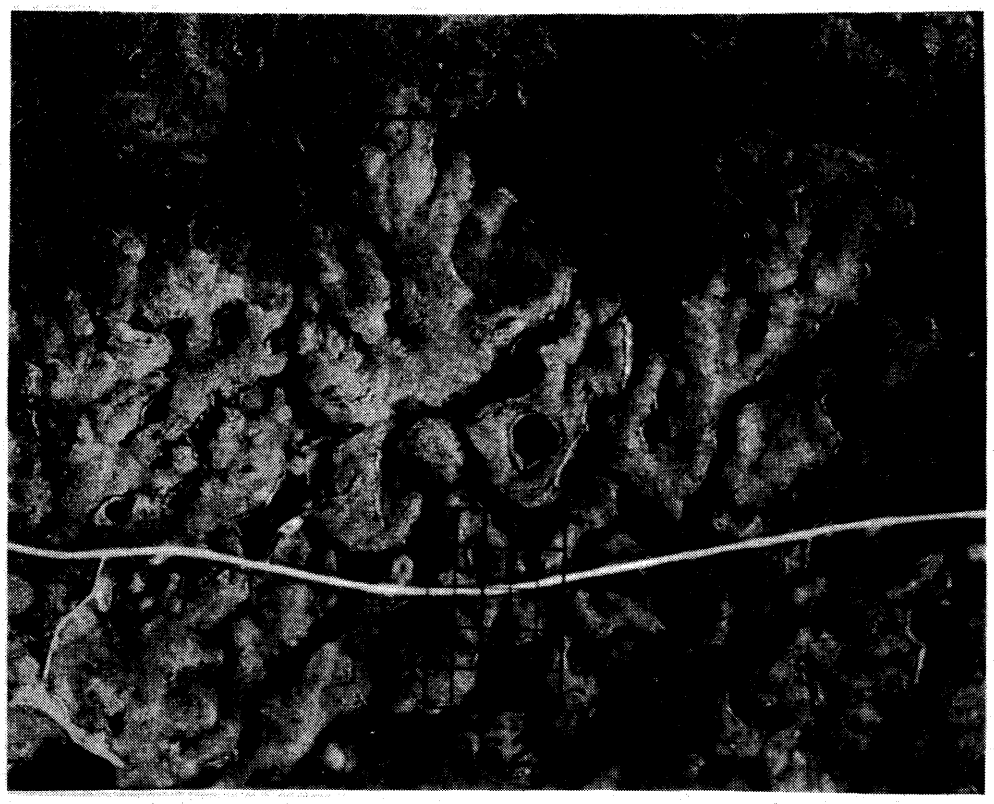

Figure 10.—Color infrared aerial photograph showing sample unit number 4962. Each sample unit was divided into 25 subplots where each subplot represents a pixel (.40 ha or 1.1 ac).

signed to the most frequently occurring class in the three pixel by three line cell. Although this technique tends to reduce misclassification caused by edge effects from several resource types, small, narrow features may be lost unless classes representing such features are more heavily weighted when the smoothing function is applied.

The final classification results can be color encoded on film, printed by a line printer, or plotted onto a map overlay with a plotter. Color encoded map overlays are made by recording onto film the classified digital data that have been geometrically corrected, registered and scaled to the desired map base. The data can be recorded either directly onto color film or onto three separate black-and-white images that can be composited into a color image (Figure 11).

Classification results can be printed with a line printer where each cover class is represented by a unique symbol.

TABLE IV.—Estimate of Agricultural Land Affected by Flood Conditions.

Cover Class	Hectares	Sampling Error
		Percent
Partial inundation	148,020	5.4
Complete inundation	236,835	6.1
All areas affected by flooding	379,165	3.9

With appropriate geometric correction functions, the data can be printed at various scales; the most common are 1:24,000, 1:62,500, and 1:63,360.

Classification results can be plotted as polygons on map overlays that have been registered and scaled to the desired map base. The final map overlay can show each polygon in color with different shading patterns or with polygons numbered to correspond to a cover class in the legend. Figure 12 is an example of a map overlay that corresponds to a portion of a U.S. Geological Survey 1:63,360 scaled map.

Other techniques exist to format classification results to a user specified grid cell size and register the data to an existing information system. This capability allows a resource scientist to merge other ancillary data (e.g., soils, landforms, hydrology, elevation, slope, aspect) with the classification results.

SUMMARY

Landsat digital data with supporting aerial photographs and sampling techniques were used to accurately map wildland vegetation and inventory flooded agricultural land. Image analysis techniques were required to make radiometric and geometric corrections. Techniques were needed to stratify the Landsat data prior to classification to reduce the probability of misclassification.

Interactive analysis techniques were used to develop training statistics and to evaluate initial classification results. The classification results were used in sampling schemes to evaluate classification accuracy and to inventory the area within each cover type. Analysis techniques were used to partition the project areas into sample units, summarize classification results within sample units, and to select and locate sample units. Image analysis techniques were also used to plot the classification results on map overlays that were registered to 1:63,360 scaled maps.

Continued development and improvement of image analysis techniques are needed to make them more efficient. As these techniques are improved, Landsat data, used in its proper context with supporting data, and sound sampling strategies, can be an effective tool in conducting natural resource inventories.

Figure 11.—Landsat classification of land cover types near Cantwell, Alaska. A spatial smoothing algorithm was used to eliminate the "Salt-and-pepper" appearance as shown in figure 5. The smoothing was done to simulate an approximate four ha (ten ac) minimum mapping unit. Barren lands are shown in black. Clear water and sediment laden rivers are shown in dark green; low shrub is shown in light green, and tall shrub is shown in red. Open conifer—tall shrub is shown in light red; open conifer—low shrub is shown in violet, and dense conifer is shown in purple.

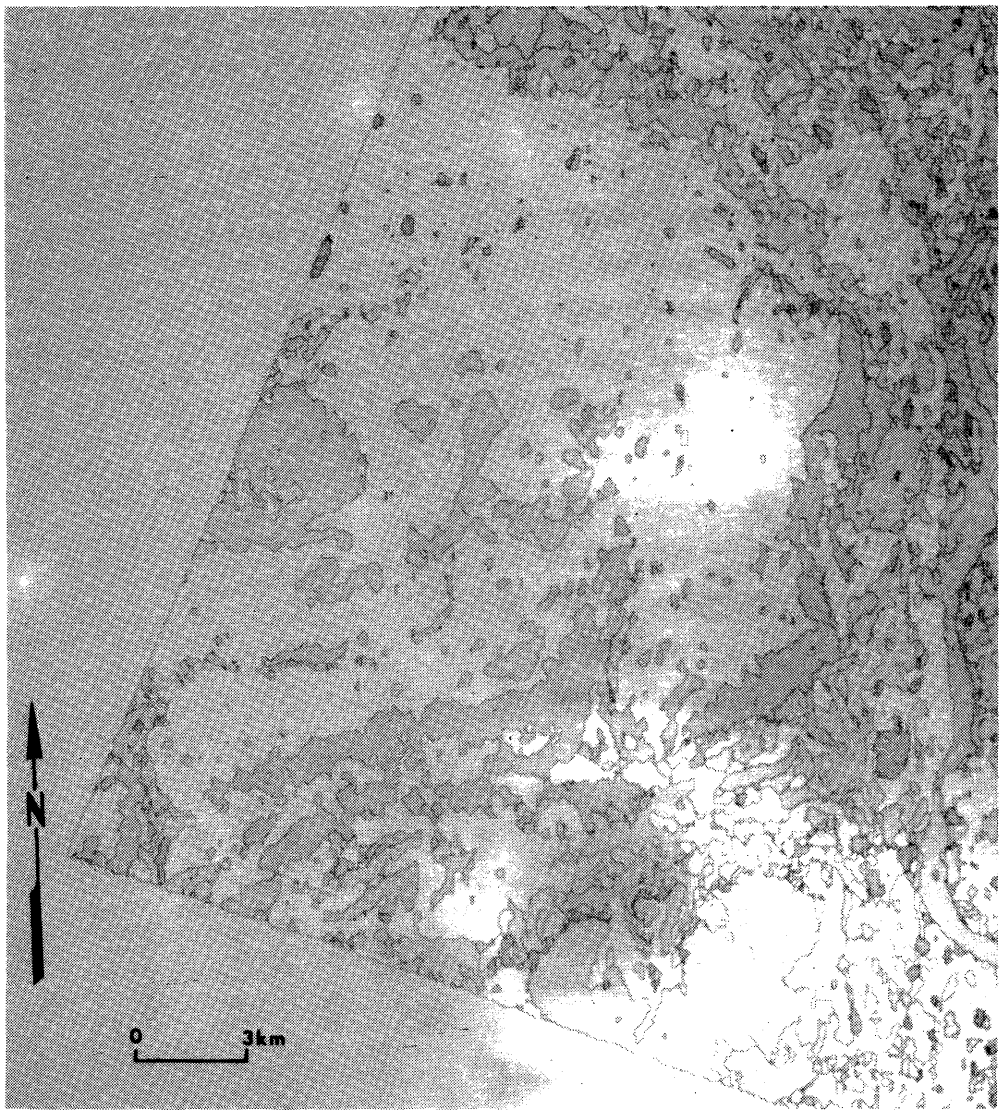

Figure 12.—Example of Landsat classification results that have been geometrically corrected and plotted on a map overlay. This overlay is part of the total area shown in figure 5. The map overlay was scaled to register to the U.S. Geological Survey 1:63,360 Healy A2 map sheet. Barren land is shown in blue, single-horizontal lines. Clear water and sediment-laden rivers are shown in dark blue, double-horizontal lines and blue dots, respectively. Tundra is shown in white, low shrub is shown as green dots, and tall shrub is shown in red dots. Open conifer—tall shrub is shown as green triangles, open conifer—low shrub is shown as dark red, double-vertical lines, and dense conifer is shown as dark red single-vertical lines.

Digital image analysis applications in state natural resource agencies

by PAUL A. TESSAR
National Conference of State Legislatures
Denver, Colorado

INTRODUCTION

State government agencies are becoming increasingly involved in developing and applying digital image processing capabilities to fulfill state responsibilities. Experimental visual Landsat applications were attempted by many state agencies from the launch of Landsat-1 in July, 1972. Digital applications, however, were generally not attempted in state agencies until the middle of 1974. Since then, many states have been involved in investigations and demonstration projects utilizing digital image processing techniques. Several states (e.g., Texas, Georgia, and South Dakota) have established in-house operational or quasi-operational digital Landsat capabilities. It is clear that the trend of the future is toward the establishment of such capabilities in many states.

Often, the development of digital Landsat analysis and application capabilities is within the context of a state natural resource information system. Digital Landsat data is extremely compatible with geographic information systems, once compensation is made for technical problems. Existence of a state system provides a focal point for adopting satellite remote sensing techniques, thereby facilitating technology transfer efforts. On the other hand, in states which do not have a natural resource information system, the development of Landsat digital analysis capabilities has often led to the examination of more general computerized natural resource data analysis systems. In either case, there is a synergistic effect from the mixing and comparing of several types of data in a computer.

The experiences of two state programs in developing or acquiring and applying digital Landsat analysis capabilities are discussed below. The approach, emphasis and results are quite different in each case. All fifty states, however, are different in terms of institutional structure, political climate, role of state government and local needs. While each state is unique overall, a number of features and experiences are shared by many. By studying similar type developments in other states before attempting them at home, pitfalls can be avoided and successes repeated. Hopefully, the experiences of North Dakota and South Dakota will prove useful in this vein.

THE NORTH DAKOTA REGIONAL ENVIRONMENTAL ASSESSMENT PROGRAM'S STATE LAND COVER ANALYSIS

The North Dakota Regional Environmental Assessment Program (REAP), a division of the State Legislative Council, was created by the 1975 North Dakota Legislative Assembly as a result of a recognized need for a comprehensive and coordinated source of natural resource-related information. The immediate impetus for such a program was current and prospective large-scale coal development in southwestern North Dakota. Enabling legislation directed REAP to carry out studies and research related to natural resources and to develop a comprehensive information and analysis system for the storage, retrieval, and analysis of such information. Furthermore, REAP was especially directed to develop the capability of forecasting the impact of natural resource development alternatives which may be considered by the state.

In order to meet its responsibilities, REAP has undertaken four specific tasks: (1) the collection of existing baseline data, together with a major effort to fill recognized data gaps; (2) the design, development, and installation of a computer-based information system capable of storage, retrieval, representation, and analysis of appropriate data; (3) development of a variety of capabilities, including models, for assessing the impacts of proposed natural resource development; (4) the establishment of a means for the regular monitoring and updating of data so the information system will remain current and the analyses relevant.

In the fall of 1975, REAP conducted an exhaustive study of the relevant data sources and gaps. Through this effort, it was recognized that there was no comprehensive land cover inventory for the state of North Dakota. Accordingly, REAP identified the completion of such an inventory as a major task requiring early attention.[1]

Several different technologies were consideered for inventorying the land over the entire state of North Dakota, approximately 180,000 sq. km. (70,665 sq. mi.) in area. The technology chosen, satellite remote sensing, uses imagery obtained from the Landsat satellites launched by the National Aeronautics and Space Administration in July 1972

and January 1975. One of the major advantages of Landsat imagery is that the entire state of North Dakota can potentially be covered every nine days, and therefore repetitive comparative imagery is available. This technology therefore provides a mechanism for conducting a baseline land cover analysis for the state and for monitoring how that land cover changes over time. Since a near-permanent platform for imaging is available at no cost to the state, it is more economical to use such a system than to undertake complete aerial photographic coverage of the state, and to propose frequent repetition of the coverage for monitoring purposes. Another distinct advantage is the large areal coverage for any given image which permits discerning gross land features often not perceivable with aerial photography. Landsat imagery is particularly amenable to computer analysis, whereas such techniques have not been well developed for photographic imagery. A disadvantage of utilizing Landsat imagery is that a high degree of detail, particularly in urban-type areas, is usually not available. Thus, it is generally not feasible to attempt to obtain a full level II land cover analysis utilizing Landsat imagery; a thorough level I analysis is readily obtainable, however.[2]

Categorization

Computer processing of the Landsat data from computer tapes as received from the EROS Data Center was performed by the Bendix Aerospace Systems Division using a Bendix datagrid digitizer system and the Bendix multi-spectral data analysis system (MDAS).[3] The process involved identifying an area on a computer display terminal which coincided with the exact shape and location of a given training set. A computer was then coded to identify all areas in that particular scene with a similar reflectance. Finally, a color was assigned to indicate all such areas. In a follow-up process, color-coded areas of a particular category were checked against the available ground truthing information to ensure that the computer search for similar cover was complete. This process was repeated for each of the land cover categories. The final result was what is called a "categorized" tape.

As a result of categorization of the 19 Landsat scenes, as few as 12 and as many as 36 different categorizations were determined. For example, in two different scenes up to 14 different categories of water were identified. As many as nine different categories of cropland were detected but there were only three different wetland categories. All categories identified through this process have been retained on the categorized tapes. However, for purposes of displaying the results of this land cover analysis on colored maps, an extensive merging of categories was undertaken.

Ten different land cover categories were selected for display on maps and a color was assigned for each category. The 10 categories selected for map display include all seven applicable Level I categories suggested by the U.S. Geological Survey,[2] and five Level II and Level III sub-categories.

Results

North Dakota is one of the first states for which detailed land cover analysis has been completed utilizing computer processing of digital Landsat imagery. The results of this land cover analysis have been incorporated in several different products which will be available for public purchase and technical use. Each of these products will be described in some detail below.

The first product of the land cover analysis is a color-coded map for each of the 53 North Dakota counties at a scale of 1:126,720 (exactly two miles to the inch). On each map, a color is used to designate each of the 10 different land cover categories as indicated in Table I. Each county map contains information on the scale, the color legend, the name of the county, a small map of the state with the county darkened, and an outline of the county containing the date(s) of the Landsat imagery used for the analysis. To produce these maps Bendix developed a technique to create a high quality color negative merging the land cover and the base map data. The land cover data was produced by the computer processing discussed above, and the base map was an edited version of the detailed county highway maps.

The second product of this analysis is an area tabulation for each township, county, and the state. For each of these geographic units, a table was prepared indicating the acreage covered by each of the 10 land cover analysis categories. The area tabulations were prepared by reading a digital tape file and summing the land cover to the appropriate geographic area. The area tabulation for the entire state is shown in Table I.

The third product of the land cover analysis is a map of the entire state of North Dakota at a 1:500,000 scale (approximately eight miles to the inch) which contains the land cover illustrated by the appropriate color, the same as used on the county maps, a legend and the county boundaries.

The final product of the land cover analysis is a digital tape file of land cover data prepared in a specified cell format. The objective of this effort was to prepare land cover information aggregated to 40-acre cells, registered by

TABLE I—North Dakota Land Cover by Category

Land Cover Category	Acres	Percent of Total
Built-up Land	19,777	0.04
Cropland	15,956,690	35.24
Fallow Land	6,189,168	13.67
Exposed Subsoil or Saline Seep	100,952	0.22
Rangeland	11,889,387	26.26
Mixed Range, Agriculture, and Pasture	7,630,329	16.85
Forest	386,823	0.85
Water	1,265,812	2.80
Wetland	780,284	1.72
Barren Land	975,863	2.16
Uncategorized	80,787	0.18
Total	45,275,872	99.99

quarter-mile section of the Public Land Survey. Thus, all pixels with center points lying within the given quarter-quarter section were tabulated and grouped by land cover category.

Summary

The first complete land cover analysis of the state of North Dakota has been conducted utilizing computerized analysis of Landsat imagery. The products of the analysis are color-coded maps of each of the 53 counties in the state and a state map. Tables of area coverage of each land cover category are also available. The digital information for each pixel in the state is recorded on computer tape for subsequent utilization in the REAP computer system.

This analysis has revealed a number of unique capabilities of the Landsat imagery process, those utilizing more than a single Landsat scene. The products of this analysis are already being used in corridor analysis for transmission lines, resource analysis, water management problems, non-point source pollution studies, and regional environmental analysis. The results provide an essential data base for the REAP system and will serve as the basis for monitoring changes in land cover in the state of North Dakota.

LANDSAT APPLICATIONS OF THE SOUTH DAKOTA LAND RESOURCE INFORMATION SYSTEM

In the early 1970's, the South Dakota State Legislature recognized the need for land related policy and planning decisions to be based on solid, objective data. In 1974, the Legislature facilitated the establishment of this information base by authorizing the South Dakota State Planning Bureau to investigate the means for collecting the desired land resource data. This investigation resulted in the initiation of the South Dakota Land Use Inventory and the formulation of the Land Resource Information System (LRIS). The inventory, using both photographic and digital Landsat data, began as a three-year, three-phase cooperative project between the State Planning Bureau and the EROS Data Center. The agreement specified that EROS would supply technical assistance and imagery, while the state would supply personnel to initiate and maintain an in-house system for interpreting, storing and applying the land use data to South Dakota operations.

One important factor regarding the South Dakota Land Use Inventory needs to be emphasized. The State Land Use Inventory program established an in-house analysis capability that will allow mapping as the need arises. The ability to perform special manipulations with existing data, the tools for updating the inventory, and the capability for special projects such as the 208 work make the program especially flexible and valuable to the state. Many of the applications outlined below have resulted from ad hoc projects that necessitated some form of additional manipulation of analysis of the standard county land use data.

Phase I—Land use analysis

The initial phase of the South Dakota Land Use Inventory produced a map displaying a generalized picture of the distribution of major land uses across the state. Seventeen Landsat scenes from the spring of 1973 were required to provide cloud-free coverage of the entire state. These images were manually interpreted to determine the dominant land use found within every quarter section (160 acres) in South Dakota. The categories classified included urban, rangeland, agriculture, forest, water, wetlands, and barren land.* This phase of the land use inventory was intended to produce an educational tool in the form of a map that displayed the complexity of land use across South Dakota. The total production time for this map was 24 weeks. The total cost for production and dissemination of the map was $4,920, or 6¢ per square mile.

The Phase I state land use map provided an overview of the current land use of South Dakota. Due to the crude level of detail, the map could not be utilized for detailed planning activities. However, it did stimulate much interest in the value of Landsat data for large area investigations. While most requests were from educational organizations interested in its academic value, several agencies did utilize the map for management purposes.

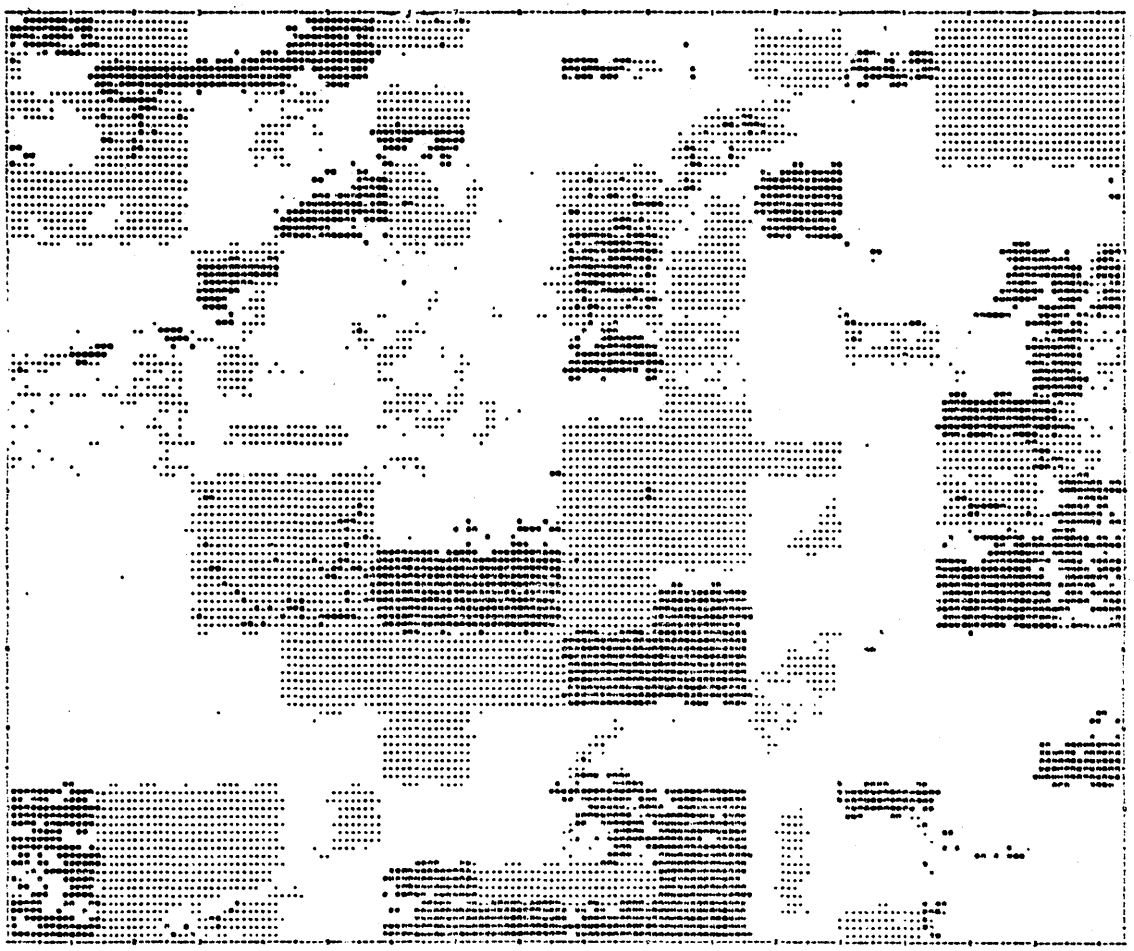
Phase II and III land use

State Planning Bureau anlaysts decided that more detailed land use information could only be obtained from Landsat data by utilizing more advanced analysis techniques than those used to produce the Phase I map. Landsat computer compatible tapes, which contain the same information as photographic Landsat imagery but in much greater detail (1.1 acre cells), provide this additional information. Computer software allowing this analysis was developed during fiscal years 1976 and 1977, and is contained in a computer package entitled *Landsat Imagery Analysis Package* (LIMAP).[4] These methods were employed early in Phase II to initiate a comprehensive, statewide land use inventory. The major differences between the output of this inventory and the Phase I land use mapping effort are:

(1) The maps produced in Phases II and III are based on data in 1.1 acre cells rather than 160 acre cells. The 1.1 acre data can be displayed with that cell size or aggregated to any meaningful larger cell size such as 10 or 40 acre cells (Figure 1).
(2) The classification scheme of Phases II and III contains more detailed land use categories. Table II contains a complete listing of the categories used in the digital land use inventory.
(3) Phases II and III maps are produced on a county

* This classification scheme is a Level I categorization adopted from: Anderson, J. R., et al. *A Land-Use and Land Cover Classification Scheme for use with Remote Sensor Data* USGS Professional Paper 964, Washington, D.C., 1976.

1.1 acre display



10 acre aggregation

Figure 1—Cow Creek Township, May 15, 1973, data aggregation

rather than on a statewide basis. The enormous quantity of data required to complete a 1.1 acre inventory of South Dakota necessitated storing the data in county files. These files, however, can be easily manipulated to produce maps of many different areas, including townships, watersheds, multicounty regions, or other regular and irregularly shaped areas.

(4) The digital format of the Phases II and III data permitted the development of computer software to rapidly scale the data to virtually any scale and cartographic projection. This added flexibility satisfies the needs of a variety of users by matching the scale of the land use data to customized base maps.

These increases in data content and display capabilities greatly enhance the potential applications of the land use data to planning and managing South Dakota's natural resources.

Current inventory status

The State Planning Bureau initiated the digital processing of Landsat imagery in 1975. As of September, 1977, 50 of 67 South Dakota counties had been mapped with four additional counties in progress.

The Planning Bureau has recently initiated a program to assess the accuracy of the completed portion of the land use inventory. Preliminary indications are that the average accuracy of the data is approximately 75 percent. Analysis results have progressively yielded higher accuracies with the most recently mapped counties being as accurate as 96 percent. Recognizing the importance of accurate land use data to decision makers, the State Planning Bureau has adopted a policy of only disseminating maps of at least 85 percent accuracy.

Costs

The time and cost requirements that must be met if the inventory is to be economically viable are critical. The State Planning Bureau has committed approximately five man-years and $300,000 toward the completion of the South Dakota Land Use Inventory. This includes a large amount of time and money devoted to computer software development. While this has increased both time and cost expenditures, it has allowed the formulation of an analysis system equipped to meet South Dakota's specific needs.

A detailed look at current analysis costs, excluding overhead, training and development expenses, shows the economic feasibility of recently produced land use maps. Analysts have been able to map a 3320 square mile area in northeastern South Dakota (approximately 4 counties) for a total analysis cost of $5,703.36. The Landsat data was mapped using four categories: water, large grains, small grains and pasture. The level of detail was 1.1 acres and the cost per square mile was $1.72 or $0.0027 per acre. Table III contains a detailed listing of mapping costs. These figures will not necessarily apply directly to other geographic areas, but can be considered fairly typical.

Applications

The true value of any land inventory is best determined by its applicability to management and policy problems. In addition to the South Dakota applications mentioned in Table V, the State Planning Bureau has provided publications and advice to 40 states and four foreign countries. While this indicates wide interest in the innovative nature of the South Dakota Land Use Inventory and the Land Resource Information System, it is the state applications that best illustrate the overall value of the program.

Limitations of Landsat data

While Landsat has generally been adequate as the primary data source for the land use inventory, it does have limita-

TABLE II—South Dakota Landsat Land Use Classification Scheme

Level I	Level II	Level III
100 Urban		
200 Agriculture		
	210 Cropland	
		211 Bare soil
		213 Small Grains
		215 Large Grains
300 Rangeland		
400 Forestland		
	410 Deciduous	
	420 Evergeeen	
500 Water		
600 Wetlands		
	630 Riparian Vegetation	
700 Barren Land		

TABLE III—Time and Cost Data for Digital Land Use Mapping of a 3320 Square Mile Area in Northeastern South Dakota.

TIME	
Data Rectification	2 hours
Classification	21 hours
Verification (Accuracy)	68 hours
Final Map Production	18 hours
	109 hours
COSTS	
Landsat Imagery	
1 CCT @ $200	$ 200.00
Computer Time	
7.182 hours @ $625.00/hr.	$4,488.75
Salary	
109 hours @ $6.94/hr.	$ 754.61
Ground Data Acquisition	
4 counties @ $40.00/county	$ 160.00
Misc. Supplies (Paper, tapes, etc.)	$ 100.00
	$5,703.36

adequate for the task of mapping certain land use categories. Wetlands, for instance, have an appearance similar to large grains on Landsat data obtained during the summer months. This often results in the misclassification of wetlands. While techniques exist to correct this problem, they increase both analysis time and cost. Sensor resolution limitations preclude the use of Landsat for meaningful classification of the state's urban areas. Again, alternative inventory methods such as aerial photography are available but at an increased analysis cost.

Another limitation of Landsat data is its timeliness. Raw data in the form of computer compatible tapes is currently available between three and four months after the satellite has recorded the scene. This data turnaround is often inadequate for ad hoc analysis since categorization of the data can require up to an additional month. Landsat can be a timely tool for monitoring natural disasters such as floods and droughts. However, to be of use, the data should be available within one to three weeks. When this data availability problem is solved, the utility of Landsat data to South Dakota will be greatly enhanced.

When the limitations of the Landsat data are recognized, satisfactory results can be easily and consistently obtained. The South Dakota State Planning Bureau has generally been satisfied with the results of its statewide digital land use inventory. The Bureau plans to complete the land use inventory during fiscal year 1978, and then to publish a state land use atlas containing the resultant data. Because of the successes achieved so far, the State Planning Bureau intends to continue using Landsat as an important tool in the planning and decision-making process.

IMPLICATIONS TO THE COMPUTER WORLD

The accelerating development of state digital image processing systems and natural resource information systems will provide many challenges for the computer world over the next decade. A great deal of development will need to be completed on both hardware and software.

Multivariate statistical analysis of image data requires a great deal of computing power. As future image data sets grow an order of magnitude in size and additional channels are added to future sensors, much faster processors will be required. Mass storage devices capable of storing hundreds of megabits of data with access times comparable to main storage need to be developed for specialized processing applications such as data rectification and image enhancement. Video image display devices will have to be upgraded to handle larger volumes of data. Remote data transmission devices will have to be accelerated as distributed image processing systems become more prevalent and transmission requirements are greatly increased. Color hard copy output devices will need to be improved to upgrade product quality and reduce production costs. Above all, a great deal of system's integration work will be required to effectively and efficiently pull together all the various hardware components required for operational image processing applications.

On the software side, a great deal of development can be expected. Generalized applications software packages will need to be prepared for a wide variety of mainframes and minicomputers as more and more organizations adopt remote sensing technology. Much custom software development will be required to tailor such packages to meet individual user needs. Interactive systems will become more prevalent as user sophistication increases.

Overall, development of image processing and information system capabilities provides the computer industry with an important opportunity to contribute to improving the quality of life and the wisdom of resource management in America and the world. While land and resource shortages have not yet reached crisis proportions, world population growth is bringing that day increasingly closer. New technologies alone will not solve these problems. Hopefully they will prove to be useful tools to the people who must.

In perspective—Meeting the image processing challenge for remote sensing

by PHILIP H. SWAIN
Purdue University
West Lafayette, Indiana

INTRODUCTION

Although man has been observing the condition of his environment from aerial vantage points for many decades,[1] developments of the 1950s and 1960s could be pointed to as the origins of modern remote sensing technology.[2] The last twenty to thirty years have seen dramatic advancements in the design of sensor systems, particularly in the measurement of infrared energy, the advent of the digital computer, and progress in modeling some of the processes associated with human intelligence, notably pattern recognition. Within this decade we have developed the capability to marry these advancements with spaceborne systems which can provide us image data of the earth—and other planets as well—of unparalleled scope, scale, resolution and timeliness. The "dimensions" of the data, however, overwhelm our human capabilities to assess and assimilate it. The human visual system cannot deal effectively with the four or thirteen or more than twenty concurrent images of the same scene produced by modern multispectral imaging systems. Nor can we begin to cope with the volume of image data that has suddenly become available through the orbiting of such systems.

And thus the challenge: to develop effective computerized image processing techniques, either to reduce the flood of data to proportions we can handle in a useful way or to amplify our powers to manipulate the data and discern the useful information contained in it. How are we meeting this challenge? First, let us look a bit more closely at what is involved.

UNIQUE ASPECTS OF THE PROBLEM

In remote sensing, information about the earth and its atmosphere is conveyed to the sensor system through the spatial, spectral and temporal variations of the electromagnetic energy emanating from the scene.[2] Typically we organize the spatial variations into an image which can then provide a two-dimensional characterization of "things" in the scene in terms of their shape, size, orientation, and context.

To a limited extent, the spectral or wavelength-dependent variations in the scene can also be incorporated into an image through the dimension of color. However, these variations can be quantified to only a limited extent in this way because discernible "color" is a net effect which is uniquely definable by at most three fundamental components. Thus since our modern sensor systems can precisely measure more than three distinct spectral components we are bound to suffer loss of data (and usually, but not always, of information) if we attempt to represent these components in terms of color. An alternative is to represent the various spectral components as multiple images rendered in gray tones. Unfortunately such a representation is not only awkward but fails to display explicitly the subtle relationships between spectral components which may be essential for characterizing different ground covers.

Attempting visual display of temporal variations simply makes matters worse. Assuming that images of a given scene collected at different times can be precisely registered (the technology for accomplishing this has in fact been developed[3]), color renditions and multiple gray-tone images can again be used to convey temporal variations in the scene. But taking these variations together with the key spectral variations leads to a level of complexity guaranteed to overburden the human sensory system.

Thus, a characterizing feature of remote sensing data is its multi-image nature. Roughly speaking, a computer is as capable of dealing with four or thirteen or twenty dimensional data as it is with three dimensional data.[4] So it is natural to turn to the computer for assistance in making use of remote sensing data.

We have already mentioned the volume of remote sensing data that is available. Even early airborne systems (circa 1960s) typically produced "scenes" consisting of 10^6 multispectral pixels ("picture elements"). Today we often wish to process ten times that many pixels as a single unit. By the early 1980s, improvements in sensor resolution will increase the figure by another order of magnitude.[5]

Data volume is therefore another characterizing aspect of remote sensing imagery. We need computers to catalog as well as to analyze very rapidly the massive quantities of available data. But even with computers serving in these capacities, the situation is characteristically more demand-

ing in the case of remote sensing than in any other application of image processing which comes to mind.

Remote sensing is very much an applied technology. Historically its development has been and continues to be most rapid when a potential application provides a focus. As a result, image processing for remote sensing has characteristically been a multidisciplinary effort, resulting in a need to make scientists who may not be computer-oriented feel "at home" with the image processing machinery. This has been accomplished by paying serious attention to the man/machine and man/data interfaces, developing, for example, English-like command languages to be used for directing the image processing operations.[6,7]

Having sketched some characteristic aspects of image processing for remote sensing, we shall now turn to an overview of some of the efforts which have been directed toward meeting the challenge, what is happening today, and some apparent needs for the future. In doing so, it is helpful to think in terms of fairly distinct image processing activities: enhancement, preceding either visual or machine-implemented analysis; analysis, typically but not exclusively classification; and product formating, storage and retrieval.

WHERE HAVE WE BEEN?

Attention began to focus on the computer analysis of multispectral remote sensing data in the mid-1960s.[8] To limit the task to one of manageable proportions, it was decided to concentrate in the main on the spectral variations in the data, practically ignoring, for the time being, the spatial and temporal variations. This choice was largely motivated by the wealth of information that the spectral domain was assumed to contain and optimism with respect to how much effort would be required to extract a significant proportion of that information.

Much of the earliest multispectral image data was recorded in analog form, either photographically on film or electronically on magnetic tape. Once it had been decided to use digital computers to analyze the data, techniques and hardware were needed to convert this data from analog to digital form and store it on computer-compatible tape. But of course the data analyst then needed a facility for displaying the digital data and referencing specific locations in it. These combined needs gave great impetus to the development of image digitizing and digital display devices. In essence, the skills and theories which had been developed for the photographic darkroom had to be translated into a new digital technology.

Statistical pattern recognition was quickly adopted as a promising approach for analyzing the multivariate data associated with each pixel in the multispectral image.[9] One of the earliest applications was crop species mapping. Commensurate with the relative complexity of this task (some of the spectral differences among crops in the field are fairly subtle), maximum likelihood classification assuming multivariate Gaussian data distributions was often used to accomplish the analysis.[4] Interestingly, although many alternative classification methods have been investigated since those early days, the Gaussian maximum likelihood classifier has remained the most widely used. Some reasons which account for this include its ease of implementation, its moderate level of computational complexity and memory requirements, and its ability to represent moderately complex decision surfaces in the feature space through use of second order statistics (class covariance matrices as well as means).

The products of the data analysis were largely in two forms: classification "maps" in raster format analogous to the data input, usually printed on conventional computer lineprinters using distinct characters to represent the ground cover classes; and tabular summaries listing total area coverage by class and, for selected areas for which adequate ancillary data were available, an estimate of classification accuracy. These products were fine for illustrating the kinds of information which could be extracted from remote sensing data, but they would eventually be found to fall far short of the needs of the potential users. The map makers needed photo-quality images with tightly controlled geometric characteristics and somewhat less detail than the computer analyses generally produced; and in color. The policy makers needed results reported according to specialized categories not always identifiable by their spectral properties alone; and on the basis of oddly shaped political or jurisdictional regions. Once the need for these types of products was realized, vigorous work toward their generation met with success.[10]

Most of the remote sensing data processing capabilities were initially implemented on general purpose computers. Although ideal for research and development purposes, these implementations were clearly inadequate for the high-volume processing which would be called for when satellite-borne remote sensor systems were orbited in the early 1970s. A few research organizations and commercial establishments attempted to predict the image processing capabilities which would be needed and to construct special purpose systems to meet the anticipated need. Although they succeeded in demonstrating that special purpose systems could achieve dramatically improved throughput performance compared to general purpose versions they also proved that the remote sensing image processing technology was advancing at a great rate: their systems were obsolescent even before producing their first results.

WHERE ARE WE TODAY?

Present-day image processing technology has gone beyond the spectral domain alone, making significant strides into the spatial domain and some tentative steps into the temporal domain.[8]

A number of cosmetic enhancements are routinely applied to the digital multispectral data.[11–16] These include a wide range of false color display techniques, geometric adjustments to match existing map products, edge enhancement, resolution enhancement (reduction of blurring due to various sensor system characteristics), and other filtering operations.[17] Methods have been developed for precisely registering multiple images of the same scene to a common tem-

plate scene.[3,18,19] All of these advances have improved the interpretability of remote sensing image data and increased the potential utility of the final product to the user.

Methods for extracting information from remote sensing image data have developed to the point where they are testing the boundaries of what can be accomplished based on the spectral domain alone. With respect to some potential applications, the results achieved with data available from current sensor systems, of relatively limited spectral coverage and course spectral resolution, have fallen short of the results anticipated. This has had the unfortunate effect of discouraging segments of the potential user community and causing them and many interested layman to prematurely judge the limitations of the technology.

Texture and spatial contiguity are two geometric characteristics of the image data which have been demonstrated to be useful in the analysis process. Texture characterizes some ground covers of interest; the challenge has been to find effective measures of observable texture.[20-22] Detection of spatial contiguity permits scene segmentation and the delineation and classification of "objects" in the data.[23] When a large number of "objects" consist of many pixels, this leads to greater classification efficiency and accuracy. Statistical "sample classifiers" have been developed for this purpose.[23]

The products of the image processing operations today are a far cry from those available even a few years ago. Computer-driven precision film writers, ink-jet and electrostatic printers have made possible excellent quality map-like products at increasingly palatable prices. Capabilities for digitizing arbitrarily shaped polygonal boundaries have made it possible to report quantitative areal tabulations on a very flexible basis.[10] For applications where areal estimates are more feasible than "wall-to-wall" inventories, sophisticated statistical design and evaluation methods have been developed.[24,25]

Although they are exceedingly expensive, a few relatively powerful image processing systems are available for remote sensing data processing.[26] In the development of these systems, great attention has been paid to facilitating the role of the system operator who, in fact, is assumed to be a very capable data analyst. Thus an important element of the system is an interactive high-resolution digital display with a color CRT. A programmable array processor rather than a hard-wired special purpose processor may be used to implement the compute-bound steps in the processing. The processes for determining the appropriate parameters for various stages of the processing still involve the data analyst and often require considerable trial-and-error, however. As a result, the throughput of these specialized systems remains rather limited.

THE NEEDS OF THE FUTURE

We know from the performance of skilled image interpreters faced with visual analysis of available remote sensing data that there remains a wealth of information in the spatial and temporal domains as yet untapped by computer-implemented algorithms. Effectively characterizing and extracting this information constitute the challenge for the future.

A number of image enhancements appear feasible but have yet to be developed sufficiently for routine application. Examples include haze removal, scene-to-scene tonal normalization, and boundary detection and enhancement. The utility of the data and the task of the data analyst would both be improved by development of effective methods for coordinating ancillary data with the associated image data. This is not a trivial matter when one considers the spectrum of data types and formats that can be involved. It is not at all clear how to most effectively coordinate point, polygon, and line data with image data.

With precisely registered multitemporal remote sensing data promising to become more readily available, what means can be developed to effectively display the data and to enhance features of interest (often changes) to the image interpreter or the data analyst? What new problems will we have to deal with due simply to the gigantic proportions of the data sets? (Current Landsat scan lines consist of just over 3200 pixels, each of which is 4-dimensional. Projected systems will yield over 6000 6-dimensional pixels per scan line[5]).

Judging from the evolving image processing research, quite a range of new approaches for characterizing and extracting spatial information will be tested on remote sensing data and appropriately adapted. Texture, a complex visual phenomenon, is one of the features which seems quite obviously useful to human photointerpreters. Many very different approaches to the quantitative characterization of texture have been attempted and, in some instances involving remote sensing data, have been moderately successful. More progress in this area is needed.[21]

Where texture is a rather local spatial phenomenon, context might be thought of as a property bridging the local on one hand and the global on the other. Context is another phenomenon used effectively in manual photo-interpretation, since it can be quite helpful in characterizing a pixel or an object to take into consideration the nature of its neighbors. It has been demonstrated that the capacity to do this can be incorporated in pattern recognition algorithms for remote sensing, although the computational cost is substantial.[27]

Global relationships in images can be characterized using syntactic pattern recognition techniques.[28,29] This approach to remote sensing image analysis is very important because there are many instances in which rather general spatial relationships are key identifying characteristics. Rivers can be discriminated from lakes because they are "string-like" rather than "blob-like"; clouds can be discriminated from snow because clouds cast shadows. To use this approach, however, requires the abilities to infer the characterizing relationships from typical imagery and to capture them effectively in "pattern grammars". These are very difficult problems of image analysis in general and much remains to be done before practical applications of syntactic pattern recognition will be seen in remote sensing.

The decision processes needed for remote sensing data analysis can often be cast rather effectively as hierarchical

and/or sequential processes.[30] One can envision, for example, classifying a pixel into successively more specific categories by selectively using additional spectral bands or other features. The features to be used could be adaptively determined by the decisions made at each stage. This sort of hierarchical process can lead to both faster and more accurate classification. Still another classifier model can be used to efficiently process multitemporal image data from successive passes of the sensor over the scene.[31] In this case, likelihood computations are "cascaded" and the results of each stage of computation are made available to the next stage when later data is obtained.

Early in the history of the development of image processing for remote sensing, the goal of total automation of the process was established. It was assumed that only through total automation could the throughput of the processing system be made adequate to the data volume and demand for processing. Now, more than a decade later, that goal still remains the ideal, but it is widely recognized that it may be some time before we learn how to make computers perform certain complex tasks that humans perform rather well. Experience has demonstrated that, at least for the present, we cannot devise streamlined automated analysis algorithms employing available technology which can serve as a reasonable replacement for the data analyst who has training related to the application of interest and the computerized analysis tools as well. For the foreseeable future, then, we can expect to see continued research to improve the effectiveness of the human data analyst as part of the total image processing system. We have already noted the need to better coordinate the various forms of data the analyst must use (point, line and polygon data as well as the image data). More effective means of interacting with the total data bank are needed, utilizing, in all likelihood, interactive display facilities with graphics, image overlay, and color image capabilities. Similar remarks apply to interaction with intermediate and final processing results so that the analyst can function in a feedback loop to iteratively improve the results obtained.

Most beneficial use will be made of both the sensor data and the image processing facilities when a common set of these resources can be made available to a wide range of potential users. One way to accomplish this is to store fairly detailed analysis results in a flexible "earth resources information system" capable of being interrogated and providing a wide range of graphical and statistical information. This can be thought of as the "users' data base", containing more "refined" information developed by applying image processing to the "remote sensing data base". Some efforts have already been made along these lines,[32,33] but the needs of the user community are not yet being widely met.

Finally, the still rapidly evolving computer technology—microprocessors and parallel and pipeline computation—have important implications for the future of remote sensing image processing. The sheer volume of the data to be processed has already provided motivation for implementing relatively conventional analysis methods (multispectral clustering and maximum likelihood classification) on the ILLIAC IV parallel processor. Demonstration runs have resulted in computational speed-up factors of two to three orders of magnitude (between 10^2 and 10^3).[34] Yet this represents a rather "general purpose" implementation using obsolescent technology. The near future will see availability of very high speed microprogrammable processors which can be dynamically organized into parallel/pipeline configurations potentially capable of performing staggering numbers of computations per second.[35] It will be no small challenge to utilize such computational power effectively. Significantly, the prospect of having such power available is allowing us to think about image processing in new ways, to consider developing computational methods which were infeasible for practical applications when conventional serial implementations had to be assumed. The programability of these advanced systems will at once ensure their general applicability and make them available for further evolving the remote sensing image processing technology.

Programming hardware for remote sensing image analysis

by DAVID G. GOODENOUGH
Canada Centre for Remote Sensing
Ottawa, Ontario, Canada

INTRODUCTION

The costs of processing large numbers of images can be reduced substantially if use is made of minicomputers combined with special purpose hardware and array processors. The experience with systems of the Canada Centre for Remote Sensing (CCRS) is drawn upon to show how parallel processing of images can be achieved. Data formats are described which accommodate a wide variety of imaging sensors from scanners to radars. We present the software architecture for the movement and analysis in parallel of large images stored on disks. One such system at CCRS is able to perform a 4-feature, LANDSAT maximum likelihood classification of seven million pixels into 93 classes in 15 minutes and a two-dimensional Fourier transform of a 512 by 512 image in 12.0 seconds. The array processor which achieves these rates is discussed at length including its software and hardware components.

CCRS IMAGE SOURCES AND STRUCTURES

The Canada Centre for Remote Sensing (CCRS) receives image data from the LANDSAT-1 and -2 satellites of the United States and from sensors on four CCRS aircraft. The primary digital image sources for CCRS are listed in Table I. In the near future NASA will launch the LANDSAT-C and SEASAT-A satellites for which we will receive data of Canada. The sensor in most demand now is the four-channel LANDSAT multispectral scanner (MSS). The synthetic aperture radar (SAR) of SEASAT-A may allow effective all-weather sensing of ice, ocean, and land features which make this also an important source of data. The satellite image sources are characterized by wide area coverage, frequent coverage (when compared with an aircraft program) and high data rates. CCRS pursues projects involving airborne MSS and SAR systems. Each image source produces data with unique characteristics and errors. For CCRS remote sensing systems, the received data are passed through a Ground Data Handling Centre (GDHC) which organizes and corrects the data for the most serious errors and produces a computer compatible tape (CCT) for subsequent remote sensing image analysis. By remote sensing image analysis we mean the semi-automatic extraction of information from a data set, which may be composed of data from multiple sources, and the generation of a tabular, graphical, or digital representations of this information for later use by resource managers. The primary output products desired from the CCRS Image Analysis System (CIAS) are summarized in Table II. With the exception of item (4) in Table II, all other products can be produced at CCRS by a system involving a general purpose minicomputer and two special purpose hardware processors. The objective of this paper is to present for your consideration observations and conclusions related to the programming and analysis of remotely sensed data in systems with hardware processors.

The LANDSAT-1 and -2 multispectral scanners[1] generates images which are framed at CCRS to correspond approximately to a ground area of 185 km by 181 km. Each frame contains approximately 3240 picture samples (pixels) along each of 2286 scan lines. The MSS generates through 24 detectors four spectral bands, the first three (MSS 4, 5, 6) of which are logarithmically scaled and the fourth band (MSS 7) is linearly scaled. The raw spectral values are each quantized to 6 bits. The CCRS-GDHC produces corresponding CCTs containing radiometrically corrected, 8-bit quantized images. These LANDSAT CCTs follow a flexible, self-defining format[2] often referred to as the CCRS-JSC format. The basic form of this format for LANDSAT MSS CCTs is summarized in Table III. This CCT format is used by CCRS for all digital images and by other countries for LANDSAT image production.

A digitized image or picture of L lines, B bands, and P pixels is an integer array which can be represented by the real function, G, where,

$$G(L,B,P)=\sum_{l=1}^{L}\sum_{b=1}^{B}\sum_{p=1}^{P} f(l,b,p) \qquad (1)$$

and $f(l,b,p)$ is the intensity in band b for a pixel at position p on scan line 1. The order of summation in equation (1) indicates that the image is primarily interleaved by lines and secondarily interleaved by band. Such an image is usually said to be line interleaved. In remote sensing image processing, two other image forms are common, $G(L,P,B)$ with secondary interleaving by pixel (pixel interleaved), and $G(B,L,P)$ with primary interleaving by band (band interleaved). Different sensors produce different data structures which must often be reformatted into the structure most compatible with the given image processing system. Such

TABLE I.—Primary CCRS Digital Image Sources

—12000 pixels by 2400 lines for 1 band
—8 bits/pixel or 10 bits/pixel.

reformatting can be quite expensive because of the large data volumes involved.

An image contains spatial information, in addition to its spectral information, which should also be used in the subsequent data analysis. The balance in information content carried by the spatial properties of an image and its spectral properties varies from sensor to sensor, image to image, and application to application. For each combination of sensor and application, it is necessary to study this balance between spatial and spectral information. Spatial properties of a digital image are often characterized by computed spatial features which measure the differences or similarities between a pixel and its neighborhood. Such spatial features may be used as texture measures to be added to the dimensionality of the feature set describing the image or they may be used to generate edges. Edges can in turn be used to indicate homogeneous regions for which averaging of spectral features would be appropriate as a data compression aid.

TABLE II.—Primary CIAS Output Products

(1) Computer compatible tapes
—flexible, self-defining CCRS-JSC format
—up to 64 bands or features
—for input to:
(a) PDS color-write microdensitometer (high resolution)
(b) CCRS Electron Beam Image Recorder (EBIR) System (medium resolution)
(c) Color Strip Film Recorder (low resolution)
(d) Grid Structured Geographic Data Bases
(2) Approximate maps of class distributions
(a) —scaled for UTM maps from 1:50,000 to 1:1,000,000
—single class or multiple class representations
—latitude/longitude reference
(b) —photographs of CRT display.
(3) Tables
(a) measurements of class areas
(b) summaries of spectral and spatial statistics by class.
(4) Polygon Data Files
—generalizations of grid structured classifications for input into large, polygon structured data bases
—transferred by a unique tape format.

TABLE III.—CCRS-JSC Format for LANDSAT-2 MSS Images
There are five types of records in the basic 2400 ft., 1600 bpi CCT.

(1) *JSC Header Record*
—3060 bytes long
—contains information about the subsequent organization of the data on the CCT, e.g. the quantization, the processing used, the number of bands or features (up to 64), the number of pixels and lines, etc.
(2) *LANDSAT Header Record*
—1440 bytes long
—gives information specific to CCRS-GDHC processing such as orbit number, frame number, image date, special processing flags, frame center latitude and longitude, etc.
(3) *Geometric Transformation Record*
—2700 bytes long
—contains the geometric transformation parameters necessary to move from LANDSAT coordinates to the Universal Transverse Mercator (UTM) grid.
(4) *Radiometric Look-up Table Records*
—there are 4 radiometric look-up table records, one for each spectral band
—each record is 1620 bytes long
—in each record the radiometric look-up tables for the six detectors for that spectral band used to correct this CCT are given.
(5) *MSS Data Sets*
—a data set is made up of 4 records, each 3780 bytes long
—each record contains the record number, ancillary data, and video data for each spectral band
—the ancillary data includes GMT start scan time, latitude and longitude at the line center, satellite altitude and roll, pitch, yaw, and calibration wedge data.

Adding dimensionality to the data set through the addition of texture features increases the processing costs not only by increasing data volume into the analysis system, but also by increasing the costs of ground truth acquisition. The higher dimensionality of the feature set requires that more training samples be collected to maintain the same level of accuracy in the elements of the covariance matrix in order to achieve higher classification accuracies with additional features.[3] More training samples require the detailed examination of larger areas on the ground. In addition, in order to have confidence in the statistical estimates of classification error, test sites developed from ground truth should be increased in corresponding size to the increase in size of the training sites. Error estimates of classifications from training sites are overly optimistic. Similar error of classification estimates from test sites are realistic if the procedures described in a previous paper[4] are followed.

The image tape is transferred to disk in a CCRS file structure family known as UNIDSK.[5] This is a flexible, grid data base structure which can accommodate up to 64 features. Any form of interleaving is supported by this structure. The file contains a Master Header, Secondary Headers, a Video Header, and the Video Data Set. The Master Header, 1024 bytes long, identifies the file, its format, and the geographic location. The Secondary Headers are variable in number and length and contain information specific to the history of this file and pointers to related files. The Video Header contains the details of the format and preprocessing of the video data in the following Video Data Set. This family of formats also allows random access of pixel values, carries sufficient information to allow one to re-trace the steps by

which the file was created, and permits images to continue onto multiple disk packs. This UNIDSK structure is used for storage and analysis of all images at CCRS.

CIAS OVERVIEW

The CCRS Image Analysis System (CIAS)[6] consists of two minicomputer sub-systems, the IMAGE 100 sub-system and the PDS sub-system. The PDS sub-system includes a DEC PDP-11/40 minicomputer and a PDS flatbed color read/write precision microdensitometer. The PDS sub-system is connected to the IMAGE 100 sub-system via two paths, a dual port disk drive and a high speed (1 Mbit/sec) interprocessor communication link (DMC 11). The PDS sub-system is used either to digitize color aerial photographs and produce a UNIDSK file for subsequent analysis on the IMAGE 100 sub-system or to write such a file onto color film.

The IMAGE 100 sub-system, shown in Figure 1, is used for all image analysis. This sub-system is controlled by a DEC PDP-11/70 minicomputer with 256K 16-bit words of core memory. There are two additional processors in this system, a modified General Electric IMAGE 100 and a CCRS array processor called the Image Analysis Processor (IAP). There are three parallel paths for data transfers, the UNIBUS, the RH70/DWR70 data bus, and the IAP-RH11-DB1 data path. The IMAGE 100 is an interactive pipeline processing system[6,7] which supports the acquisition and non-parametric classification of 512 by 512 four-feature images. The pipeline processor permits real-time ratioing of features and 4 by 4 matrix multiplication to generate linear combinations of features.

Classification of the image is performed by comparing in hardware all image pixels with the signature distribution of the training area as represented by the distribution of 4-vectors or cells of unit volume. The frequencies of occurrences of 4-vectors may be thresholded to alter the resulting

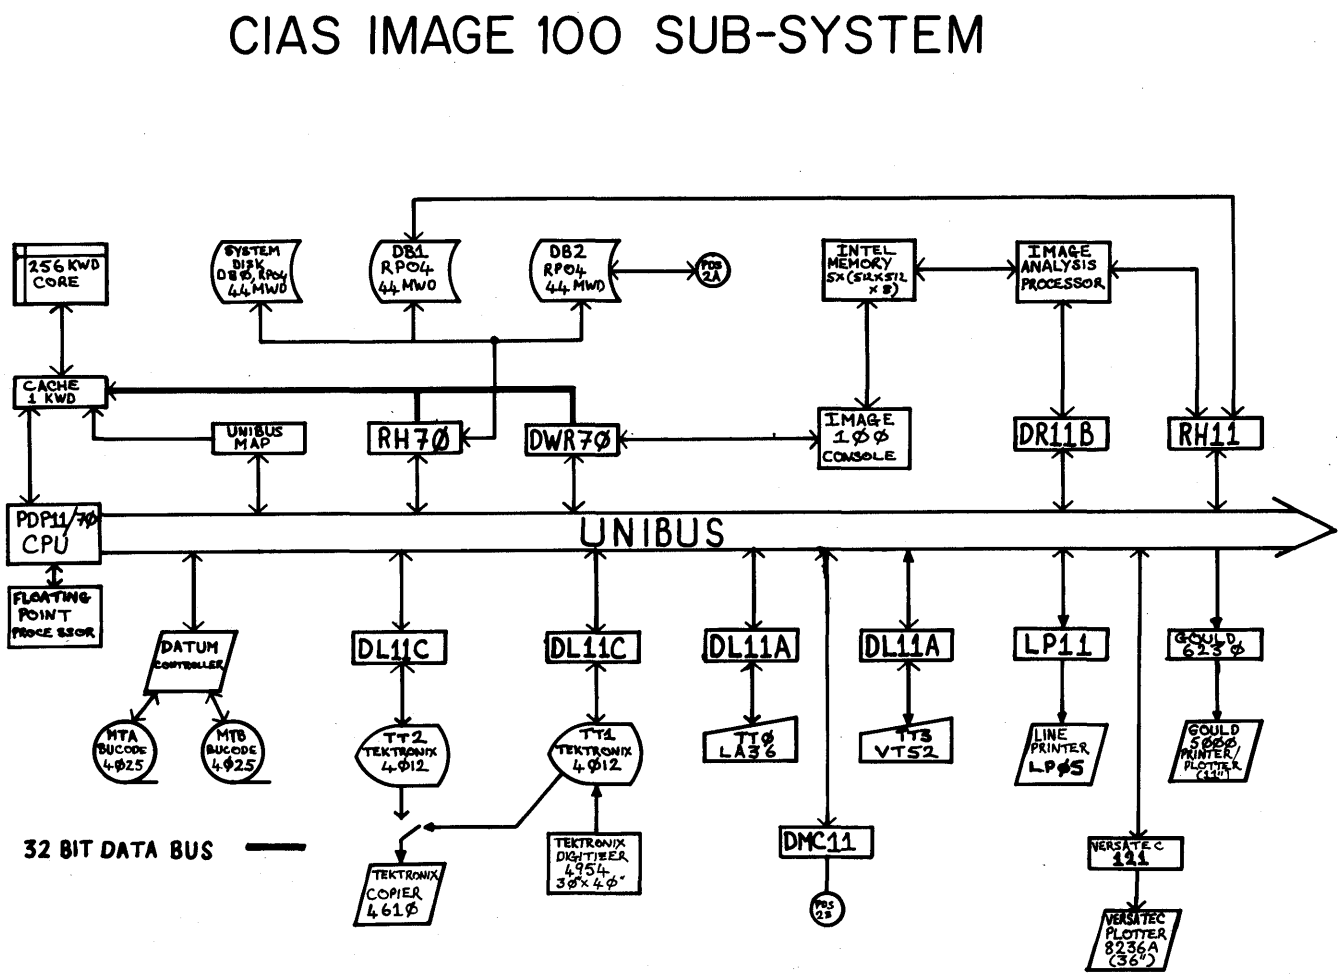

Figure 1—The IMAGE 100 sub-system of the CCRS Image Analysis System (CIAS) is shown. The sub-system is controlled by a DEC PDP-11/70 minicomputer. The other two processors in the sub-system are a modified General Electric IMAGE 100 and a CCRS/CDC array processor, the Image Analysis Processor (IAP). Note the parallel data paths permitting simultaneous image operations. The large disk, DB1, is dual ported to the IAP and serves as one of two image storage locations. As a result, the IAP can perform a maximum likelihood 93-class classification of LANDSAT four-feature frame in 15 minutes. Connections labelled PDS indicate links to the PDS sub-system of the CIAS.

classification. The resulting classification may be stored as a 1-bit overlay. The IMAGE 100 is very interactive and is particularly rapid for signature extraction. In supervised classification, a hierarchical approach is followed at CCRS from simple rectangular parallelepiped classification to non-parametric cell classification to maximum likelihood classification. The maximum likelihood classification may be performed in software in the PDP-11/70 or in hardware in the IAP. Unsupervised classification or clustering is performed in the following fashion. An image area is selected and the vector distribution determined for this area. Clustering by non-parametric or parametric methods of this distribution is carried out in the 11/70. The resulting class statistics can be loaded into the IAP and the classification executed on the whole image stored on the large disk labelled DB1 in Figure 1. Alternatively, the non-parametric class boundaries can be loaded into the IMAGE 100 and the 512 by 512 scene is then classified. Prior to the development of the IAP most of the system time was devoted to the maximum likelihood classification in the PDP-11/70 of large images.

The multiple processing capabilities of the CIAS are fully utilized under the DEC RSX-11D Version 6.2 multitasking operating system. The IMAGE 100 is controlled through an executive task. The software is written in DEC FORTRAN IV PLUS with the exception of a few input/output routines in MACRO-11. FORTRAN IV PLUS was selected because of the ease of transportability of such programs within CCRS and with our many user agencies and because of the efficient code generated by the FORTRAN IV PLUS compiler. For example, maximum likelihood classification executed three times as fast on an 11/70 in FORTRAN IV PLUS compared with DEC FORTRAN IV (FOR) on the same computer. The standardization of tape and disk formats for all our computers meant that software developed on our PDP-10/KI could be brought up in a day on our PDP-11/70. The CIAS interacts with the operator through program selection from a menu of programs presented on a Tektronix 4012 graphics terminal or by depressing any combination of function switches on the IMAGE 100. The menus available in the IMAGE 100 sub-system are listed in Table IV. Each menu is selected by letter. Each task listed in the menu is selected by number. A task in a menu may itself call a group of tasks. This approach can be contrasted with the use of complex, independent command driven tasks or picture processing languages. The menu approach is simple to implement, easy to maintain, and easily expanded. The operator is not required to learn a new language or symbol set, yet the tasks are grouped in a logical fashion to guide the operator in their use. In addition, the operator can always select directly tasks by name or by a menu letter-number combination. The two Application Menus are collections of tasks to support a particular remote sensing application such as forest inventorying, crop acreage estimation, and so forth.[6]

Image input to the IMAGE 100 sub-system is via the two 125 ips tape drives or the three disk drives. Training area selection, ground control points, and other map information may be input directly from the large digitizer tablet. Output maps and plots are generated on one of the two printer/plotters. Statistical summaries are produced on the line printer. The disk configuration permits parallel processing to be achieved and is discussed in the next section.

CIAS DISK CONFIGURATION

The arrangement of the three moving head disks in the CIAS is shown in Figure 2. Two of the large RP04 disks (88 megabytes) are dual ported. The disk unit DB0 is the system disk and has only one port. Parallel processing is achieved by connecting the Image Analysis Processor (IAP) to DB1 through the UNIBUS-B port of the RH11 disk controller. The PDP-11/70 through execution of programmed instructions directly controls all interfaces and thus, indirectly, all data transfers within the system. The core memory contains the programs under execution and the data buffers to be used by the Direct Memory Access (DMA) controllers, such as the RH70, RH11, and DR11B. Most data transfers between two devices in the CIAS use core memory as a transitory repository. Memory speed is thus a limiting factor on system data throughput with one exception, the IAP/DB1 link since it bypasses the core memory completely.

In Figure 2, the letters "D" and "C" are used to indicate paths along which data or control information, respectively, can flow. Control information between the PDP-11/70 and the three DMA controllers moves along UNIBUS-A. Data transfers from the DR11B and RH11 controllers to the 11/70 can also be carried out along UNIBUS-A. The impression of parallel transfers is created by the interleaving of these data transfers along UNIBUS-A to and from main memory. Eventually such transfers saturate the UNIBUS-A at a data rate of approximately 600 K words/sec.[8] The RH70 disk controller sends and receives control information along UNIBUS-A and Massbus-A, but directs data transfers along the Fastbus and Massbus-A. The RH11 disk controller communicates control information along UNIBUS-A but it may be selectively directed under program control to accept data transfers along either UNIBUS-A, UNIBUS-B, or Massbus-B. The two disk controllers and two data buses make it possible to have simultaneous data transfers to and from two disks.

Since the manufacturer of the dual port disks did not provide supporting dual port software, it was necessary for us to develop our own. The dual port disk DB1 can be either

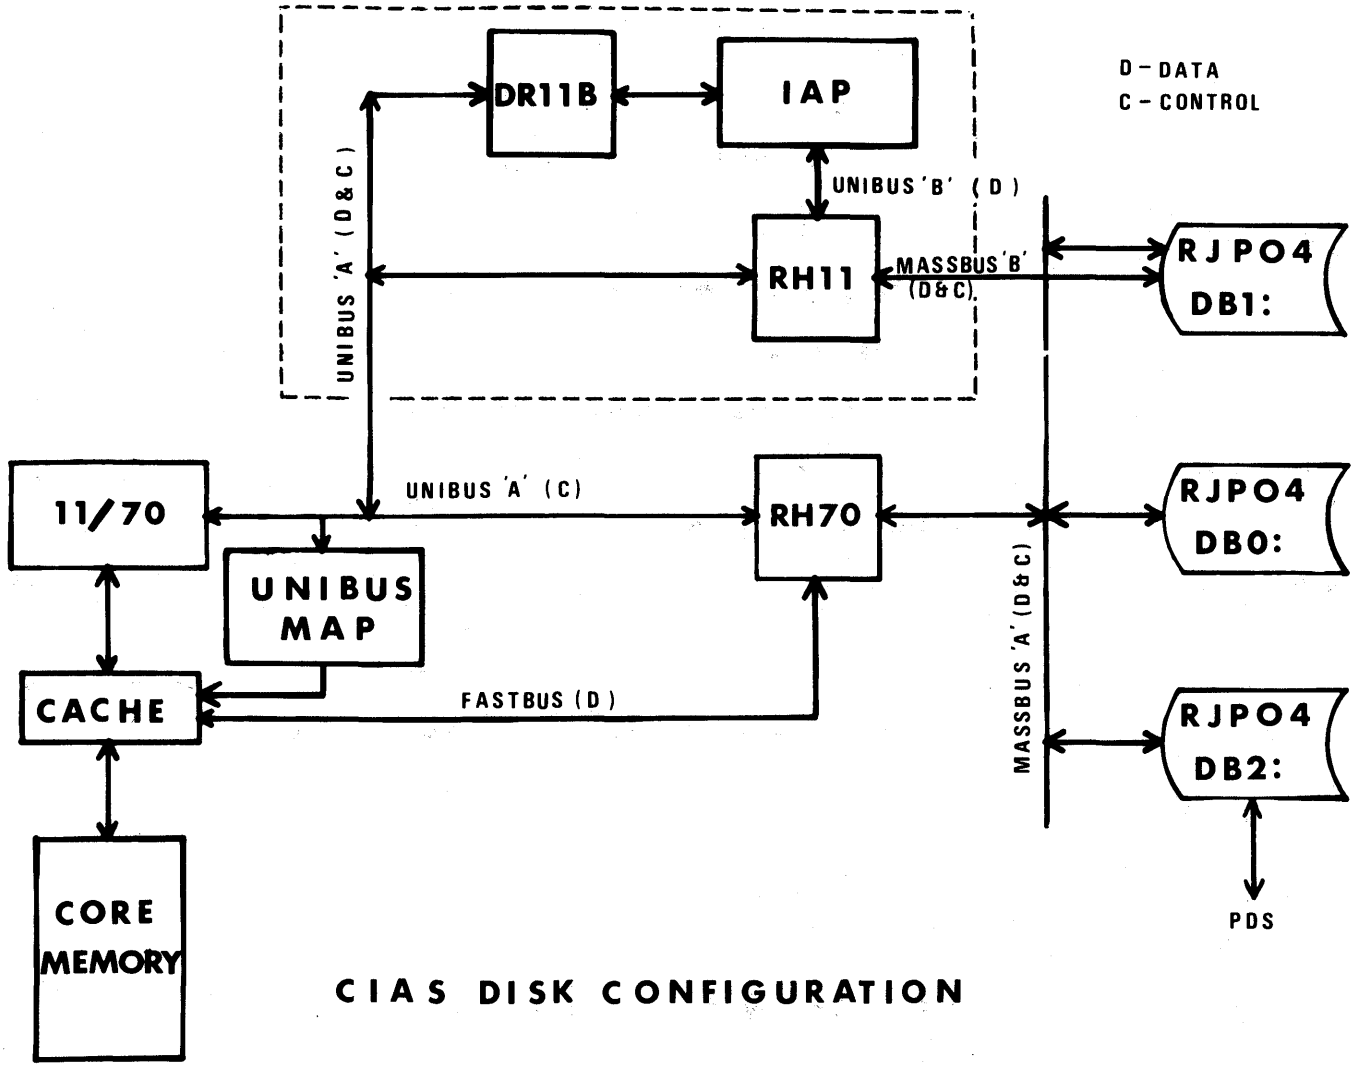

Figure 2—The details of the 88 megabyte disk connections for data (D) and control (C) information transfers are shown. The IAP can access DB1 while the 11/70 is simultaneously accessing DB0 or DB2. The IAP is also connected directly to the IMAGE 100. The RH11 and RH70 are DMA disk controllers. One disk handler handles all disk requests. Images are stored on disks in UNIDSK format (see text) compatible with DEC Files-11 structure. DB2 is used primarily for image transfers between the two sub-systems. Communication information concerning DB2 is passed along the interprocessor link, the DMC11, between two CPUs.

attached to the RH70 controller or the RH11 controller or unattached. In the unattached state either controller can attach the drive, at which point the other controller cannot access the drive. The dual port disk DB2 is interconnected between the PDP-11/70 and the 11/40 computers. This disk is used primarily for image transfers between the two subsystems and can, therefore, be dedicated to either computer for long periods of time. Communication information concerning DB2 is passed along the interprocessor link, the DMC11, between the two CPUs. For all images on disk, the UNIDSK format is used. This format has been implemented to generate files compatible with the DEC standard; namely, Files-11. The DEC disk handler, DB, passes file control functions to its ancillary processor task (F11ACP). Both DB and F11ACP have been modified to allow two additional functions which cause data transfer between the IAP and DB1. Dual port conflicts at DB1 are presented by forcing F11ACP to schedule sequentially all requests from a user task for DB1 data transfers. The IAP handler controls the DR11-B and RH11 controllers. The IAP handler does not directly accept from a user task requests for DB1 data transfers but receives such requests via F11ACP. The software development described here has enabled us to achieve the hardware data transfer rate limit of the RP04 of 2.5 μsec/word. The IAP is described in detail in the following section.

CIAS IMAGE ANALYSIS PROCESSOR (IAP)

CCRS, in cooperation with Computing Devices Company, have designed and implemented a special purpose array processor, the IAP. The IAP was intended to meet three

processing needs: (1) classification with the maximum likelihood decision rule; (2) computation of two-dimensional Fourier transforms; and (3) selection of pixels from disk images and the transferring of them to and from the IMAGE 100 solid state memory. An important cost consideration in the design of the IAP was to determine the number of bits to be carried in the arithmetic unit for the computations. The effects of coefficient quantization and arithmetic round off for the Fast Fourier Transform algorithm have been discussed previously.[10] The IAP was to calculate the FFT with decimation in time. The input data for the FFT were to be rearranged within the IAP to be in bit-reversed order prior to the pipeline arithmetic unit. The IAP would need to compute up to a two-dimensional forward and inverse FFT of a 512 by 512 input image and produce a result that agreed within 1 percent with that obtainable with 32-bit floating point arithmetic. Theoretical calculations for the FFT suggested that 18-bit floating point would likely be required. The IAP pipeline processor was then simulated on a PDP-11/40 for the FFT and the maximum likelihood calculations for four-feature images with 8-bit quantization.

The logarithm of the likelihood of observing a vector $\bar{x}$ given $\bar{x}$ is from class i with mean $\bar{m}_i$, covariance matrix C_i, and a priori probability P_i, is given by:[10]

$$l(\bar{x}/i)=\frac{n}{2}\ln 2\pi-\tfrac{1}{2}\ln \mid C_i \mid +\ln P_i$$

$$-\tfrac{1}{2}(\bar{x}-\bar{m}_i)^T C_i^{-1}(\bar{x}-\bar{m}_i)$$

The maximum likelihood decision rule is a comparison of this likelihood in which the vector $\bar{x}$ is assigned to the class for which the likelihood is a maximum and exceeds a selected threshold. The accuracy and speed of the computation is concerned chiefly with the last term, so that the preceding equation can be cast in the form for 4-feature data as:

$$L=\sum_{i=1}^{4}\sum_{j=1}^{4}(y_i Q_{ij} y_j)+K$$

where K is a constant, Q_{ij} is the ijth element of the inverse covariance matrix, and $y_n=x_n-m_n$. Because of the 16-bit minicomputer and the ease of 16-bit data manipulation, 16-bit fixed point with scaling for this equation was stimulated for the IAP pipeline processor with the number of bits for the Q-matrix and y values varied from 6 to 14 and 6 to 11 bits, respectively. The product was always truncated to a 16-bit integer. It was found that 16-bit fixed point with scaling was unsatisfactory and always produced results on real data for which the likelihood value differed by more than 10 percent from those obtained by a 32-bit floating point. With 18-bit floating point, the likelihood value was always within 0.1 percent of that obtained with a 32-bit floating point.

A simulation of the IAP pipeline processor for the FFT algorithm was then performed. The two-dimensional discrete Fourier transform, $X(k,l)$ is given by:[11]

$$X(k,l)=\sum_{m=0}^{M-1}\sum_{n=0}^{N-1}x(m,n)W_M^{km}W_N^{ln}$$

with $k=0, 1, \ldots, M-1$ and $l=0, 1, \ldots, N-1$ and where $x(m,n)$ is the periodic input sequence, and $W_N=\exp(-j2\pi/N)$. The two-dimensional FFT (2-D FFT) was simulated by performing two forward FFTs followed by two inverse FFTs on sample 512 lines of 8-bit input data. Figure 3 is an example of the results obtained by this simulation. The ordinate axis is the root-mean-square variation of the absolute error in percent for the real image (RSMR). The absolute error in feature intensity in percent for the real image (APER)[8] when compared with the real image intensity resulting after a forward and inverse 2-D FFT was applied to the real input image is defined by:

$$\text{APER}=100\left|\frac{\text{Real Input}-\text{Real Result}}{\text{Real Input}}\right|$$

The maximum value of RSMR on the ordinate axis is 0.226 percent and the minimum value is 0.008 percent for 512 input 8-bit samples. The solid and dashed line curves correspond to having 5 bits or 6 bits for the exponents(E) of the floating point numbers, respectively, with a variable number of bits in the mantissa (M). It is clear from this figure that the error for E=5, M=13 is lower than that for

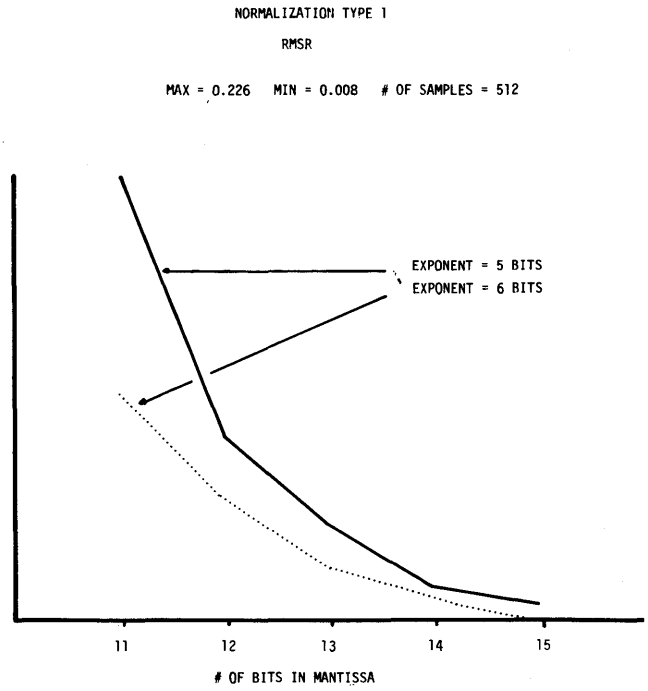

Figure 3—The IAP arithmetic pipeline was simulated for two-dimensional Fast Fourier Transforms (2D-FFT) by performing two forward FFTs followed by two inverse FFTs on sample 512 lines of 8-bit input data. The objective was to determine the number of bits required in the IAP computations to obtain the same result, to within 1 percent, as that obtained on a 32-bit machine. This figure is an example of the results obtained. The ordinate axis is the root-mean-square variation of the absolute error (RSMR) in percent for the real image after a 2D-FFT. The maximum value of RSMR here is 0.226 percent and the minimum value is 0.008 percent. For 18-bit floating point the real and imaginary image errors were always less than 1 percent. From this figure we see that 5 bits in the exponent and 13 bits in the mantissa gives the lowest error for an 18-bit floating point calculation.

E=6, M=12. A similar result was obtained for the imaginary images. We, therefore, selected 18-bit floating point with 5 bits in the exponent and 13 bits in the mantissa.

The interfaces of the IAP are indicated in Figure 4. The lettered lines connect to those in Figure 5 in which the IAP control computer and pipeline processor are shown. The IAP is interfaced to the PDP-11/70 for control and data through the DR11B. The IAP is interfaced to the RH11 so that the RP04 disk may be used for storage and retrieval of images in parallel with other CIAS activity. The IAP is also interfaced to the IMAGE 100 processor through the Line Buffer Memory (LBM). The LBM is a high speed random access memory (RAM) which can store 4096 bytes of image data at the 10 MHz data rate required to buffer the Intel 10 Megabit recirculating memory of the IMAGE 100 processor. The IAP can function either independently of the IMAGE 100 processor or in combination with it to use the ratioing and matrix multiplication hardware. The FIFO or First-In-First-Out memory receives data and control information from the DR11-B or data from the RH11. The FIFO is a 1000 18-bit word RAM which buffers the flow of data to permit the IAP's control computer to service higher priority activities.

The IAP Control Computer (CC) and Pipeline Processor (PLP) are shown in Figure 5. The programmable CC controls the initialization of registers which in turn control the other elements of the IAP. The CC performs any format conversion required of the data and is used to transfer data from one memory to another.[8] The instruction word for the IAP is 18-bits long. A cross-assembler between DEC Macro-11 style instructions and the IAP's microcode is used to simplify the programming of the CC. The Program Memory (PGM) shown in Figure 5 is used primarily to store the programs of the CC. The PGM consists[8] of 256 words of read-only-memory to store interrupt and bootstrap programs and 1 K 18-bit words of RAM.

The Pipeline Processor is an 18-bit floating point arithmetic unit composed of four major sections, the Pipeline Memory System (PLMS), the Scratch Pad Memory System (SPMS), the Pipeline (PL) and the Output Buffer. Once the PLP has been initialized by the CC, the PLP can perform independent computations. Thus, the CC and PLP can be operating in parallel. The PLP has a throughput rate of 100 ns which is achieved by having each section operate in parallel. The PLMS includes three 18-bit 1 K RAMs, marked as PLM1 to PLM3 in Figure 5. For maximum likelihood 4-feature, 8-class calculations, for example, PLM1 would contain 256 4-feature pixels, PLM2 would store 8 4-feature means, and PLM3 would have 8 inverse covariance matrices plus the decision rule threshold. Complex address calculators in the PLMS ensure that the address sequence required for FFTs is performed correctly. Data from the PLMS is called for by the SPMS which then delivers the data to the Pipeline according to the sequence of instructions held in the Scratch Pad (SP) memories. The SPs can hold up to 32 16-bit instructions plus 8 18-bit data words. Each SP program instruction is executed in 100 ns so that data may be passed to the Pipeline at that rate. The data from SP3 in Figure 5 is delayed in order to arrive at the second multiplier coincident with the output from the first multiplier. The output of the second multiplier is a 23-bit floating point number with 5 bits for the exponent and 18 bits for the mantissa. To achieve the required speed in the accumulator, it was found necessary to convert from a floating point number to a fixed point (47 bits) number (unfloat in Figure 5), accumulate, and then convert back to an 18-bit floating point number. When the required number of terms have been summed, the computed likelihood value, for example, is passed to the Output Buffer. The Output Buffer simplifies the programming of the PLP and determines the maximum likelihood value, thresholds this value, and outputs the resulting class number (16-bit integer) and likelihood to value to PLM1. The class number may be coded as an integer or with one bit set corresponding to the class. In the FFT mode the real and imaginary values are returned to PLM1 and PLM2, respectively. Thus, as data are flowing out of the PLMS, results are flowing into the PLMS. When the data have been processed, the array of results are sent to DB1, the IMAGE 100 or to the PDP-11/70 memory.

The size of memories in the PLP restrict for maximum likelihood the number of features and classes which may be accommodated in one pass. The number of terms, N_T, in the maximum likelihood expression for N features is: $N_T=N(N+1)/2$. If we assume one SP instruction is required for each term, then only 32 terms can be accommodated by the SP memory. If $N=7$ features, then $N_T=28$ terms which means the IAP is limited to 7 features in one maximum likelihood pass. The maximum number of classes, $M_{\max}$, for one pass is limited by N and by the size of the PLM according to: $M_{\max}\cdot(N_T+1)\leq 1024$. For four features, $M_{\max}=93$ classes. Other examples are listed in Table V. The PLP can calculate the maximum likelihood function for M classes and N features at a rate of $10^{-7}\cdot M\cdot(N_T+1)$ seconds per pixel. Program and input/output overheads increase this time for large images as is evident in Table V.

The IAP, although originally designed for rapid quadratic and FFT calculations, has other important features. The IAP can perform table look-up in 200 ns through one CC instruction. This is useful for radiometric and atmospheric corrections, image enhancements, and other image intensity manipulations. The IAP can reformat data simultaneously as they are moved from one memory to another which reduces substantially the processing costs associated with different input formats. The IMAGE 100 can display up to 8 classes as colored 1-bit overlays over a 512 by 512 pixel scene. The IAP can convert rapidly class numbers into 1-bit overlay patterns for subsequent IMAGE 100 display.

In classifying an image, the CIAS can first be used in a learn mode with sub-images displayed on the IMAGE 100. In this mode representative areas for supervised classification or for clustering are selected and parametric statistics for each class or cluster generated. The supervised classification is interactive and flexible. Parameters entered in response to teletype requests for a program are entered in files for subsequent utilization by that program and the IAP in a bulk processing mode.[8] For the classification of an N-feature, 512 by 512 scene, the statistics and input video files are read by the IAP and the scene classified. Figure 6 shows

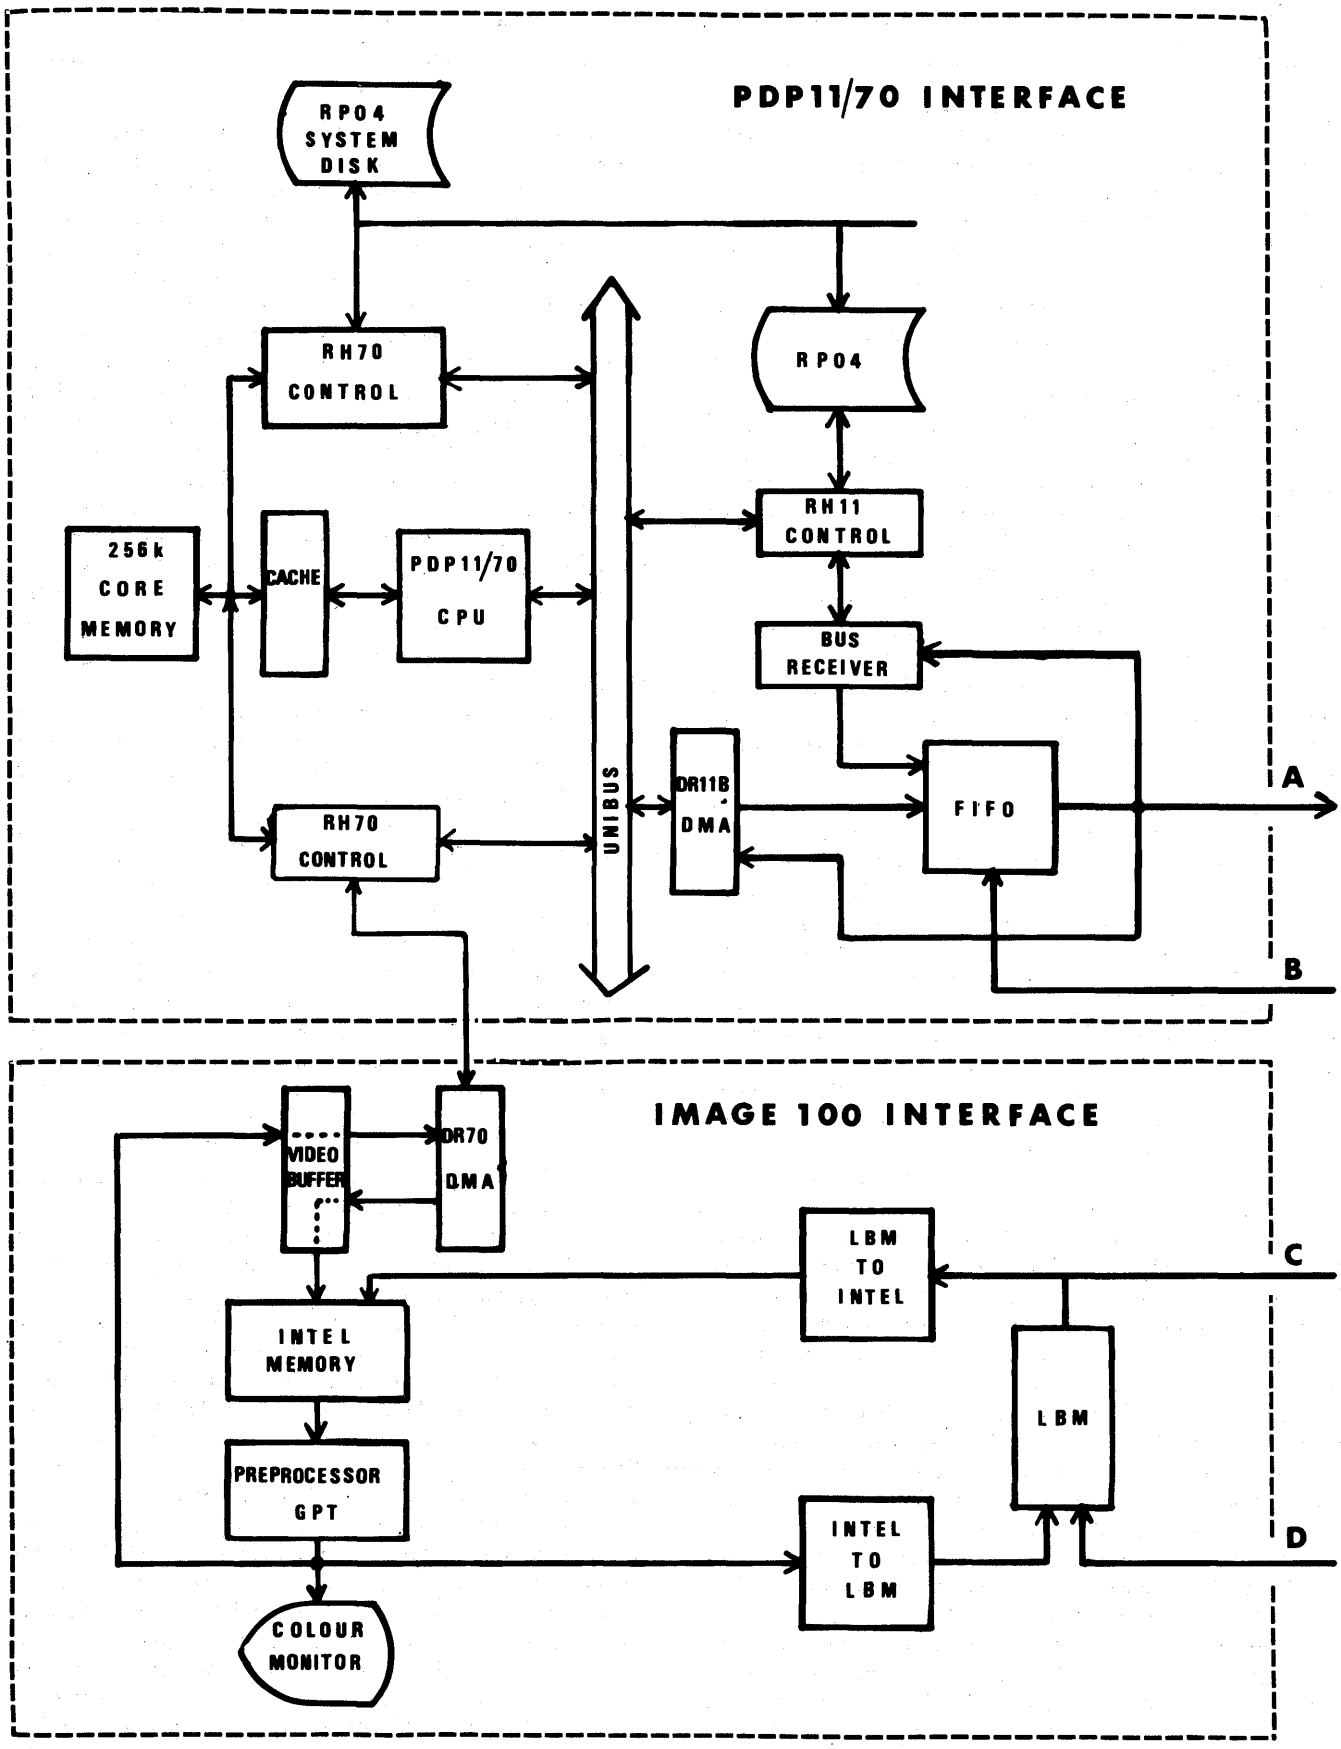

Figure 4—The IAP is interfaced through the First-In-First-Out (FIFO) 1 K word memory to the PDP-11/70 through the DR11B and to a large disk through the RH11 disk controller. The IAP is also interfaced to the IMAGE 100 through the 4 K bytes of Line Buffer Memory (LBM). This latter connection allows the IAP to use the ratioing and matrix multiplication hardware of the IMAGE 100, to use the 10 megabit Intel memory, and permits rapid image transfers between the IMAGE 100 and the disk DB1 through the IAP. The lettered lines connect to Figure 5.

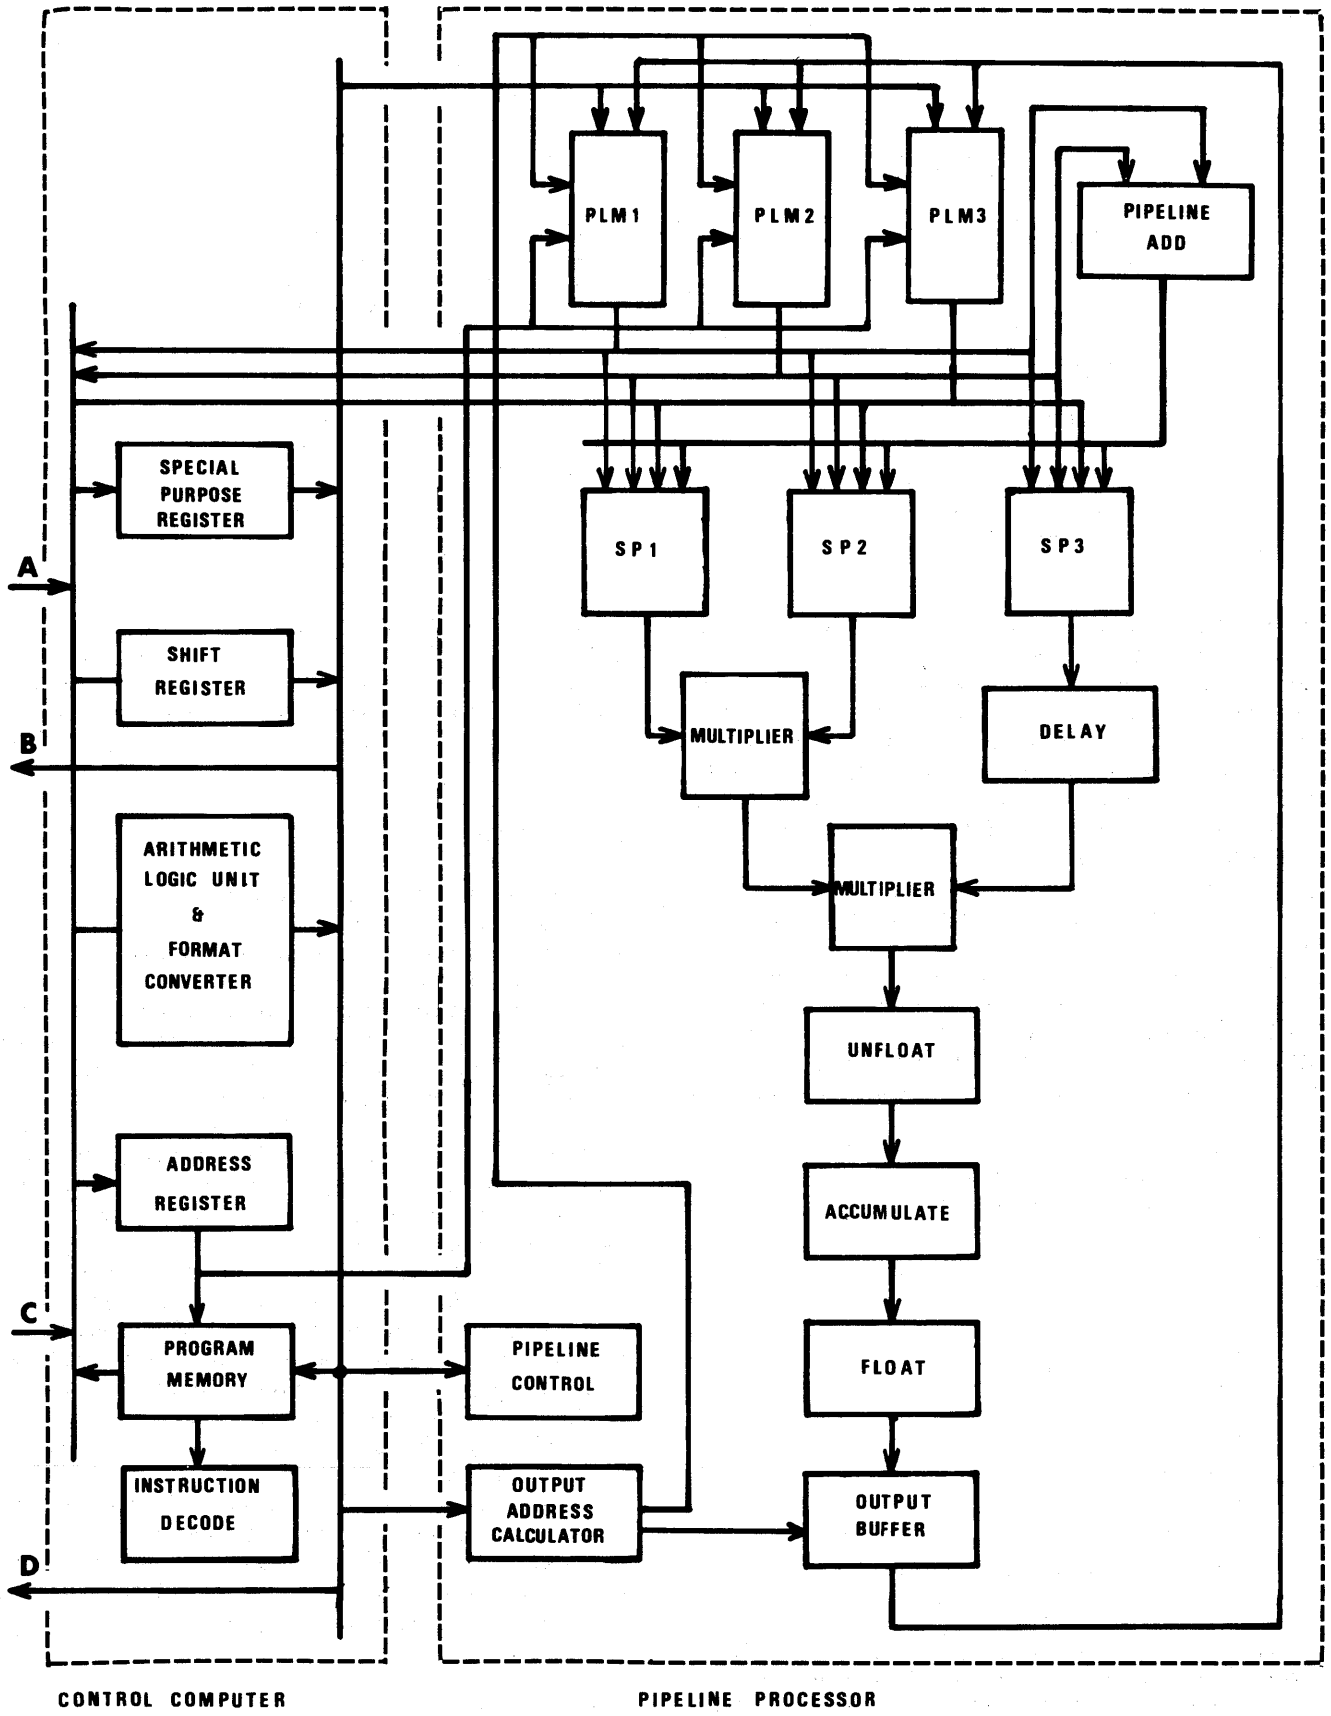

Figure 5—The IAP's Control Computer (CC) and Pipeline Processor (PLP) are shown. The CC is programmable and controls the initialization of registers which in turn control the other elements of the IAP. PLMs are 18-bit 1 K RAMs which hold the data, means, and covariances for maximum likelihood, for example, and in which the results from the output buffer are stored. Scratch Pad (SP) memories hold instructions on which PLM to select and deliver data to the pipeline. The pipeline computes quadratic summations at 100 ns per term. The IAP can perform a forward 2D-FFT of a 512 by 512 8-bit input image in 12 seconds. It can also perform a table look-up in 200 ns and reformat data rapidly as they are moved from one memory to another.

TABLE V.—CIAS/IAP Processing Times

I. Maximum Likelihood Classification: (excludes statistics generation)	No. of Classes	No. of Channels	Line Length	No. of Lines	Processing Times
LANDSAT-1,2	32	4	512	512	12 sec.
	32	4	3300	2286	5.8 min.
	93(max)	4	3300	2286	15.0 min.
LANDSAT-3	64(max)	5	3300	2286	15.2 min.
MSS(1 Pass)	35(max)	7	2048	2048	8.2 min.
Multisensor or Multitemporal (3 Pass)	32	11	2048	2048	20 min.
II. 2-D-FFT		1	512	512	12.8 sec. forward 17.0 sec. inverse
III. IMAGE 100 Transfers from Disk					
Decimate a LANDSAT Frame to:		4	512	512	28.0 sec.
Move an I-100 Screen to:		4	512	512	12.0 sec.

how the processing times for the maximum likelihood decision rule (MLDR) vary with number of features (4 to 7) and number of classes. The stars in Figure 6 mark the maximum number of classes which can be processed in one pass for the number of features indicated. At low numbers of classes one is limited by the minimum time (2.5 seconds) required to input the image to the IAP. The classification results flow to core memory and then to disk. It is of interest to note that for more than 21 classes, an image on a 1600 bpi magnetic tape can be directly read in on our 125 ips drives and classified by MLDR with no loss in processing speed.

Table V summarizes the processing rates achieved by the CIAS with the IAP for maximum likelihood classification, 2-D Fast Fourier Transforms, and transfers from the large DB1 disk to the IMAGE 100 solid state memory. These rates are high enough that most of the CCRS bulk processing

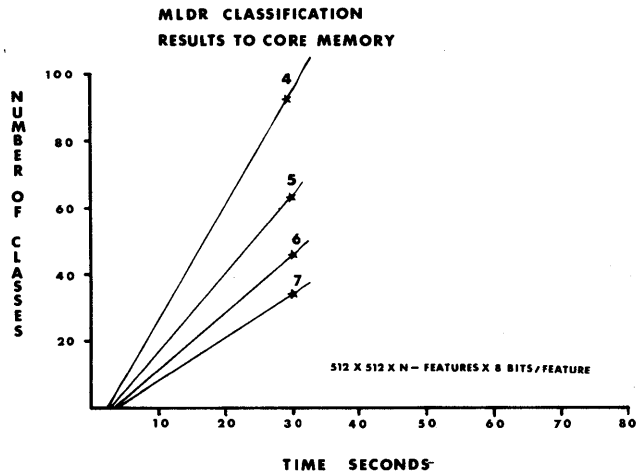

Figure 6—The variation of IAP processing times are shown for maximum likelihood decision rule (MLDR) classification for normal distributions for a 512 by 512 image of N features with 8 bits per feature. The number of features has been changed from 4 to 7. The stars mark the maximum number of classes the IAP can process for the indicated feature space dimensionality. At low numbers of classes one is limited by the minimum time (2.5 seconds) required to input the image to the IAP. The classification results flow to core memory and then to disk.

requirements for LANDSAT data can now be met by the CIAS. The parallel processing permitted in the CIAS by the 11/70, IMAGE 100, and IAP and the parallel processing within the IAP itself mean that the rates (within 10 percent) given in Table V are achieved even under full system load.

CONCLUSION

The minicomputer when combined with an array processor and display hardware can match or exceed the image processing performance of larger, general purpose computers. The complexities caused by the additional hardware can be reduced by following programming standards and conventions consistent with the software operating environment selected for the system. The use of a single standard tape format and a single disk format minimizes the number of input/output programs required to support the additional hardware. The inclusion of parallel processing and multitasking permits a minicomputer based system to achieve phenomenal image processing throughput at lower costs than conventional systems.

Flexibility can be maintained without inordinate sacrifices in speed. It is often expressed that software image processing systems are much easier to change than systems with special processors. Our experience has been that software systems of hundreds of programs developed a rigidity comparable to systems with hardware processors. Both approaches require that good documentation and change procedures be followed.

The application focus of this paper has been image processing in remote sensing. Many of the techniques presented here are, however, applicable to other areas of image processing and can be used in those areas to obtain lower cost solutions to their image processing problems.

Use of textural features in the analysis of Landsat images

by H. K. RAMAPRIYAN, S. H. CHANG, and R. L. McKINNEY

Computer Sciences Corporation
Falls Church, Virginia

INTRODUCTION

The use of remotely sensed data for land-cover categorization has been well demonstrated in recent years.[1] In addition to the use of conventional methods, such as windshield surveys and low- and high-altitude aerial photographs, satellite data are being employed by several planning agencies for creating land-use and land-cover data bases to assist in decisionmaking.

Human interpretation of aircraft and satellite imagery is still used extensively and is essential for certain applications (e.g., lineament studies in geology). However, automatic interpretation of the image data using digital computers significantly complements human analysis and is advantageous in providing consistency, labor savings, and timely availability of interpreted data for postprocessing and inclusion into data bases.

The major differences between human and machine interpretation of images are as follows. A human interpreter uses color, spatial variation of color, and relative location of objects (i.e., spectral, textural, and contextual features) in an image simultaneously. Starting with a synoptic view of the image, the human interpreter partitions that image into homogeneous segments and associates labels with each of them. It is difficult to design algorithms for machine interpretation which simulate the human photointerpreter. However, machine analysis has the advantage of high resolution not achievable with human interpretation. Although it is possible to incorporate spectral, textural, and contextual features into machine analysis, the most commonly used classification algorithms employ only the spectral data and assign categories (or class labels) to single resolution elements (pixels) independently of other pixels.

The accuracy of classification maps is a principal concern for users. Studies of classification algorithms have been conducted which compare ground-truth maps with the classification maps generated by machine interpretation of Landsat multispectral data using only the spectral features at individual pixel locations. For example, in Reference 2, confusion is shown to exist between certain urban and agricultural cover types. This is due partially to the similarity in the spectral characteristics and partially to the differences in human and computer characterization of classes (e.g., when a region with large residential lots is encountered, human interpretation for the entire region is "urban," whereas machine interpretation is dependent on the urban-vegetation mixture). To distinguish between categories exhibiting similar spectral reflectances, the use of additional features dependent on texture and/or context is helpful. For example, although the spectral characteristics of some urban and agricultural cover types are similar (due to the variety of objects constituting urban pixels and the relatively homogeneous nature of agricultural regions), the variations of spectral reflectances within an urban region can be expected to be greater.

In the past several experiments have been performed on the use of textural features in classification. A review of the work on textural feature definition is given in Reference 2. In Reference 3, a comparative study of texture measures used for terrain classification is presented; the features are categorized as based on Fourier power spectra, second-order grey-level statistics, grey-level differences statistics, and grey-level run-length statistics. Examples of textural features based on Fourier transforms of image segments are given in References 3-5. In Reference 4 textural features invariant under translation and rotation are derived in terms of discrete Fourier transforms of square image segments and are shown to improve the accuracy of classification. Several studies by Haralick and his coinvestigators[6-12] employ various textural features defined in terms of grey-level co-occurrence matrices which can be regarded as second-order grey-level statistics; "contrast," "angular second moment," "entropy," and "correlation," which are functions of such matrices, are demonstrated as particularly useful. Grey-level difference statistics, defined in Reference 3, are obtained in terms of the frequencies of occurrences of particular values of grey-level differences at given separations and orientations in an image segment. The features derived from the grey-level co-occurrence matrices and the grey-level difference statistics are somewhat similar. Other measures of texture are defined in Reference 13 in terms of the frequencies of "runs" of grey-levels in given ranges in specified directions.

The utility of these textural features has been demonstrated for terrain classifications using aerial photography and Landsat data. However, in all of these studies, the features have been defined over large blocks of data, which implies a loss of effective resolution. The purpose of this paper is to develop a set of features which are a compromise between using large blocks of data (reducing resolution) and

using only spectral information at a single resolution cell. These features will be defined at every point in the image but will use combinations of spectral reflectances at neighboring pixels of each pixel. Thus, an augmentation of the conventional spectral features with spatial and, in turn, textural information results. Preliminary experimental results on the reduction in dimensionality of such feature vectors and a comparison of classifications generated by the conventional and the proposed techniques are presented in the following sections.

STATEMENT OF THE PROBLEM

The notation to be used in the remainder of this paper is as follows. Let P denote the array of spectral measurements, with p_{ijk} denoting the kth spectral feature measured at the ijth pixel, where i equals 1, 2, . . . , M; j equals 1, 2, . . . , N; and k equals 1, 2, . . . , K (in the case of Landsat, K equals 4).

Conventional classification techniques convert P to an array, Q, called the classification map, where q_{ij} are numbers in the range 1 to L, i and j have the same range as in the case of P, and L equals the number of classes. The decision on the assignment of p_{ijk} to q_{ij} depends only on the K numbers corresponding to the ijth pixel in P.

The problems considered in this paper are (1) how to define features at every point in the image such that the original resolution of P is preserved while, at the same time, spatial dependences of spectral reflectances are utilized in making the class assignments in Q and (2) how to use these features to obtain improved classifications without significant increases in computation.

FEATURE DEFINITION

In terms of the notation introduced previously, simple textural augmentation of spectral features can be provided as follows. For each ij define a feature vector, x_{ij}, given by

$$x_{ij}=\{p_{ij} \mid p_{i,j+1} \mid p_{i+1,j} \mid p_{i+1,j+1}\} \quad (1)$$

where p_{ij} represents the K-dimensional feature vector at ij (assuming all vectors to be row vectors).

Thus, with Landsat data 16-dimensional feature vectors result. Other similar feature vectors can be defined at every point in the image. Examples are the following:

$$x_{ij}=\{p_{ij} \mid p_{ij}-p_{i,j+1}\mid \mid p_{ij}-p_{i+1,j}\mid \mid p_{ij}-p_{i+1,j+1}\mid\} \quad (2)$$

$$x_{ij}=\{p_{ij} \quad p_{i-1,j} \quad p_{i,j-1} \quad p_{i+1,j} \quad p_{i,j+1}\} \quad (3)$$

$$x_{ij}=\{p_{ij} \quad \min_{k,l=\pm 1} \quad p_{ij}-p_{i+k,j+1}\mid \max_{k,l=\pm 1} \mid p_{ij}-p_{i+k,j+1}\} \quad (4)$$

(In all of the foregoing equations, special definitions must be made for the cases in which the subscripts of p exceed their ranges. A reasonable definition is to replace $p_{i+1,j}$ by $p_{i,j}$ and so on.)

Each of these feature vectors includes the spectral features at the point ij as well as those in the immediate surroundings of ij. These vectors could simply be used in a conventional classification algorithm such as a maximum-likelihood supervised classifier. However, because the dimensionality of the feature space has effectively been increased by a factor of four (five and three in the case of Equations (3) and (4), respectively), it is desirable to reduce the dimensionality by some feature selection or extraction technique and then perform the classification.

In the experiments discussed here, the feature vector definition (Equation (1)) is used. The Karhounen-Loeve (K-L) principal components transformation[14] is used to reduce the dimensionality. This linear transformation is derived from the orthonormal eigenvectors of the covariance matrix, C, of the 4K-dimensional data. By arranging the eigenvectors such that they correspond to the eigenvalues of C in descending order, the first few components of the transformed feature vector can be used for classification, because most of the significant information is contained therein. An alternative method is a canonical transformation,[15] the use of which facilitates separability of the categories of interest. This transformation is derived using the statistics of the individual classes to be separated. The transformed components are such that the separations among classes are in descending order from the first to the last component. The first few components can therefore be chosen for classification. The K-L transformation was used here because the software implementing it was readily available.

EXPERIMENTAL RESULTS

A 250-by-250-pixel subset of a Landsat scene (ID 1999-15091) covering Orlando, Florida, was used in this experiment. The four bands of the image are shown in Figure 1. Using the feature definition of Equation (1) and the K-L transformation, textural features (the features including the spatial and spectral information) were extracted. The first eight of the individual components so derived are shown in Figure 2. The first two components are effectively low-pass filter output, whereas the subsequent components tend to emphasize the edges of the image. This is also evidenced by an examination of the eigenvectors used for the transformation as shown in Figure 3.

Using training samples, eight classes were defined in this scene:

Class	Name	Description
1	Residential 1	Residential with significant tree cover
2	Residential 2	Residential with sparse tree cover
3	Vegetation 1	Dense trees and shrubs
4	Vegetation 2	Dense trees
5	Vegetation 3	Dense shrubs
6	Vegetation 4	Sparse trees and shrubs
7	Water	Water
8	Swamp	Mixture of wetlands and vegetation

The image was classified using the spectral and textural

features separately. The two resulting classification maps (CMs) are shown in Figures 4 and 5, respectively. The major differences between the two CMs are in the swamp (class 8)/vegetation (class 3) area on the left side of the image and in the increase of residential classifications in Figure 5 relative to Figure 4. The main increase in the residential classes comes from the locations in Figure 4 which were classified as vegetation. Although a ground-truth verification was not performed in this experiment, a slight overestimate, rather than underestimate, of the residential class is desirable (e.g., in census applications in which decisions on locations for manual data gathering are made based on the CMs). Also, the CM in Figure 5 is more uniform within each class than that in Figure 4. Figure 6 shows a confusion matrix between the two CMs, with the ith row, jth column element equal to the number of occurrences of the ith class in Figure 5 and the jth class in Figure 4. Defining the similarity measure between the two CMs to be the trace of the confusion matrix expressed as a percentage of the total number of pixels, it is found that the two CMs are 63.4 percent similar. Because the major differences between the CMs are in classes 3 and 8, the spectral and textural features were further investigated by generating plots of the spread of data values in each of the eight classes. These plots are shown for the spectral features in Figure 7 and for the first four textural features in Figure 8. It can be seen that, in the row data bands, the overlap between classes is greater than in the case of textural features, especially for classes (1, 2) and (3, 8). Because the separability of classes is better in the case of textural features, it is highly likely that the classifications in Figure 5 are more accurate than those in Figure 4.

CONCLUSIONS

Simple features using spectral and spatial information have been defined in this paper. A difference between the textural features defined herein and those defined in previous works

637	927	1	12	0	0	48	0
1769	17616	365	1654	1017	369	1866	0
12	215	2695	411	678	29	5	320
2	189	138	701	291	0	1	1
1	560	365	307	1959	156	0	29
0	337	120	3	583	5501	162	157
275	2888	102	129	286	2106	6838	14
0	0	3129	9	169	669	0	3677

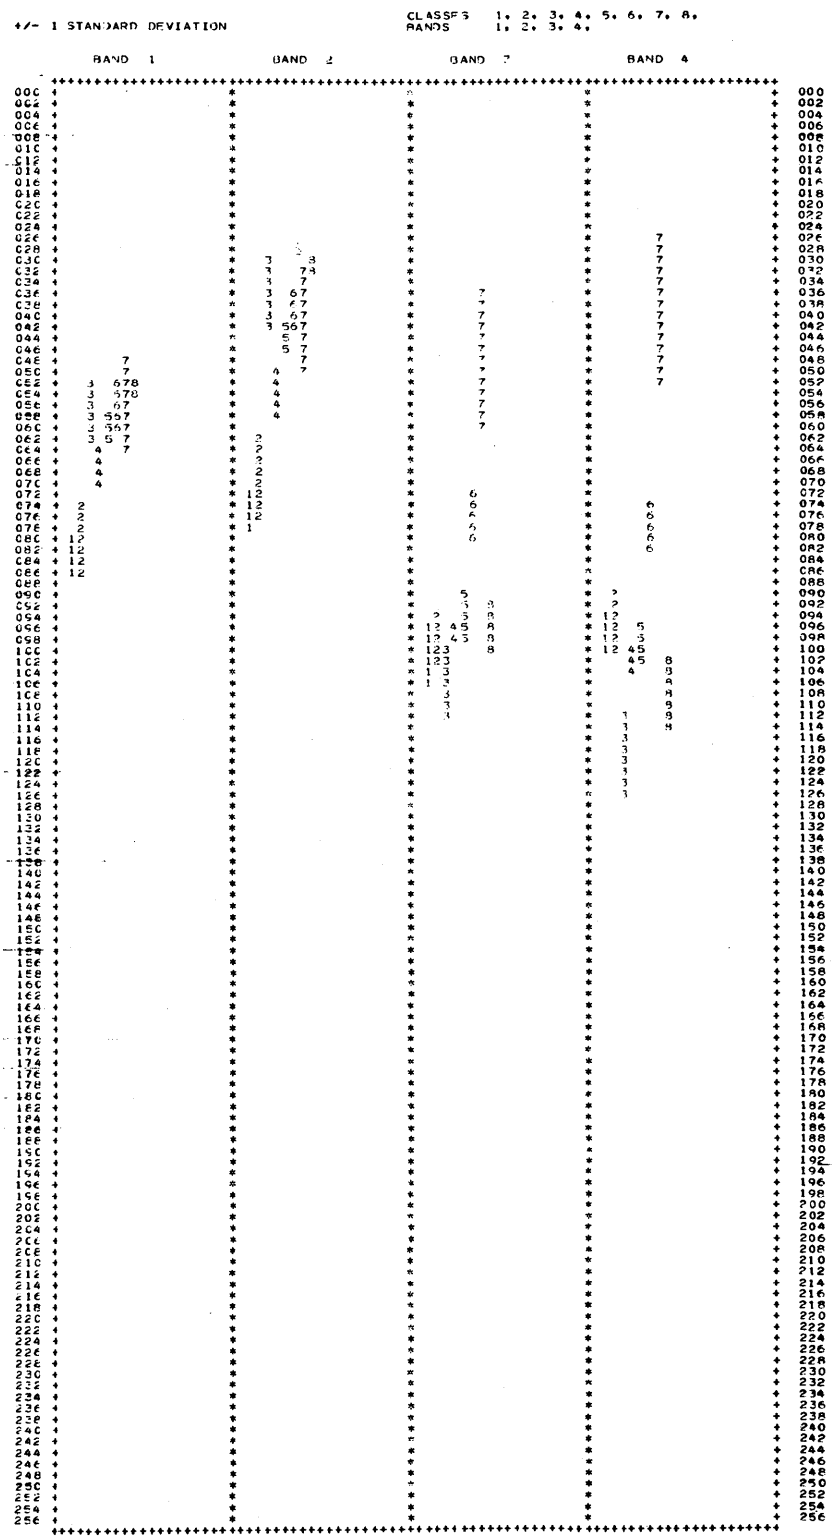

Figure 7—Distribution of channel values for spectral features

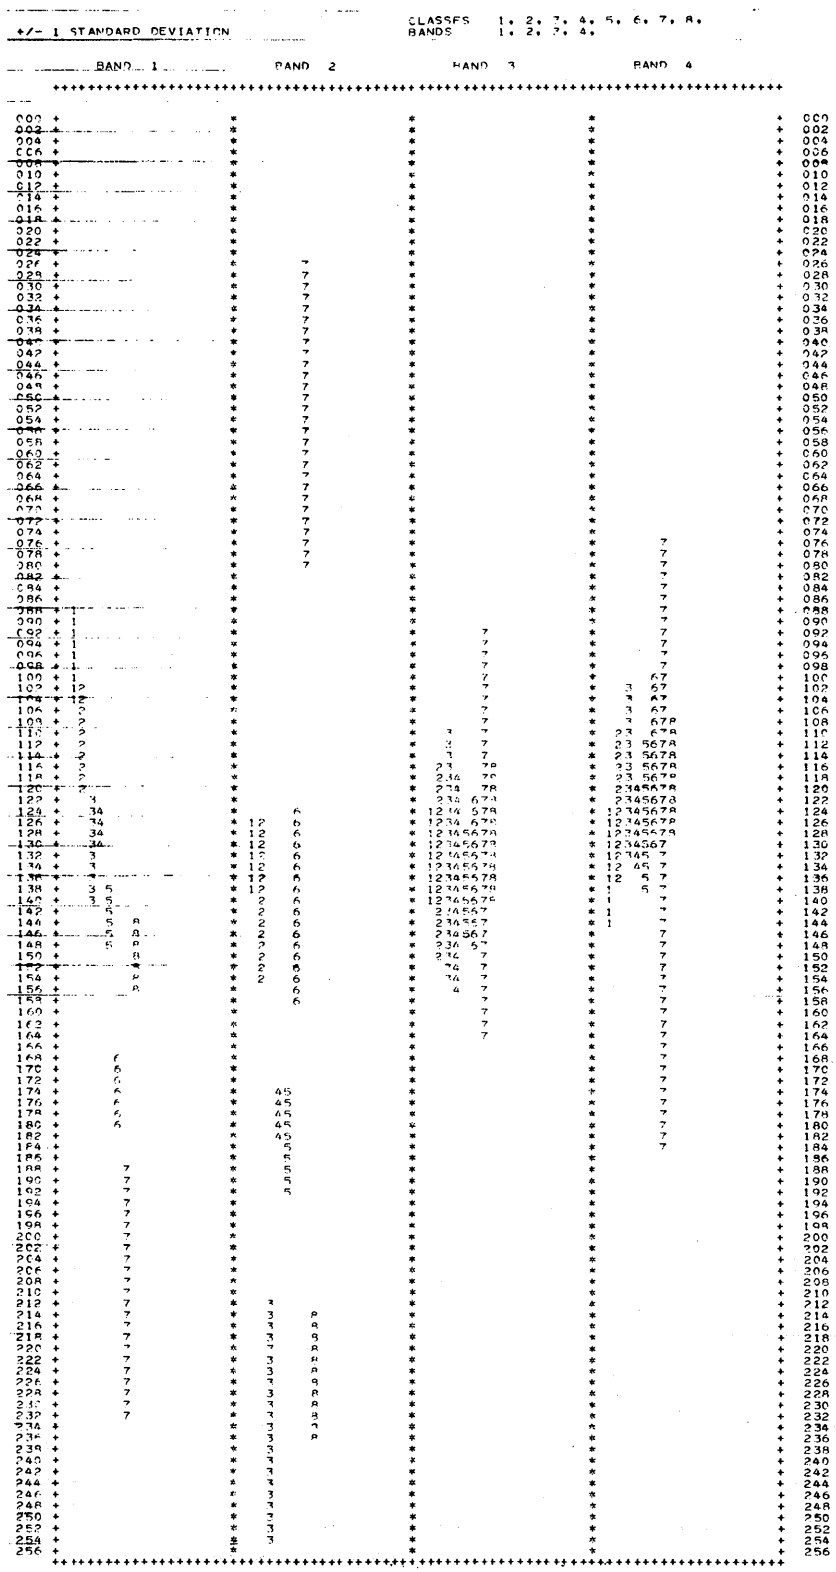

Figure 8—Distribution of channel values for K-L transformed components after textural augmentation

is that the features are defined here at every point in an image and the effective resolution is not reduced. An interpretation of the features extracted through linear combinations of the spectral reflectances of the nearest neighbors of a pixel is that the effects of the spatial variation in the immediate vicinity of the pixel are taken into account in making decisions on its classification. Experimental results are shown for a small subset of a Landsat scene using one of the feature definitions and the K-L transformation to reduce the dimensionality. The main differences between the classification map using spectral features and that using textural features are that the latter has a higher number of residential pixels and is smoother in appearance. An examination of the plot of the spreads of the spectral and textural feature values for the various classes reveals better separability of classes with textural features.

Further experiments with the features and dimensionality reducing transformations should include the use of symmetric feature vectors such as in Equations (3) and (4) and the use of a canonical transformation.

Combinations of three of the first few components obtained using the transformations can be used for producing color composites. Such color images will have an enhancement of the edges and are expected to be similar to the output of high-emphasis filters.

Applications of digital image processing techniques to problems of data registration and correlation

by WILLIAM B. GREEN
California Institute of Technology
Pasadena, California

INTRODUCTION

JPL's Image Processing Laboratory (IPL) has been processing imagery using digital computers for approximately ten years. During that period, the computer capability at the IPL has developed from a single job batch oriented system with no volatile image displays to a multi-task environment accommodating both batch processing and several interactive tasks simultaneously, supporting a variety of general purpose and special purpose interactive image display systems. The sophistication of the various applications has also developed from simple subjective enhancement of planetary imagery to complex applications requiring correlation of remotely sensed imagery with auxiliary data and with non-imaging data bases. This paper describes the evolution of the IPL facility, and illustrates the increasing complexity of the image processing tasks with examples of various applications from the planetary program and the earth resources activities that have utilized the IPL facility.

HISTORICAL BACKGROUND

Ten years ago at JPL, digital image processing of lunar images from Ranger and Surveyor was performed using a central general purpose computer in a batch environment. An analyst submitted his job and often had to wait several days to view the result, since the job had to be run in competition with other tasks using the same computer and the output image had to be recorded on film, processed and printed before he could see the results of processing.

In 1968, IPL acquired an IBM 360/44 computer system that was dedicated to image processing applications. This computer, and the 44 PS operating system, were capable of supporting a single user at any given time; the analyst again had to wait to view the result of his processing until film recording, film processing and printing had occurred. At that time, there were no commercially available image display systems that could be easily interfaced to a digital computer so the IPL developed a core-refreshed display (CRD) system. The CRD used the 360/44 core memory as its refresh memory, and the display was capable of displaying a 256 picture element square image with 4 bits of intensity quantization. The core memory of the 360/44 was read every 1/30 of a second to refresh the video display at video rates. The CRD made it possible to display imagery as soon as it had been processed, although the display was limited to 256 square resolution and 4 bits of intensity information. It had the obvious disadvantage of precluding any processing while image display was occurring, since the 360/44 memory was totally committed to image display refresh buffering whenever an image was being viewed on the CRD. Nevertheless, it represented the first interactive image processing capability at the IPL, and substantially shortened the turnaround time for subjective enhancement processing.

The 360/44 operating system and hardware display support improved between 1968 and 1975. A new image display system employing lithicon storage tube refreshed display systems was implemented to support the Mariner 9 Mars orbital mission in 1972. By 1974, it was possible to run two or three jobs on the system in a timesharing mode, using foreground and background partitions. However, processing became severely limited by the constraints of the 360/44 system as the size of the imagery returned by the planetary missions increased, as the number of images returned from each mission increased dramatically, and as large multispectral images became available from the LANDSAT satellites. In 1975, a decision was made to upgrade the entire IPL computer configuration and associated display systems to meet the following objectives: (a) increase batch processing capacity by at least a factor of three, (b) enable simultaneous interactive image processing to occur at the same time that batch processing was occurring, (c) enable at least two interactive image processing users to be active at any given time.

The next section describes the current IPL computer and display configuration, and the remaining sections discuss a variety of applications for which the system has been used.

CURRENT IPL CONFIGURATION

The current central computer in the IPL is an IBM 360/65 with a megabyte of memory, eight tape drives, and 900 mbytes of on-line disk storage; 800 of the 900 mbytes of on-line storage consists of Memorex 3670 high speed disk drives.

The 360/65 operating system is OS/MVT, and TSO is used to support timesharing operations. The Informatics MARK IV data base management system is also available, and is used to catalog processed imagery produced by the IPL each day. In addition, MARK IV is used to maintain catalogs of auxiliary data relating to each image processed by the IPL. For example, an image of Mars recorded by the Viking Lander will have a variety of parameters associated with it, such as local Mars time at which the exposure was made, camera gain and offset settings, solar illumination angle at the time of exposure, etc. MARK IV is used to construct, update and search these catalogs.

The interactive processing is supported by a variety of terminals and display systems. A Digital Equipment Corporation PDP 11/40 computer is interfaced to a channel on the 360 via a DX-11B channel interface. The PDP 11/40 supports several dial-up and hard-wired interactive terminals, and three image display systems. The interactive terminals include both IMLAC graphics/CRT terminals and TI Silent 700 terminals. The current IPL configuration is shown in Figure 1.

The image display systems are all commercially available equipment. They include a RAMTEK display system that accommodates 6 bit black and white imagery up to 640×512 elements. The RAMTEK also has two one-bit graphics overlay planes and two trackball/cursor units. Each of the RAMTEK output signals (video only, video plus either graphics plane, or either of the graphics planes) are available as video signals that may be separately accessed and displayed. Thus more than one user can use the RAMTEK system at a given time. For example, one user can access the black and white video image with one graphics plane overlaid, while a second user can access just the second graphics plane. All video signals are routed into a video network that includes several black and white monitors distributed in two user area locations at IPL, and a user selects the video signal he wishes to utilize and displays that signal on a monitor near his terminal. One view of one of the interactive user stations is shown in Figure 2, and a user interacting with an image display is shown in Figure 3.

The other image display systems consist of two COMTAL display systems. A COMTAL 8003 system provides 512×512 resolution for six bit images, and includes graphics overlay planes and trackball/cursor unit. The COMTAL

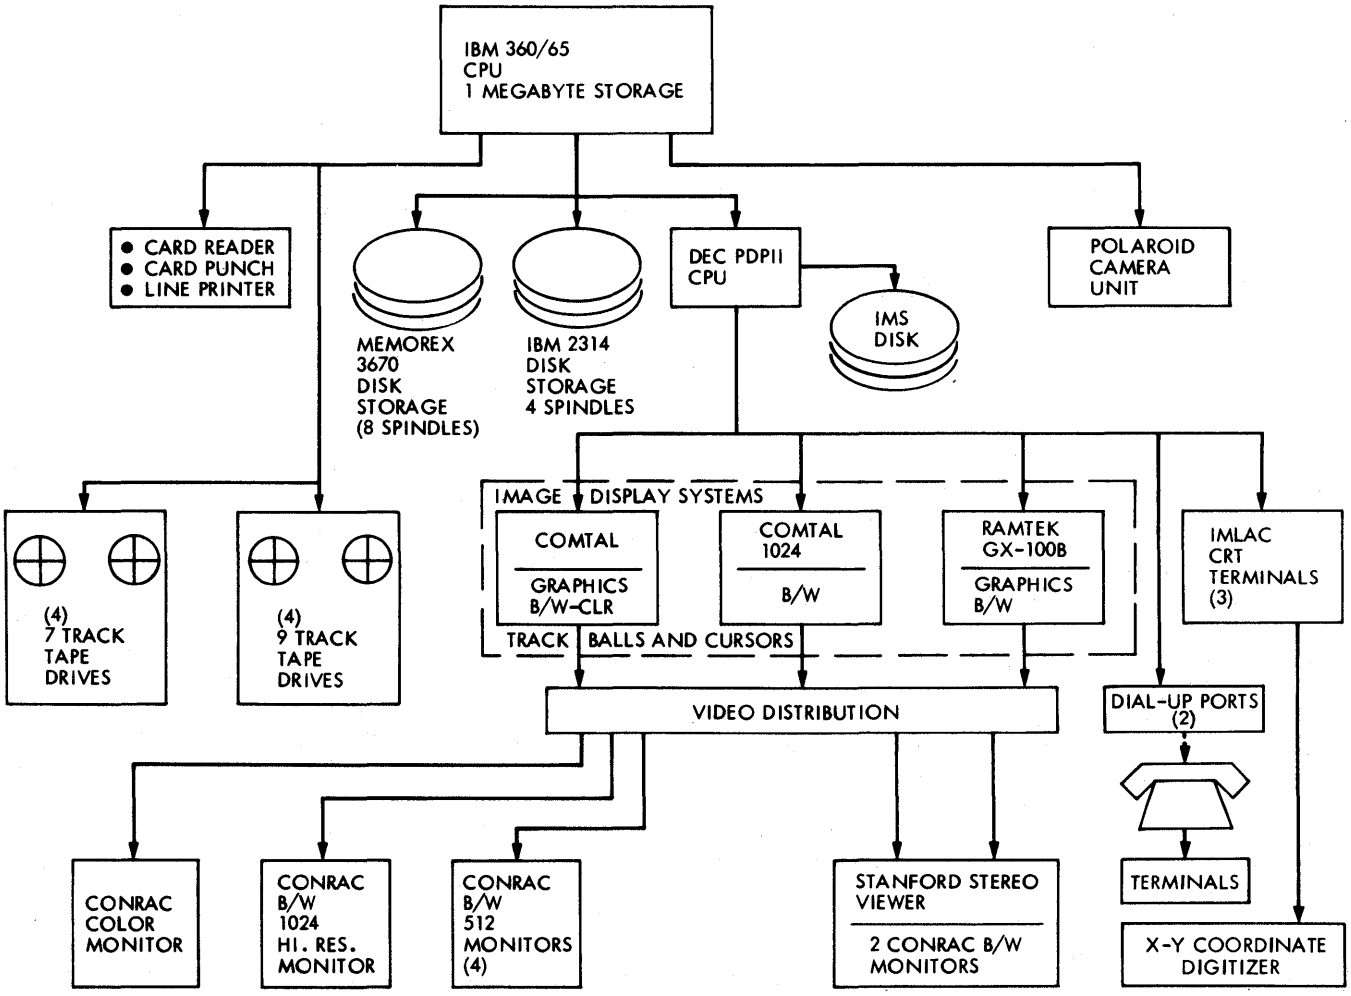

Figure 1—JPL Image Processing Laboratory computer configuration

Figure 2—User area station at JPL's Image Processing Laboratory. The user seated at the IMLAC terminal can select video signals to be routed to the display monitors using the video switching box on the right side. Audio communication with the computer operator is also provided. (JPL Photo Lab Negative No. 324-2009Ac)

8003 provides either a single color image at 512×512 resolution or three black and white images at the same resolution. Again, each output video signal is separately accessible, and can be routed to any monitor in the user areas.

A COMTAL 1024 system provides capability for display of black and white imagery at 1024×1024 resolution. Because of the high bandwidth, the video output of this device is routed to a single specially modified monitor. The 1024 system also includes graphics overlay and trackball/cursor unit.

A complete description of the IPL computer configuration and the interactive capabilities supported by the PDP 11/40 computer is contained in Reference 1.

GEOMETRIC TRANSFORMATION

IPL has been performing digital geometric transformation of imagery for approximately ten years. The earliest applications included removal of camera system induced geometric distortion[2–4] and projection of planetary imagery to standard cartographic projection.[5] More recently, geometric transformation has become an important tool in registration of imagery and non-imaging data represented as imagery to standard georeferenced coordinate systems, and in registration of multiple images of the same surface area recorded at different times.

Geometric transformation of digital imagery begins by locating a set of tiepoints within the original image and defining the locations of those tiepoints in the output image. The transformation of the tiepoints may be determined by a mathematical algorithm or by analysis of the imagery itself. For example, image transformation to standard mapping projections can be defined by establishing a uniform grid of tiepoints in the output image aligned with a longitude/latitude coordinate system, and then mathematically computing the locations of those tiepoints in the untransformed image based on a model of the spacecraft location and imaging sensor geometric characteristics. The locations in the input image corresponding to points between tiepoints in the output image is computed by an interpolation procedure.

The intensity of picture elements in the output image that do not fall on exact points in the input image is computed by performing an intensity interpolation (or resampling) in the input image. The process is shown in Figure 4. Normally, the intensity of each sample on each line of the output image is computed in turn, starting at the upper left corner of the image and working down to the lower right corner. For each output sample, the corresponding location in the input image is computed, and the intensity of that sample is computed based on an interpolation scheme if the location in the input image is not exactly at a discrete image sample point. Typical interpolation schemes include nearest neighbor, bilinear interpolation, and cubic spline.

An example of geometric transformation is shown in Figure 5. A Viking Orbiter image of Mars is shown before and after orthographic projection. The unprojected image shows the large crater to have an elliptical shape, due to distortion

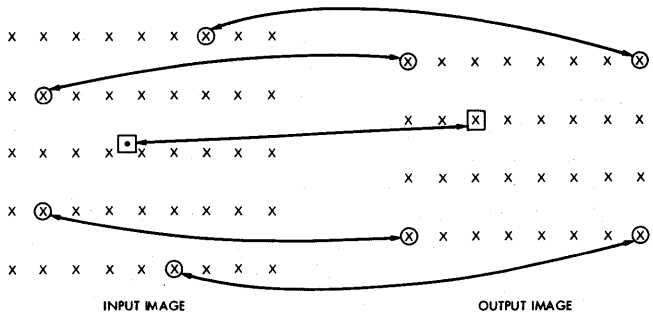

Figure 4—Digital geometric transformation

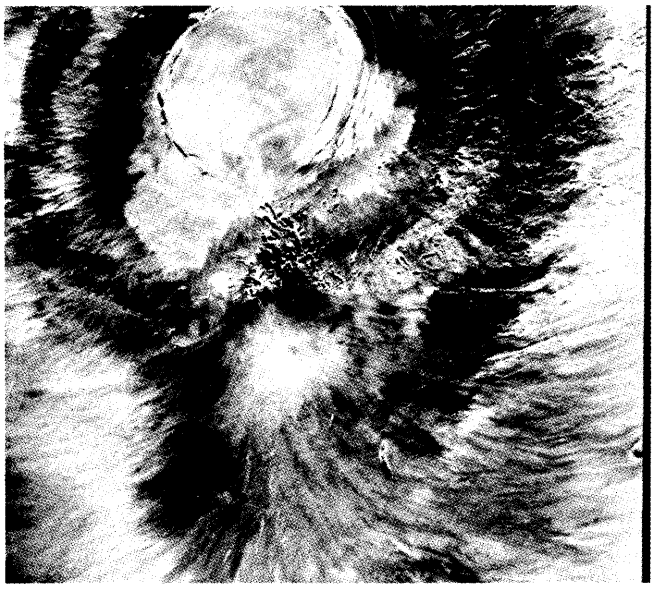

Figure 5—Left—Contrast enhanced version of a Viking Orbiter image of a large Martian crater. The crater is ellipsoidal, due to spacecraft viewing geometry.

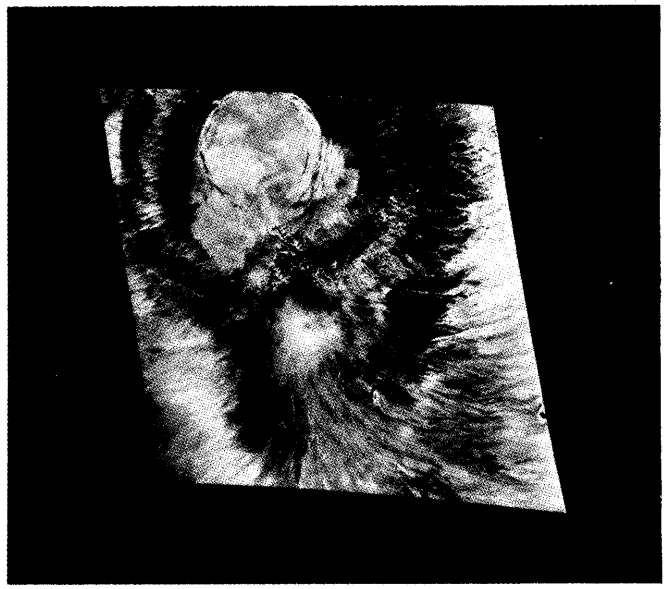

Figure 5—Right—The same image after orthographic projection. Shape distortion due to viewing geometry has been removed. (IPL Pic ID 76/09/09/173047 and 76/09/09/175425)

introduced because the image was recorded when the camera was at an oblique angle relative to the local surface normal. The orthographic projection is performed to depict the images as if the camera were viewing the scene from directly above the center of the field of view, and the transformation is defined based on spacecraft position and camera orientation data returned in the spacecraft telemetry.

AUTOMATED IMAGE REGISTRATION

It has frequently been possible to perform image registration in an automated manner in the NASA planetary program. Typically, each planetary spacecraft records a large number of images of a planetary surface, and the science investigators require construction of photomosaics showing large portions of the surface of a planet in a single photographic product. In most cases, it is possible to perform standard mapping projections by computing the geometric transformation for each individual image based on auxiliary data returned with each image that describes the spacecraft position relative to the planet and the camera viewing angle. The transformation is computed based on the mathematical model of the planet (generally an oblate spheroid is used as the planet model), the camera system optical components, and the spacecraft and camera viewing geometry.

IPL produced over 1200 images projected to an orthographic projection during the Mariner 9 Mars orbital mission. Each image was individually corrected for camera system geometric distortion, enhanced, and then projected to an orthographic projection. The projected images were then photographically scaled and used to construct the first global photomosaic of a planet ever constructed from remotely sensed imagery. The photomosaic was constructed on a three-foot diameter globe, and a portion of the photomosaic is shown in Figure 6.

The Mariner 10 flyby mission to Venus and Mercury provided several thousand images of the surface of Mercury. IPL produced photomosaics of many standard mapping quadrants on the planet's surface. Figure 7 shows one of the mapping quads produced from over fifty Mercury images from Mariner 10. Again each image was individually processed to remove camera system induced distortion, enhanced, and projected to Mercator projection. Other map-

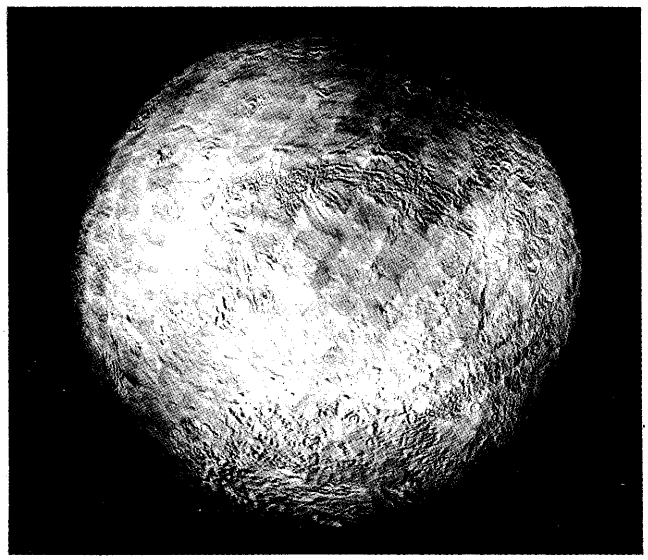

Figure 6—One hemisphere of the photomosaic globe of Mars produced using over 1200 enhanced and orthographically projected images from the Mariner 9 Mars orbital mission. (JPL Photo Lab Negative No. 320-284B)

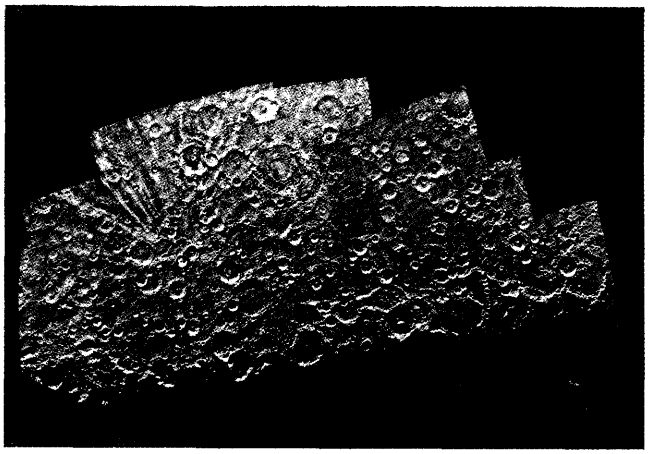

Figure 7—Computer generated mosaic of the region near the south pole of Mercury, constructed from over twenty separate Mariner 10 vidicon images. A special scene dependent high pass filter has been applied to bring out local detail throughout the scene, and especially near the terminator. (JPL Photo Lab Negative No. 324-2306)

ping projections in standard use at IPL include Lambert Conformal Conic and Polar Stereographic.

In both of the cases described above, the navigation data was of sufficient quality to enable mosaicking of automatically projected imagery. After each individual image was projected, it was not necessary to refine the projection transformation to achieve a better match of the imagery. However, there are instances where precise registration to less than a picture element across the entire area of interest is required. In those cases, it is often necessary to perform manual or interactive processing to refine the transformations that are performed. Typical applications of this type are discussed in the next section.

SEMI-AUTOMATED IMAGE REGISTRATION

IPL has developed the capability to perform interactive refinement of image registration for specific applications. An example of an application requiring registration accuracies of less than one picture element is image differencing. For example, the Mariner 9 Mars Orbiter provided repetitive coverage of portions of the Martian surface during 1972. Determination of surface feature variation was one scientific objective of that mission. It was possible to achieve gross (accuracy $\geq$1 picture element) registration of two images of the same portion of the surface taken at different times during the mission by performing standard mapping transformations. However, change detection can be confusing if there is misregistration on the order of one picture element, since changes are masked by overall misregistration when a difference image is produced. It was necessary to refine the registration using an interactive display and supporting software. The software originally developed for Mariner 9 has been extended and refined for later applications, but the general principles remain the same.

An analyst selects a feature in one of the two images he wishes to register. He then identifies the same feature in the second image. The program uses his second location in the second image as the center of a search area, and performs correlation calculations within a local moving window in the second image. A point of maximum correlation is selected as the location in the second image that corresponds to the selected location in the first image, and the offset of that point relative to the location in the first image is retained. The analyst proceeds to select a set of features and performs the same routine with each point, so that a set of offset vectors is ultimately available throughout most of the region of overlap. When an adequate number of feature offsets has been acquired, a geometric transformation is defined that will map the second image onto the first image. Normally, if the two images have been processed to a standard mapping projection prior to the identification of feature points, the second geometric transformation is a small refinement. The result is a registered pair of images where registration has been achieved to less than one picture element accuracy.

Figure 8 shows one of the output products from the Mariner 9 image differencing task at IPL. The top two images are segments of Mariner 9 imagery of the same part of the surface recorded approximately two weeks apart. The lower left image is an unenhanced difference picture, and the lower right image is a contrast stretched version of the difference picture. Any differences in intensity between the two images is displayed as either whiter or blacker than mid-gray in the difference image.

If the two images had been misregistered by more than a picture element, all features in the scene would appear in the difference image as both black and white detail. For example, the crater edge would appear as a double image, one black and the other white. Because the registration is precise in the example shown in Figure 8, the crater edge appears only once in the difference image, and the difference image correctly portrays the change in crater edge definition and albedo that occurred as the great Martian dust storm of 1972 continued to clear during the two-week period in which these images were recorded.

REGISTRATION OF IMAGING AND NON-IMAGING DATA

The registration of non-imaging data to imaging data has always been important in digital image processing applications at IPL. Processing of planetary imagery often required knowledge of auxiliary data relating to each recorded image. For example, generation of geometric transformation parameters to transform an image into a standard mapping projection requires a knowledge of the spacecraft position and the camera viewing angle at the time the image is recorded. It is also often desirable to remove the shading effects in planetary imagery that are caused by variation in solar illumination and viewing angles from image to image, and removal of these effects is performed using auxiliary ephemeris information and spacecraft position and view angle data.

The planetary program initially provided the motivation for geographically referenced image data bases. It was nec-

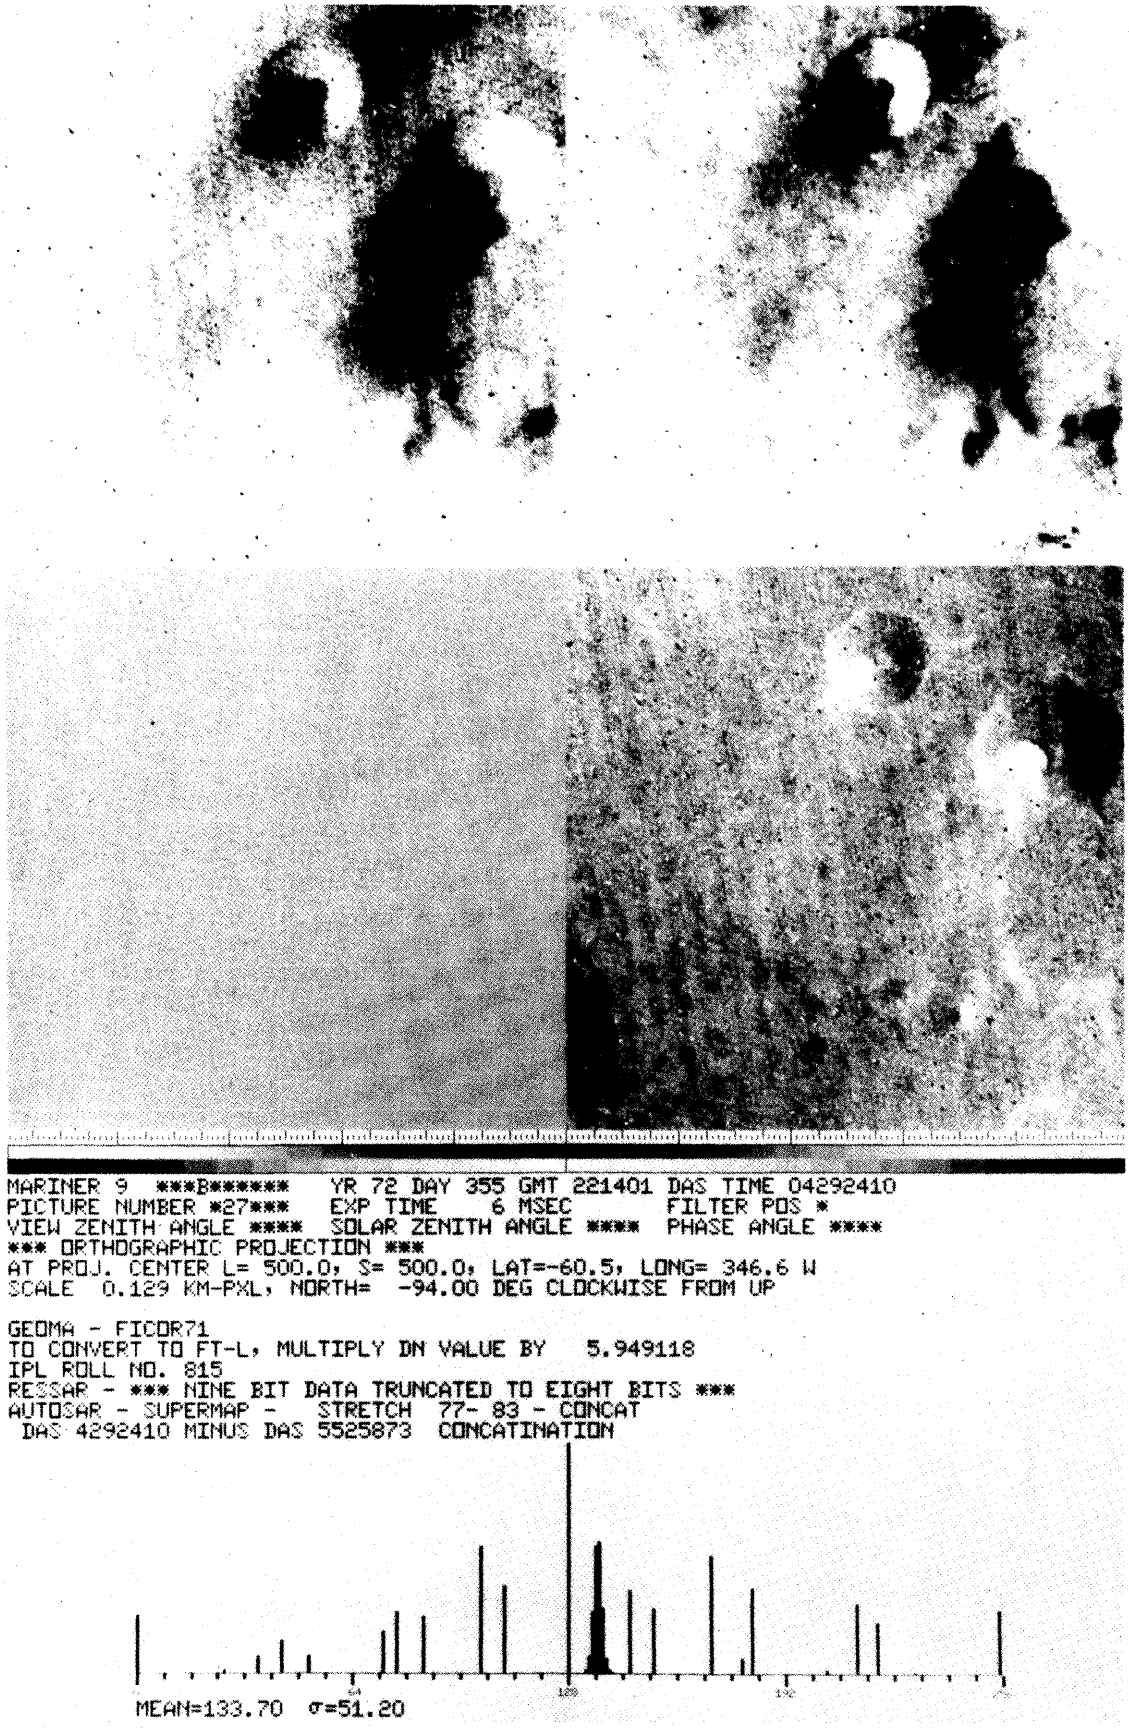

Figure 8—An example of image differencing. Top two images are segments of Mariner 9 images of Mars recorded approximately two weeks apart during clearing of the great dust storm of 1972. The two segments are in precise registration. The bottom left image is an unenhanced difference image, and the bottom right image is a contrast enhanced difference image. Changes in albedo in the center of the crater show as white areas in the difference image. (JPL Photo Lab Negative No. 324-2293A)

essary to index each image based on the longitude and latitude coordinates of the surface area recorded in each individual image. Computerized data bases were created for imagery of Mars, Venus and Mercury that enabled interactive interrogation to determine surface coverage as a function of a variety of parameters. It is possible at IPL to perform a search to locate all images taken of a particular portion of the planet surface that were taken under a particular set of conditions. Thus an analyst can interactively query a picture catalog to answer the following type of question:

"What Viking Orbiter images exist that show the area within 10 degrees of latitude 65° west longitude 120° after 3:00 p.m. local Martian time that were taken through the red spectral filter? Limit the search to those images recorded after the 35th day of the Orbital mission."

The LANDSAT satellites have increased the emphasis on correlation of geographically encoded data bases. There are literally hundreds of existing geographically encoded data bases in routine use throughout the country by a variety of federal, state and local government agencies. One of the most familiar examples is the data base maintained by the United States Census Bureau. LANDSAT satellites provide repetitive multispectral imagery of the earth's surface, and have been used to monitor agricultural parameters, geological properties, and land use patterns throughout the country, to list just a few applications. In almost every case, there is a need to relate results obtained from analysis of LANDSAT imagery to existing geographically referenced data bases. In recognition of this need, IPL has developed the Image Based Information System (IBIS).[6,7] This system utilizes the geometric transformation capabilities originally developed for the planetary program to correlate imaging and non-imaging data bases. Figure 9 shows the results of a standard thematic classification of land use in the Portland, Oregon area.[9] Each picture element in a LANDSAT multi-

The district image display product is created from the digital district image using a five-color algorithm;[9] the district image is registered to the LANDSAT thematic map shown in Figure 9.

spectral image is assigned to a particular class of land use based on the relative spectral response in each of the four spectral bands recorded by LANDSAT. Training areas for which ground truth is known are often used to define the spectral signature corresponding to each desired land use category.

The graphical overlay visible in Figure 9 represents the boundaries of the Census tracts for the Portland area. The Census information has been registered to the LANDSAT image using the same registration techniques previously described for the planetary applications. The U. S. Census Bureau provides geographically indexed graphical files on magnetic tape. The data base provided by the Census Bureau includes the geographic location of each of the vertices visible in Figure 9, and a set of parameters for each census tract (e.g., population, age distribution). The Census tabular file is read, and a district image is created. The district image is registered to the LANDSAT image, and contains picture elements that are coded to indicate the census tract identification number in which that picture element lies. An image display product of the district image is often created as a visual check on the district image. Figure 10 shows a district image for the Portland area, based on traffic zone definitions within the city of Portland rather than the Census data. It is important to note that often several overlapping geocoded data bases exist for a single area. In the case of the Portland application, we see that both Census data and traffic zone data bases exist, and that the boundaries of the traffic zones do not correspond to Census tract boundaries. This is one reason that an image-based correlation procedure is useful. It is possible to perform cross-correlations between multiple overlapping geographically referenced data bases and remotely sensed multispectral imagery using the IBIS system; the tabulation is achieved by simple line by line summation using the multiple registered imagery. As an example, Figure 11 contains a portion of a tabulation of land use by traffic zone in Portland. The land use data is obtained from the thematic map shown in Figure 9, and the tabulation by traffic

zone is achieved by correlation of the traffic zone district image with the thematic map.

The IBIS system has recently taken advantage of the interactive capabilities of the current IPL computer system. In particular, the image display systems provide a convenient way to perform precise registration of non-imaging and imaging data bases. As an example, the Census Bureau tabular data base often contains errors, resulting in failure of tract boundary lines to meet at vertices or generation of erroneous tract boundary lines and an erroneous district image when the tabular data is converted to image format. An interactive display system with graphics overlay capability provides an efficient tool for editing of the census data base to correct or remove occasional erroneous data entries.

SUMMARY

This paper has provided an overview of the evolution of the computer configuration at JPL's Image Processing Laboratory, and a summary of the development of techniques for geometric transformation of digital imagery. Image registration techniques originally developed for the planetary program have been described, and have become an important component of the registration of non-imaging geographically encoded data bases with multispectral imagery returned by earth observations satellites. Registration of existing geocoded data bases with LANDSAT imagery will continue to be important if the LANDSAT data is to be truly useful to the user community.

ACKNOWLEDGMENTS

The recent upgrade of the IPL computer facility was performed by the IPL Operations Group under the direction of Joel Seidman. The interactive display support software was developed under the direction of Paul Jepsen. The image registration software at IPL has evolved through the efforts of Tom Rindfleisch, Arnold Schwartz and Jean Lorre. Dr. Nevin Bryant and Dr. Albert Zobrist have been responsible for leading the development of the IBIS system; they are members of the Earth Resources Applications Group supervised by Richard Blackwell. The Mariner 9 image differencing example was provided by Paul Jepsen, and the Mariner 10 computer-generated mosaic was produced by Joel Mosher of our Space Image Processing Group supervised by Donald Lynn.

This paper presents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology under contract NAS 7-100, sponsored by the National Aeronautics and Space Administration.

Design of pipelined systems for landsat image processing

by DONALD C. BRABSTON and JOHN E. TABER
TRW Systems
Redondo Beach, California

INTRODUCTION

With two LANDSAT satellites in orbit and a third to be launched in the near future, the use of imagery obtained by satellite for monitoring the earth's resources is well established. The timely, efficient, and routine handling of this image data is not so well established, however, and large systems for this purpose are just now coming into being. Two examples of such systems are NASA's MDP system being developed by IBM, and Department of the Interior EROS Data Center's EDIPS system being developed by TRW. Under consideration for the future is a system for handling imagery from LANDSAT D, whose data volume and throughput requirements are substantially more severe. This paper discusses some of the design considerations forced by the requirements of such systems and suggests solutions.

The main driving requirements for systems processing LANDSAT data are the extremely large data volume and the high throughput necessary to handle the data in a timely manner. These two requirements also separate the design of these systems from normal data handling systems which deal with lower volumes and throughput. The nature of the processing performed on LANDSAT data also differs from the processing performed in other applications. Special processing may include geometric warping of the imagery, radiometric correction, edge enhancement, and manual display interaction. Finally, the output products of these systems include annotated image films, and digital tapes of the imagery for specific users. The data volume and throughput, special processing, and special output products of LANDSAT data all press for unique solutions not found in other data processing systems.

Due to the high throughput and variety of special processing to be performed on the data, a pipelined design for the system is frequently the best choice. With a pipelined system, data from one scene may be read into the system while data from another scene is having special processing performed, and yet another scene is being output to film. Pipelining here results in maximizing system resource utilization and throughput while minimizing the total amount of hardware required. It is thus an efficient, high throughput, and cost effective design. Pipelining at a low level may mean the use of pipelined signal processors or microprocessor hardware. Pipelining at a high level involves the use of several general purpose computers, each of which is dedicated to performing a processing segment in the pipeline flow, in parallel with the other computers. What level of pipelining is best depends on the specific application and the hardware available. Figure 1 shows the processing flow of a typical pipelined system.

The next section discusses the specifics of LANDSAT image systems requirements; the third section briefly discusses special processing performed on the data; the fourth section discusses key design considerations and suggested solutions; and the last section summarizes the key points.

SPECIFIC LANDSAT IMAGE SYSTEM REQUIREMENTS

LANDSAT image processing system requirements are driven by the image sensors aboard the spacecraft.[1] For LANDSAT's 1, 2, there are two sensors: The Multispectral Scanner (MSS) and a set of Return Beam Vidicons (RBV). The vidicons have not been operational since early in the mission. On LANDSAT C there is an MSS and a pair of higher resolution RBV's. The MSS has 26 detectors arrayed to image four spectral bands with a resolution of 79 meters and a fifth band with a resolution of 237 meters. In geometrically correcting the MSS scenes, the images are oversampled so that each picture element (pixel) is 57 meters square. An MSS scene is 185 kilometers square, so that an output image is $4^1/_9$ bands of about 3300^2 pixels. A similar computation yields a LANDSAT C RBV scene of about 5300^2 pixels, but only one band. A complete MSS scene is imaged roughly every 30 seconds, and the sensor is used over one hour per day. Combined data from LANDSAT's 1, 2, and C totals about 200 MSS scenes and 160 RBV scenes per day. Thus, a typical system requirement is to process this data in a two-shift working day. Total data volume is about 14 billion bytes per day. Allowing for gaps, spacecraft telemetry data, and annotation data (added in later processing) on the high density tapes on which the data is typically recorded, the system must be able to process data at a continuous rate of about 500,000 bytes per second.

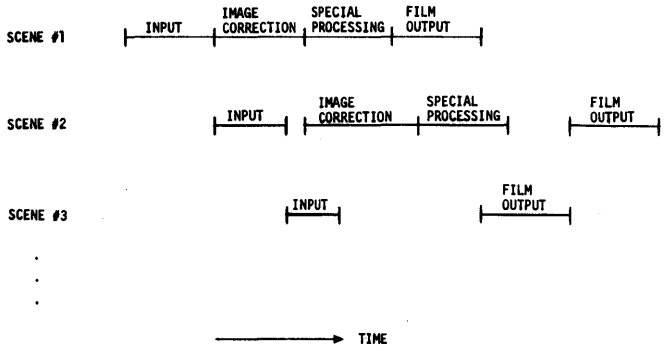

Figure 1—Processing flow of a typical pipelined Landsat image processing system

In addition to throughput requirements, LANDSAT image processing has accuracy requirements on the special geometric and radiometric correction processing performed on the data. Typical requirements are that the output pixels be accurate to within one gray level (eight bit data having 256 gray levels) after radiometric and geometric correction, and that the geometric correction algorithm used introduce no more than $^1/_{10}$ of a pixel spacing error (i.e., $^1/_{10}$ of 57 meters for the earlier LANDSAT's) in the location of the output pixels. Further, in the case of geometrically correcting the data to register it to other LANDSAT images or to control points on the earth with known locations, the position error of output pixels may be required to be less than ⅓ or ½ pixel spacing. These accuracy requirements impose stringent conditions on the algorithms used, more than on the system design. However, the overall system design may well be impacted by the increased complexity and computation time of the sophisticated algorithms necessary to meet the accuracy requirements.

Reliability requirements for this type of system cannot be overlooked in the system design. System availability requirements of 85-90 percent are typical. Hardware redundancy, switchable peripherals, hot spares, and modular replacement of hardware components at the board level are all potential methods for meeting the reliability requirements and must be considered in the selection of a system design. Software reliability is also important. Detailed fail-safe error checking by the software modules, top-down design, and structured programming can and do help to insure reliable software, and are considered in the design and development of the system.

Although requirements on accuracy, reliability, special processing, etc., are important, the throughput requirement remains the most critical in selecting a system design. How these requirements determine the key issues in the system design will be discussed in the fourth section.

SPECIAL PROCESSING

The nature of LANDSAT imagery frequently requires special processing on the image data. This section briefly discusses some of the special processing, including geometric warping, radiometric correction, image enhancement, and format conversion of the input data. Although not all of these processes are required for every system, they are typical of the kinds of processing done on LANDSAT data and frequently drive aspects of the system design.

Geometric correction

The characteristics of the spacecraft, earth, and imaging sensor combine to distort the true ground data into the raw image data received from the spacecraft. This raw data must be corrected to show the true ground picture. The effects of earth rotation, spacecraft position and attitude, sensor scanning nonlinearities, earth curvature, and time delay between adjacent detector's exposures must all be removed by the geometric correction processing. In addition, the output products are frequently required to be in one of several map projections, the most common being the Universal Transverse Mercator (UTM[2]). Finally, the image data may be required to be registered to an earlier scene or to ground control points of known location. These effects are also allowed for in the geometric correction processing.

The geometric correction processing may proceed in two stages (which may be two segments of the pipeline). The first is the generation of a set of values at a grid of regularly spaced locations throughout the corrected image. The values specify the location of the corresponding pixels in the input, uncorrected image. The accuracy requirement drives the number of grid points, which in turn determines the computation and storage load for this portion of the processing. This grid is generated from the equations for the distortion effects mentioned above, the most significant being the spacecraft attitude and the map projection. The equations are complicated and their computation time must be carefully estimated.

Once the grid of locations is determined, the warping itself must be performed. Each pixel of the output image is located by interpolation from the grid of input locations in the input image to a fractional pixel location. The output pixel value is then interpolated from the values of its input pixel neighbors.

The complexity of the warping algorithm and its parametric nature generally preclude its implementation purely in hardware, but the right choice of a hardware-software mix is not always obvious. The generation of the grid of location values in the first stage of the geometric correction involves computation of complex equations and is usually done in a general purpose computer. The nature of these computations, however, does impact the computer selection.

Radiometric correction and image enhancement

For the MSS sensor (and the TM sensor to be on LANDSAT D) there are multiple detectors with different characteristics. Therefore, different detectors will give different outputs for the same input radiances. Removing the detector

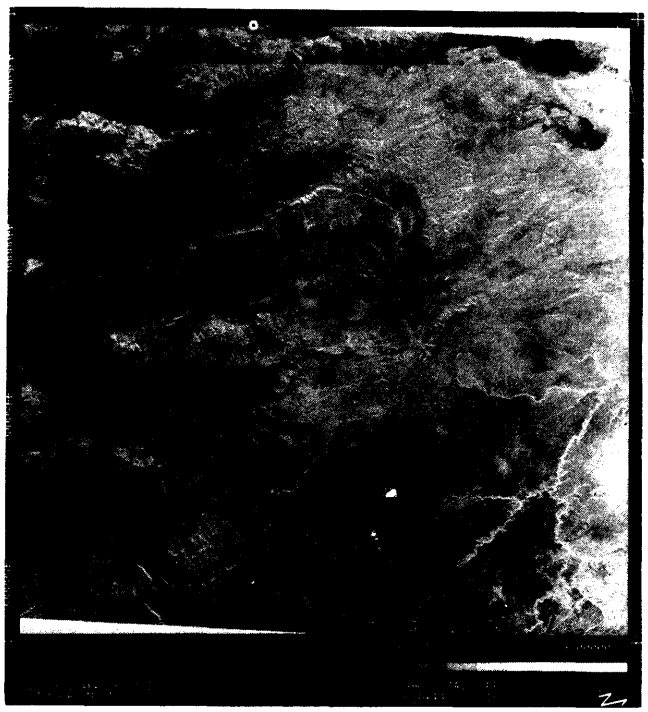
specific errors in the pixel values is known as radiometric correction. This may be done by constructing a table for each detector which maps the pixel values received from the spacecraft into radiometrically correct values. Thus, for LANDSAT's 1, 2, and C there would be 26 tables of 64 elements each (since the data as received is 6 bits per pixel). As with geometric correction, this proceeds in two stages (which again, may be separate segments of the pipline). The first stage is the construction of the detector-specific tables themselves, and the second is the mapping of the pixels through the tables. Construction of the tables may require obtaining statistics about the image data in the form of mean and variance or histograms of the pixel values or calibration data in order to remove image striping caused by the differences between detectors. In a general purpose computer, computation of these statistics requires several microseconds per pixel; hence, special purpose hardware or firmware is frequently dictated by the requirement to construct these tables.

Once the tables are constructed, the pixels must be mapped through the tables to generate the radiometrically corrected values. Since this again requires handling each pixel, special purpose hardware may be the solution to mapping the pixels at the required throughput.

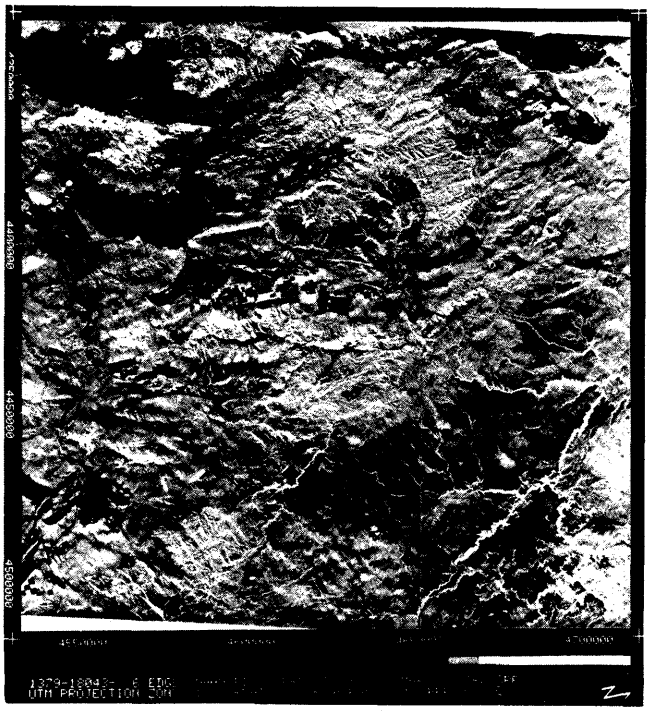
Image enhancement may involve filtering the input (corrected or uncorrected) image to enhance edges, or remove haze or contrast stretching the image so that scenes of low contrast look better visually. These processes may take advantage of the scene statistics gathered at an earlier stage of the pipeline. Depending on the complexity of the algorithms used, special purpose hardware or firmware may be used, but again, normally a general purpose computer lacks sufficient speed to handle these operations. Figure 2 shows a corrected unenhanced image compared to the same image after edge enhancement.

Format conversion

LANDSAT image data as received from the satellite is interleaved by detector in a formal called "band-interleaved-by-pixel" (BIP), i.e., one pixel is received from each detector before the second pixel is received from each detector. Since an image line is formed by one detector as it scans the earth, in order to reform the image into image lines, the data format must be converted first into lines (band-interleaved-by-line or BIL) and finally into band-sequential (BSQ) where all lines of an MSS (or TM) spectral band are consecutive. Converting from BIP to BIL again involves handling each pixel, but only moving it from one location to another. Thus, specially addressable memories or computer controlled direct memory access devices (DMA's) may be the solution here. For 26 detectors of 2300 pixels per input line, a memory of 60,000 bytes would be required—quite reasonable for modern minicomputers. Conversion from BIL to BSQ, however, could require a memory large enough to hold an entire scene (31 million bytes for the earlier LANDSAT's) unless enough devices were available in the next pipeline segment to handle all bands simultaneously. Thus, a mass storage device such as a disk is usually needed



UNENHANCED LANDSAT SCENE



EDGE-ENHANCED LANDSAT SCENE

Figure 2

here. Formatting this storage device so that image data is written on in BIL and later read off in BSQ, both at the required data rates, is a nontrivial task. Disk formatting will be discussed in more detail in the next section.

The special processing described in this section often necessitates special purpose hardware or firmware for handling the individual pixels. Even where pixels are not handled directly, the algorithms involved may impact hardware selection. The next section discusses further these and other key design issues.

KEY DESIGN ISSUES

The requirements of throughput, accuracy, reliability, economics, and special processing described above, force the selection of a system design. This is not to say that there is only one solution to these problems, but that there are certain key design issues which must be dealt with. Some of these, such as the choice of special hardware and memory sizing have been mentioned above. Other issues are the selection of general purpose computers, the need for a process control scheduler to handle the pipeline flow, efficient use of mass storage devices, and software development methodology. Obviously all of these cannot be discussed in depth here due to lack of space; however, this section looks briefly at each issue, showing the problem, and suggesting a method or methods for its solution.

System loading considerations

The throughput requirement of hundreds of kilobytes per second frequently means many transfers per second through a general purpose computer's memory, perhaps several times the overall throughput rate. For example, suppose the system of Figure 1 were to be implemented on one general purpose computer. The transfers shown in Figure 3 may then be executed for each scene. Although the pipeline segments' processing occurs sequentially for a given scene, normally the pipeline will be kept full and all of these segments will be executing on different scenes simultaneously.

In this example, ten transfers to and from memory are executed per pixel. At a data rate of, say 700,000 bytes per second on the average, this means an average data rate of

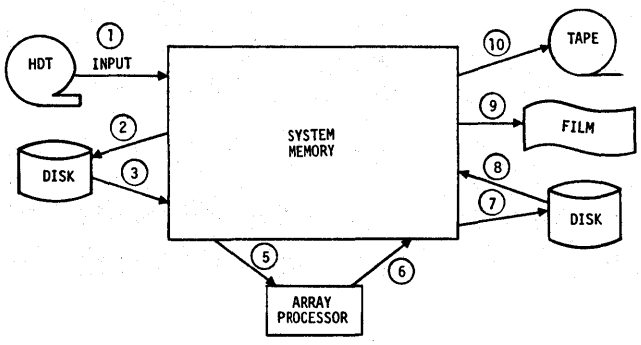


Figure 3—Memory transfers in a pipelined system

7 million bytes per second. In practice, the actual peak data rate may be substantially higher than this. For example, although the high density tape (HDT), film generator, and array processor transfer at a fairly constant rate, the disk and tape transfers occur much faster while actually performing the record transfers than the average rate which includes inter-record gaps. Thus, the transfers 2, 3, 7, 8, and 10 may reach 1.2 million bytes per second each. This gives a total peak rate of 9.5 million bytes per second (or actually more since the CPU normally fetches instructions and data from this memory as well). Thus, system loading considerations may force the division of the flow into specific pipeline segments independent of the allocation of processing functions to segments. This requires a memory with an access time of about 100 nanoseconds per byte. Furthermore, in the case of many minicomputers (e.g., PDP-11, ECLIPSE, SEL 32, etc.), the data must travel via one memory bus; hence, this bus must be capable of sustaining the data rates calculated here.

One potential solution to this problem is the selection of a computer with several data busses or even high speed I/O channels dedicated to transfers between certain peripherals and memory. Still another solution might be the selection of several banks of memory, each with its own memory controller to give independent parallel access to each bank. With this solution, (assuming the memory bus or busses could handle the data rate) buffers could be placed in different memory banks to reduce the load on each individual bank to an acceptable level. A variation on this solution would be to interleave the memory banks with a least-significant-bit addressing scheme to reduce the effective access time of the memory. This has a particular advantage here since most transfers are of image lines which transfer from successive locations in memory. A final solution might be to construct the process control software described later to preclude processes which strain the system's memory or bus capacity from running in parallel. If all of these potential solutions fail the analysis, more computers may be used, even to the ultimate extent of having one computer per pipeline segment. (Unfortunately, this may dictate still another computer to provide process control for the pipeline flow.)

A further problem occurs in considering the computational load on the computer's central processing unit (CPU). This is related directly to the software used by the system.

Current minicomputer operating systems, for example, have software overhead times of ½ millisecond per interrupt. If the system of Figure 3 receives an interrupt on completion of the transfer of every image line, there will be an interrupt about every 4 milliseconds for each of the ten transfers. This allows .4 msec for processing each interrupt, which may well be beyond the capacity of the system. Potential solutions to this are to get a new, faster operating system or to write device handlers which speed the interrupt processing or even trigger the start of the next transfer when the current one is complete. Another measure would be to generate an interrupt only after the transfer of several lines. Whether this is possible depends on the image data formats and the peripheral and computer hardware.

Hardware/software/firmware tradeoffs

The variety of special processing being performed on image data requires a mixture of general purpose computers and their software, firmware in the form of microprocessors or array processors, and special purpose hardware. In nearly all large scale, pipelined systems there will exist a need for a process controller. Due to the complexity of this scheduler and the need to control the various peripherals, a general purpose computer will normally form the heart of the system. This computer may also be well-suited for interacting with operators and users via displays or terminals. In addition, it may perform some complex, low throughput special processing such as the generation of the grid of geometric correction locations or the radiometric correction tables from the scene statistics described earlier.

However, a general purpose computer is not normally suited for processing that deals with pixels on an individual basis, due to a lack of the speed required by such processing. Thus, either special firmware of hardware must be employed. The choice of firmware or hardware depends primarily on the complexity of the processing and the throughput required. As an example, the more complex functions of geometric warping and edge enhancement would probably be done in firmware if the required throughput could be met, while the format conversion and contrast stretching could be done in hardware. The gathering of scene statistics and radiometric correction could be done in either hardware or firmware, depending on cost effectiveness. Very complex algorithms such as geometric correction could be done in commercially available array processors (such as Floating Point Systems AP-120B, Signal Processing Systems SPS-81, or CSP, Inc.'s MAP-300). If necessary to meet the throughput requirements, an image can be split into parallel streams, each passing through a separate array processor with the output being merged again (if the algorithm allows such a split). These array processors are sufficiently complex that configuring them with the proper memory and most suitable options raises design issues on its own.

The decision to use special hardware or firmware in various parts of the system may also force segmentation of the pipeline at specific points. This and cost-effectiveness considerations make this a key design issue.

Process control

One disadvantage of a pipeline system design is the need for a more complex process control program or scheduler. On a strictly sequential system resource conflicts do not usually occur since only one process is in progress at any time. Similarly, a totally parallel system in which all resources are duplicated does not normally give resource conflicts. However, in even a simple pipelined system such as that of Figure 1, resource conflicts do occur, and the scheduling of the pipeline processing segments must be done. In Figure 1, for example, several resource conflicts are apparent: Scene 2 cannot begin its image corrections immediately after input because the array processor required for it is in use for Scene 1; similarly, conflicts arise in the case of the output film generation hardware. Other conflicts may arise not in the use of specific hardware, but in the total system load. If several special processing segments had the hardware to execute simultaneously, they might still exceed the load capacity of the system as far as memory or bus loads are concerned. Further, the scheduler may need to prevent other processes from executing concurrently because of conflicts in accessing shared data areas. In short, in a pipelined system a scheduler may be necessary to eliminate resource conflicts. (If the processing flow is static and the same for all scenes, the scheduler may be very simple or even nonexistent in that the individual pipeline segments tell each other when they are complete or available; but for more complex systems, the scheduler may become quite involved.)

The main functions of a scheduler in this type of system are: to determine the processing flow for each scene, initiate processes, determine processing conflicts and resolve them, and to monitor the processes for termination. All processes can communicate with the scheduler to indicate termination or error conditions, and in general need not communicate directly with other processes. Other scheduler functions may include operator interaction to determine each scene's processing flow and to report error conditions. If the system runs out of resources, the scheduler may stop the flow altogether as the pipeline "backs up." For example, in Figure 1, if the film output generator fails, later scenes will be unable to complete their processing which means that they must be stored on mass storage devices. As these devices fill up, the image correction, special processing, and input segments have no place to store their data, so that finally input must stop. If the input is from tape, data may not be lost; however, if the input is directly from the satellite, data may be lost at the input end of the system. (The system designers could, of course, construct the scheduler so that data is not output to film, but is saved on tape, or other measures to prevent the loss of data.)

The internal design of a scheduler is beyond the scope of this paper, but a scheduler is one solution to the problem of process control, which is an important design consideration.

Use of mass storage devices

In order to keep the process running smoothly, it is frequently necessary to use mass storage devices such as disks as buffers between pipeline segments. Otherwise, lack of a needed resource for even a brief period may bring all processing to a halt as main memory buffers fill up rapidly. In addition, disks may be necessary to store image data written in one order to be read in another order. Since industry standard 80- and 300-million byte moving-head disks are commercially available, these are good choices for mass storage buffers. Several issues arise in using these disks efficiently.

The data formatting on the disk is a design tradeoff which must be made. Figure 4 shows a typical disk format for buffering MSS data. Each track of the disk is hardwired as

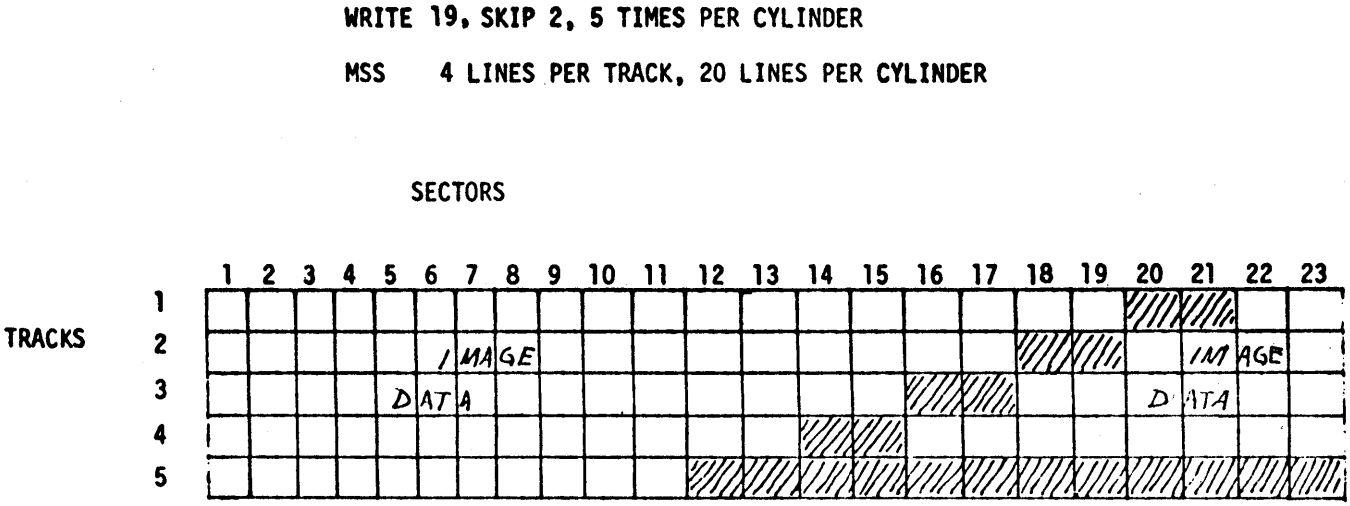

Figure 4—Typical disk format for MSS scene

23 sectors of 768 bytes each. There are 5 tracks per cylinder. There is no time penalty for disk accesses which change tracks within a cylinder, but there is a substantial penalty for switching cylinders which requires a movement of the read/write head. If each image line is 3500 bytes, then 4 lines will fit into 19 sectors. Since the disk rotates at 3600 rpm, it takes about 14 msec to read 4 lines of data. Then 2 sectors are skipped to allow about 1½ msec for software overhead before the next 4 lines are read. Twelve sectors are left empty at the end of the cylinder to allow time for the head movement to switch to the next cylinder. Thus, the reading of 20 image lines requires on the average of 5 disk revolutions. This gives a sustained throughput capacity of 840,000 bytes per second, which is in excess of the required 700,000. Hence, there is some spare time available for situations in which system loading prevents being able to read the next 4 lines within 1½ msec after the last 4 are completed.

Because of the high speed involved, there is no time available for retries of disk reads or writes in the event of parity errors. However, with modern disks, the parity error rate is so low that the expected number of errors affects the image significantly. Thus, parity checking need not be performed. If parity checking is performed, retries should not be made, and a system alarm should be generated only if the error rate becomes too high. Parity checking, formatting, high speed software device handlers, and reliability are some of the key design issues in using mass storage devices efficiently.

Software methodology

In designing high throughput, reliable systems, the hardware design is not the only consideration. The software design and implementation for general purpose computers and for microprogrammable microprocessors and array processors is also extremely important. Software design problems arise in attaining the high throughput required, and in developing reliable software which is free of timing-dependent bugs. Further, as research progresses, new algorithms are developed, and new user needs become apparent, the requirements for LANDSAT image processing change. Therefore, the software should be modular enough to permit easy modification or inclusion of new processing. The scheduler should be sufficiently flexible that addition of new segments in the pipeline does not cause major redesign or recoding of the scheduler.

One means of attaining the high throughput required in array processors is to actually code and benchmark the critical high speed inner loops of the algorithms in the design phase, rather than waiting until the coding phase. This way, a good estimate of the actual throughput of these processing segments can be obtained early.

In developing reliable software, the top-down design process is very valuable. Software tools which aid this process are very beneficial in easily developing a top-level design and expanding it to deeper and deeper levels until the software can be coded directly from the design document. If done properly, the detailed design document also becomes the main software documentation. Two good tools for software design are structured flow charts and Program Design Language (PDL). Impressive cost savings in software development through the use of PDL have been cited.[3] Software design tools aimed at aiding pipelined systems design would be of great benefit. These tools would facilitate checking for deadlocks, use of common data areas, etc. Unfortunately, we know of no such tools available at the present time.

Structured programming is also of benefit in developing software for pipelined systems, and especially for modifying it in the event of changing requirements. In using FORTRAN for the software development, the use of a structured FORTRAN preprocessor can be of benefit, especially when the design was done in a top-down structured fashion.

SUMMARY

This paper has shown how the requirements of large scale LANDSAT image processing systems force the consideration of certain key design issues. The main requirements of the system are the large data volume and high throughput, reliability, need for special processing, and accuracy. Processing peculiar to the LANDSAT systems includes geometric and radiometric correction, image enhancement, and high speed data reformatting. A pipelined design is often a natural choice for these systems. Although there are many issues to be tackled in the design of such systems, only the most important ones have been addressed here. These include system loading considerations in selecting computer hardware; the decision on where to use special hardware or array processors; the need for process control to schedule the pipeline's segments; the efficient use of mass storage devices; and software tools and techniques.

AOIPS—An interactive image processing system

by P. A. BRACKEN, J. T. DALTON, J. J. QUANN and J. B. BILLINGSLEY
Goddard Space Flight Center
Greenbelt, Maryland

INTRODUCTION

Prior to the fall of 1976, computer aided data analysis support for applications investigations at NASA's Goddard Space Flight Center was conducted on large scale IBM System/360 computers in a batch oriented environment without the aid of image display units. As a result, even simple image processing operations took from days to weeks to produce desired results and required numerous manual, errorprone steps to produce the desired end product. In addition, operations which required a high degree of human interaction with the image data during the information extraction process (e.g., derivation of wind fields from cloud motions in a time-lapsed series of satellite images) were not practical in the batch environment.

The Atmospheric and Oceanographic Information Processing System (AOIPS) was developed to help applications investigators perform required interactive image data analysis processes rapidly and to eliminate the inefficiencies and problems encountered with the batch operation discussed above. The major AOIPS hardware components are shown in Figure 1.

Initial hardware deliveries occurred in September 1975 and consisted of a PDP-11/70 computer and peripherals and a modified General Electric Company Image 100 system, which included an interactive image analysis terminal and a PDP-11/45 computer. The Image 100 system was designated as AOIPS Image Analysis Terminal 1 (IATl). Two additional image analysis terminals, designed at Goddard Space Flight Center and implemented by Hazeltine Corporation, were delivered in May of 1976 and May of 1977. These terminals have been designated as AOIPS Image Analysis Terminals 2 (IAT2) and 3 (IAT3).

In parallel with the hardware development activities, a series of applications software packages was developed to implement specific information extraction processes to meet established image data analysis requirements. AOIPS operations during 1976 and 1977 have demonstrated its capability to solve many operational image processing problems, and has greatly extended an investigator's ability to perform image information extraction operations in a flexible, efficient manner.

SYSTEM OVERVIEW

The heart of the AOIPS is a Digital Equipment Corporation PDP-11/70 computer to which three magnetic tape drives, three disk units and other standard peripherals are attached. The image analysis terminals interfaced to the PDP-11/70 central processing unit provide for user interaction in the extraction of information from digital images.

Terminal 1 (see Figure 1) provides capabilities for time lapsed display of image data and for output of video signals to a video disk storage unit. Control of this terminal is provided by its own PDP-11/45 computer. Digital images on computer-compatible tapes are loaded into a 5-channel solid-state refresh memory from two 800/1600 bit-per-inch (bpi), 9-track tape drives. The contents of the refresh memory channels are input to analysis console digital logic for ratioing, scaling, and limit comparison; the output of these operations is displayed on both color and black and white TV monitors. Using the analysis console logic, image enhancement and multispectral classification analyses are performed under control of software on the PDP-11/45. Terminal 1 is interfaced to the AOIPS PDP-11/70 computer through a dual port, shared-disk unit capable of formatted storage of 88 megabytes (8 bits per byte) of data.

Terminals 2 (see Figure 1) and 3 are identical and are interfaced directly to the PDP-11/70 through a high-speed direct memory access interface for control signals. Using the three 800/1600 bpi, 9-track tape drives of the PDP-11/70 and the High Density Digital Tape (HDDT) unit, magnetic tapes are loaded into the 5-channel solid-state refresh memories of Terminals 2 and 3. Images may also be loaded from disk or from maps or photographs digitized by a video input scanner interfaced to the terminal. The contents of the refresh memory channels pass through lookup tables, digital matrix switches, and other image manipulation logic in the console. Image enhancement and parameter extraction analyses are performed under control of software on the PDP-11/70.

The video disk, which is connected to all three terminals through a video switching system, has the capacity to store up to 600 TV-sized images. Using the switching system, images may be recorded from or played back to the TV monitors of any of the terminals.

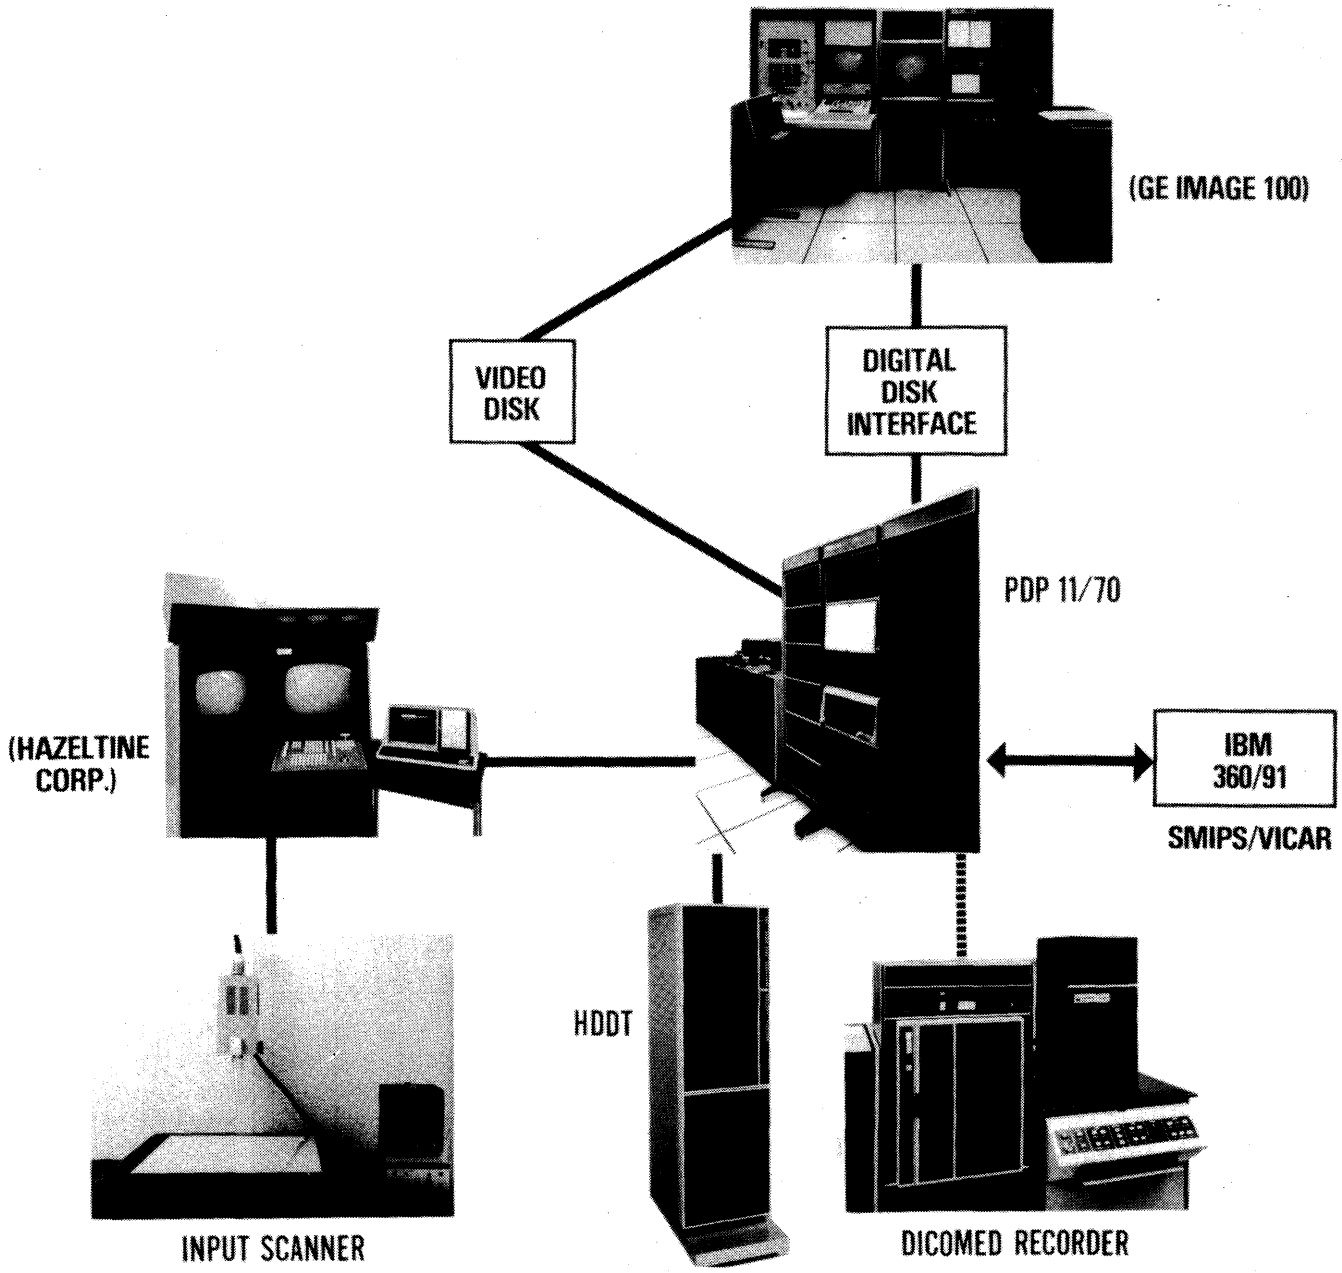

Figure 1—Atmospheric and Oceanographic Information Processing System—AOIPS

The AOIPS PDP-11/70 computer communicates with a remotely located IBM S/360/91 computer through a 4800-bit-per-second telephone line connection.

A Dicomed Image Recorder (shown in Figure 1) functions as an off-line device to convert information recorded on computer-compatible tapes (CCTs) into photo products of image and related ancillary data.

AOIPS utilizes computer-compatible tapes of multispectral digital image data generated by satellite and aircraft image scanners as well as related digital ancillary data required to perform specific information extraction operations. In the future, high density digital tapes will provide the primary input medium for meteorological satellite data. The system provides capabilities for inputting digital data in several formats; performing standard image preprocessing operations including image registration, geometric correction, scanner distortion correction, and zooming and reducing subimages; executing image processing functions including level slicing, contrast enhancement, pseudo color and false color combinations, band ratioing, linear combinations, and histogram generation; performing analytical operations including multispectral classification and special applications

analyses; and displaying and generating hard copy output of single images overlayed with data plots, contours and various forms of image annotation.

USER—SYSTEM INTERFACE

There are two types of users supported on the AOIPS: (1) applications investigators who specify and perform information extraction operations on the system for specific applications, and (2) programmer/analysts who develop new systems and applications software. Applications investigators interface with the system by requesting execution of various system processes from menus presented on interactive cathode ray tube display units. Adopting the menu approach as the primary user interface has simplified training problems and virtually eliminated the requirement for a user to learn a new computer language. A discipline oriented user is led through the entire sequence of possible processing options available by a series of prompts and a layered structure of menus which require simple responses.

Typical user data analysis sessions last for about two hours. During a session, the user has several options available to him for displaying intermediate results, generating output products, and defining sequences of processing operations. Operations may be terminated with the capability to restart in subsequent analysis sessions on the system. The user has the option to start and to save/restart analysis sessions using magnetic tape and/or disk units. The disk operations provide a significant speed advantage over the magnetic tape operations.

The second type of system user, the programmer/analyst, typically utilizes operating system facilities and the operating system commands to code, compile, link, edit, and checkout the software being developed. The programmer/analyst does not usually interact in the menu environment until the final checkout and integration phase in the development of a new applications software package.

Capabilities are being developed to allow users to define and automatically execute a sequence of menu processing steps in one interactive operation by specifying a command string which is used to initiate and control the desired processing sequence.

HARDWARE DESCRIPTION

A more detailed version of the AOIPS hardware block diagram is presented in Figure 2.

Figure 2 indicates which devices are interfaced to the PDP-11/70 through high-speed direct memory access (DMA) channels and which devices are interfaced through the UNIBUS input/output channel. The interface between IAT2, IAT3, and the PDP-11/70 is a dual interface in which all high-volume data transfers use a high-speed channel and all low data volume, control signal information transfers use a UNIBUS channel interface.

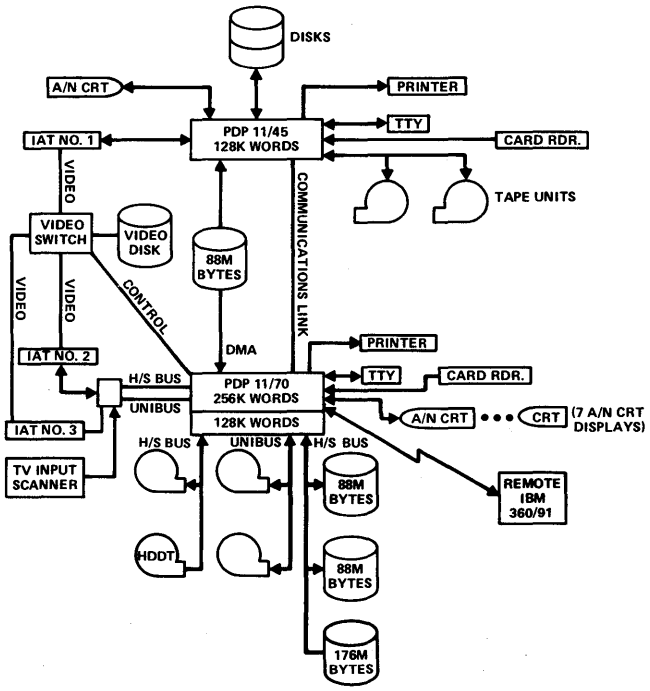

Figure 2—AOIPS configuration

Figure 2 indicates the functional interconnections of the video switching system incorporated into the AOIPS configuration. All video signals from the three Image Analysis Terminals are routed to the video switching unit. The video switch itself is under computer control by the PDP-11/70. By utilizing this control link, any video signal within the system can be routed to the video disk for storage, to video recorders, and to a large Advent TV projection screen or other TV monitors interfaced to the switching unit. It is also possible to display video which originates in any one of the terminals on any other terminal. This capability is utilized for applications requiring simultaneous use of multiple image analysis terminals during information extraction operations. In addition, the video disk unit is used to store sequences of up to 600 TV sized (512 lines by 512 picture elements per line) images for time-lapsed playback through the system.

Figure 2 also indicates the 9600-bit-per-second back-to-back DL11 teletype interface link between the PDP-11/45 and 11/70 computers. This link is used primarily to communicate synchronization and control information between the two central processing units during shared disk operations.

The shared disk unit is used to transfer data between the image analysis terminals, to transfer results of a TV input scanner operation to Terminal 1, and to provide a medium for sharing peripheral equipment between the PDP-11/70 and 11/45 computers.

The TV input scanner scans image data into any user selected channel of one of the refresh memories of either Terminal 2 or 3. The contents of this refresh channel can be rerouted to any storage device or any image display unit in the system.

One of the 88-megabyte disk units shown in Figure 2 is dedicated to Terminal 2 users for save/restart operations, the second 88-megabyte disk is dedicated to Terminal 3 users, and the 176-megabyte disk is used to support system functions and software development activities. In addition, users on either of the PDP-11/70 Image Analysis Terminals will be able to select from one to ten refresh memory channels for their image processing operations.

The PDP-11/70-S/360/91 computer link shown in Figure 2 consists of a 4800-bit-per-second remote job entry communications link. This communications path will be upgraded to a 50-kilobit-per-second link in early 1978. It will provide capabilities for AOIPS users to perform large computational jobs on the high-speed IBM S/360/91 computer and to display and analyze the results of these computations on the AOIPS. The kinds of information extraction tasks requiring this support include multispectral classification of large subimages or full images and a variety of weather, climate, and earth resources modeling activities.

Experience in interfacing various kinds of equipment to the AOIPS PDP-11/70 computer indicates that from 50 percent to 70 percent of the total theoretical system input/output bandwidth (5.8 megabytes per second) can be achieved in the current configuration. Figure 3 is an estimate of the system input/output bandwidth achievable for various levels of system activity within the current AOIPS configuration.

Experience with the AOIPS 88-megabyte disk units indicates that 60 percent to 70 percent of the theoretical input/output bandwidth (675,8400 bytes per second) can be achieved in the current system configuration.

The addition of Terminal 3 resulted in approximately 80 percent of the achievable system bandwidth being used during planned peak load conditions. For this reason, no additional image analysis terminals will be attached to the existing AOIPS PDP-11/70 computer in the future.

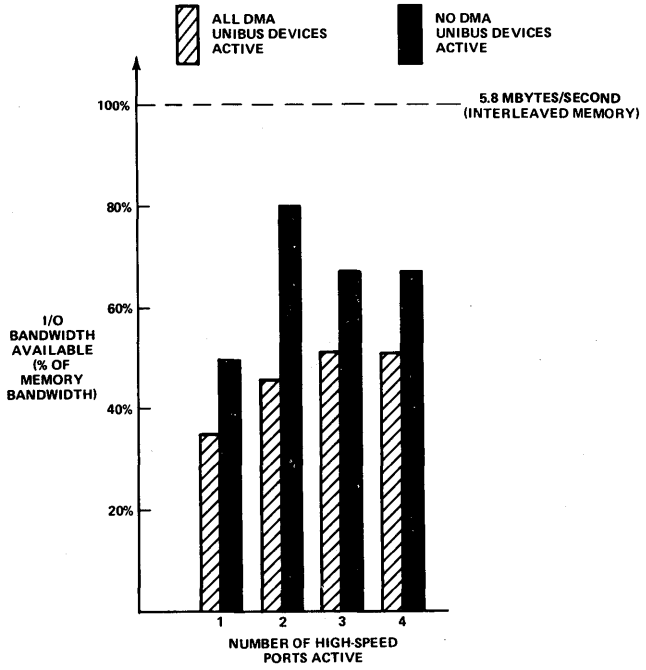

Figure 3—AOIPS I/O bandwidth vs. system activity

Further information about the alternative hardware configurations and peak load conditions considered for AOIPS is presented in Reference 1. Additional information about the existing system capabilities and a complete listing/description of the system hardware and software is contained in Reference 2.

Image analysis Terminal 1

The hardware configuration for the AOIPS PDP-11/45 Terminal 1 subsystem is shown in Figure 4.

The Image 100 Image Analyzer Console contains special-purpose hardware which operates in conjunction with applications software to rapidly analyze multispectral image data.

The Image 100 console processing hardware is designed to process image data, particularly Landsat satellite data, and to perform a parallelepiped classification of multispectral data. The user interacts with the Image Analyzer Console to execute processing functions, to select training sites, and to manipulate themes generated as a result of a classification operation.

The Image 100 Image Analyzer Console performs the following functions in hardware:

- Image Correlation—Two images are displayed alternately in a flicker presentation for image comparison and registration operations.
- Image Scaling—Thumbwheel switches are used to perform individual amplitude scaling shifts on each refresh memory channel.
- Ratioing—Images stored in the refresh memories may be ratioed and the results of the ratio operation displayed on the TV display unit.
- Image Transformation—General purpose transformation hardware exists to rotate feature axes in spectral space.
- Spectral Signature Acquisition—Hardware exists to compile histograms (frequency versus digital gray level) of areas specified by the user in each refresh memory channel. From these histograms, upper and lower gray level limits are obtained to serve as a four-dimensional parallelepiped describing the spectral signature of the specified area.
- Cursor Control—A multimode hardware cursor is sized and positioned by joystick control for the definition and selection of subimage areas.
- Image Analyzer—Special-purpose digital logic operates under software control to store and test for upper and lower gray level limits in each refresh memory channel. Parallelepiped signature regions are synthesized into decision boundaries by the Image Analyzer for classification operations.
- Theme Synthesizer—Circuitry is included in the Image Analyzer to combine themes using logical AND, OR, Exclusive OR, and theme inversion operations.

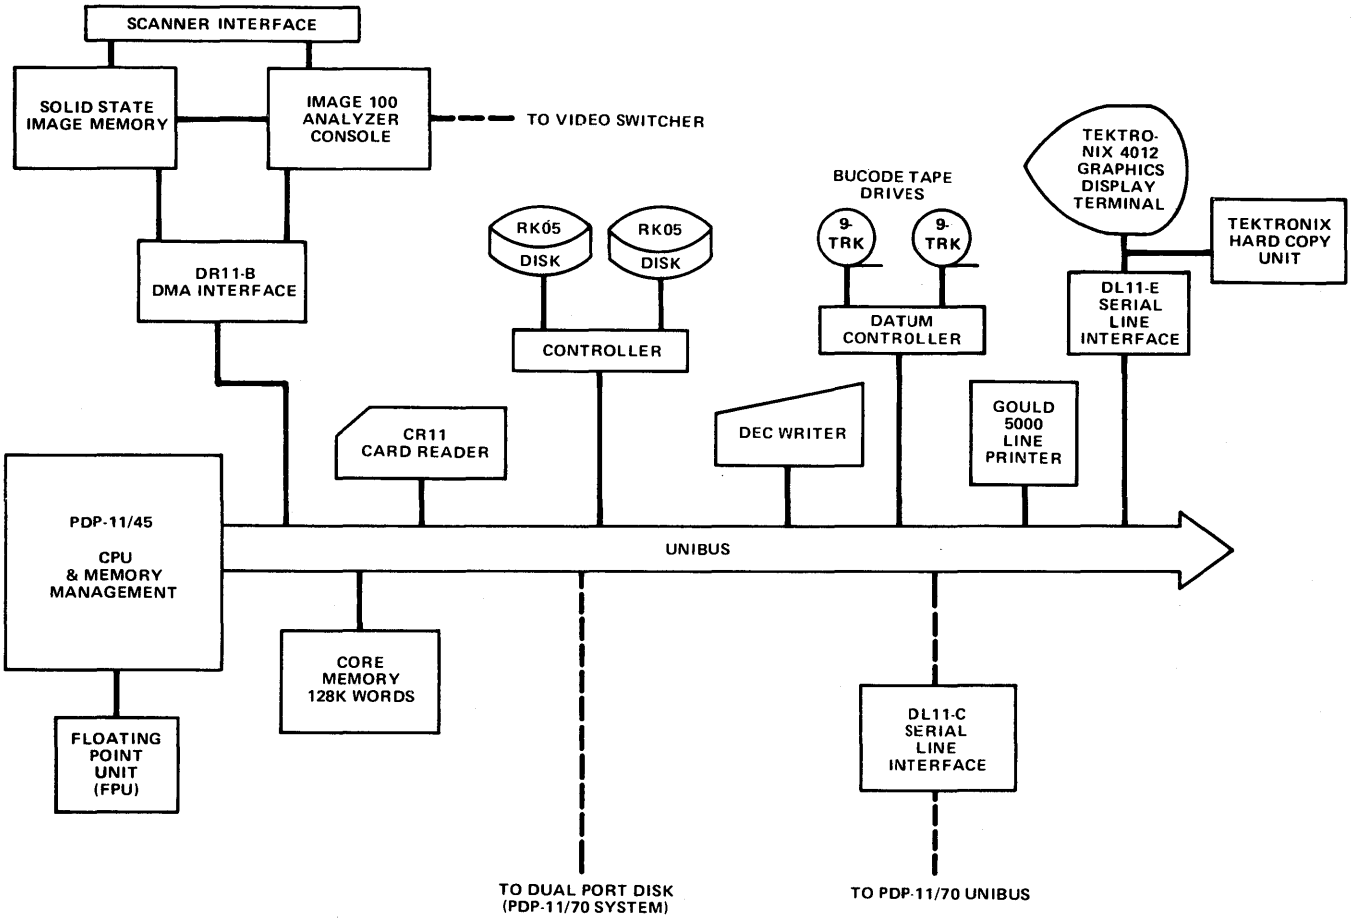

Figure 4—AOIPS PDP-11/45—Terminal 1 configuration

- Color TV Display—A color TV display provides capabilities to display image data, the results of various processing functions and thematic results of classification operations. Software also exists to generate split screen presentations.

Terminal 1 also incorporates hardware modifications for transferring video signals to and from the AOIPS video switching unit.

The two RK05 disk units shown in Figure 4 are used primarily for program storage. The dual ported RP04 disk shared with the PDP-11/70 is used for data storage and for transferring data to and from peripherals attached to the PDP-11/70 computer. The back-to-back DL11-C Serial Line Interfaces shown in Figure 4 (and in Figure 5) are used by the shared disk software to transmit synchronization and control information between the PDP-11/45 and 11/70 processors.

Image analysis Terminals 2 and 3

The hardware configuration for the AOIPS PDP-11/70—Terminal 2/3 subsystem is delineated in Figure 5. Terminals 2 and 3 provide significant image processing capabilities that are not available in second generation terminals currently being marketed. Figure 1 depicts the terminal analyzer console as seen by the terminal user. The terminal was designed to register, process, display, and analyze digital image data for a wide variety of applications. It rapidly performs many image manipulation functions in special purpose hardware which is set up and controlled by the AOIPS PDP-11/70 computer.

Computer control of the terminal hardware allows applications system designers to include hardware control functions in software designs and provides the capability to utilize the full power of the terminal to meet image processing requirements in a highly flexible and responsive system environment.

Figure 6 presents a block diagram of Terminal 2 logic components. Noteworthy elements in Figure 6 include the hardware lookup tables, the digital matrix switches, a light pen, the programmable function button array, and the five solid state refresh memories. Refresh memory 5 of both terminals is randomly addressable to the bit, byte (8 bits) or word (16 bits) level. Each of the refresh memories 1 through 4 are randomly addressable in groups of 16 words.

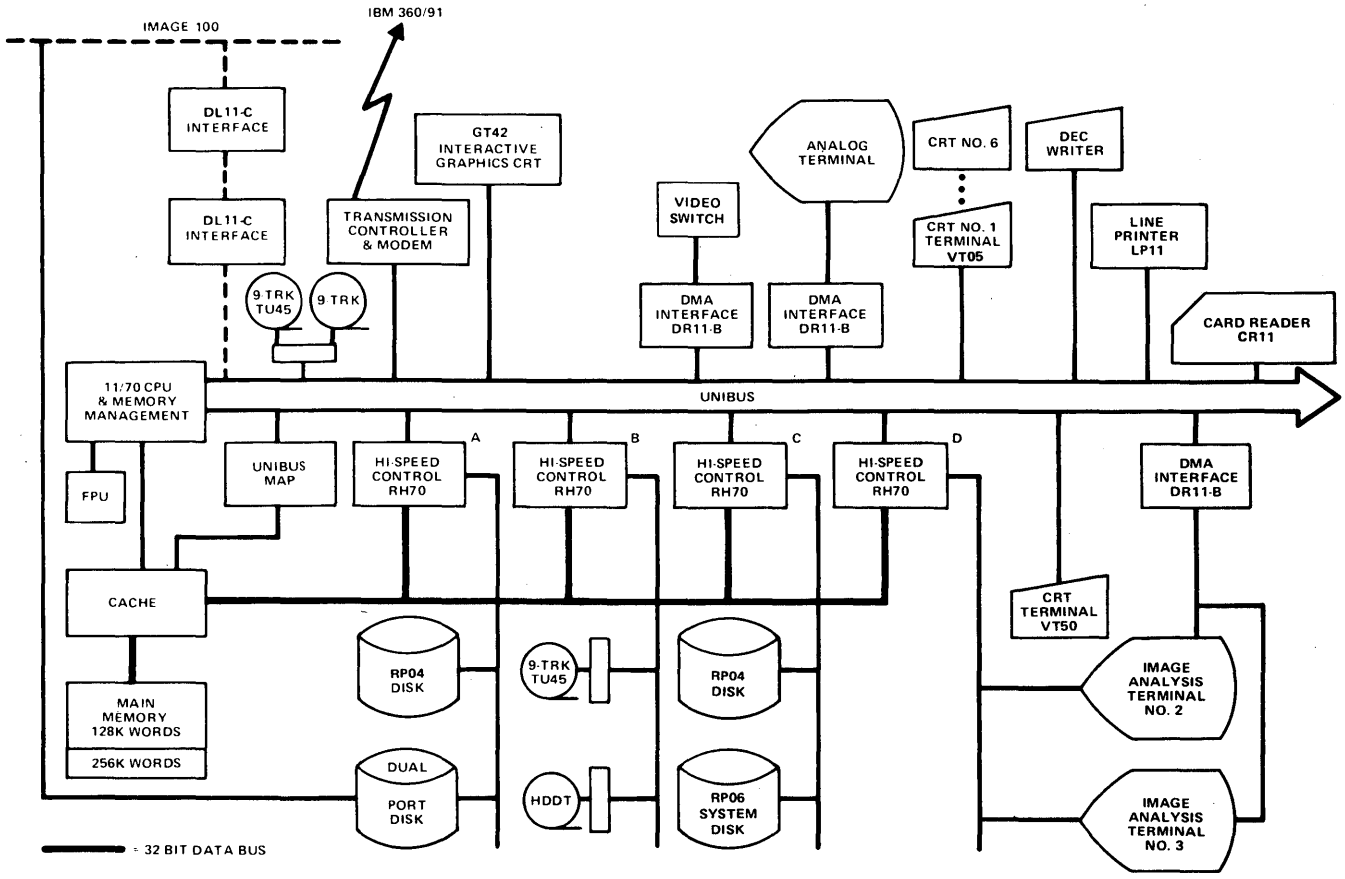

Figure 5—AOIPS PDP-11/70—Terminal 2 configuration

Terminals 2 and 3 provide hardware capabilities for:

- Image Display—The contents of each refresh memory channel are displayed on individual black and white TV monitors. Any refresh channel can also be displayed on a high quality, twenty-one inch black and white monitor. False color displays combining any three refresh channels as well as pseudo color presentations of individual channels are displayed on a nineteen inch color TV monitor.
- Time Lapse Display—The terminals provide time lapsed display of up to ten TV sized images in a movie loop presentation.
- Image Correlation—A hardware fade control is used for simultaneous display of two images during image registration and correlation operations.
- Image Translation—Hardware capability is provided for X-Y translation of images within the refresh memories under joystick control for rapid image registration.
- Graphic Overlay—Graphic overlay of image data sets with a cursor, a rectangle, randomly shaped polygons, plots and data contours is provided.
- Joystick Control—Computer control of a hardware joystick is provided to select the size and position of graphic overlays including a multimode hardware cursor, to select single picture elements or entire sub-images, to control the direction and speed of image scrolling operations, to fly one image over another for rapid image registration, and to control the speed of dynamic color table lookup 'rolling' operations.
- Image Scrolling—Flight line display of image data sets is provided under joystick control.
- Split Screen Displays—Simultaneous multiple image split screen displays are provided.
- Lookup Tables—Hardware lookup tables are used for dynamic color rolling for continuous changing of gray level—color assignments, radiometric correction, parallelepiped classification (up to 9 spectral channels and 8 classes), level slicing and contrast stretching. Each of these operations is performed within $^1/_{30}$th of a second.
- Light Pen Detection—A light pen is used to outline and select irregularly shaped image areas for processing.
- Signature Acquisition—A series of hardware registers is used to rapidly generate gray level histograms of image areas for spectral signature acquisition.
- Theme Synthesis—Thematic information is synthesized using the lookup tables and matrix switches.
- Image Combination—Images in individual refresh channels can be combined and re-recorded into the refresh memory.

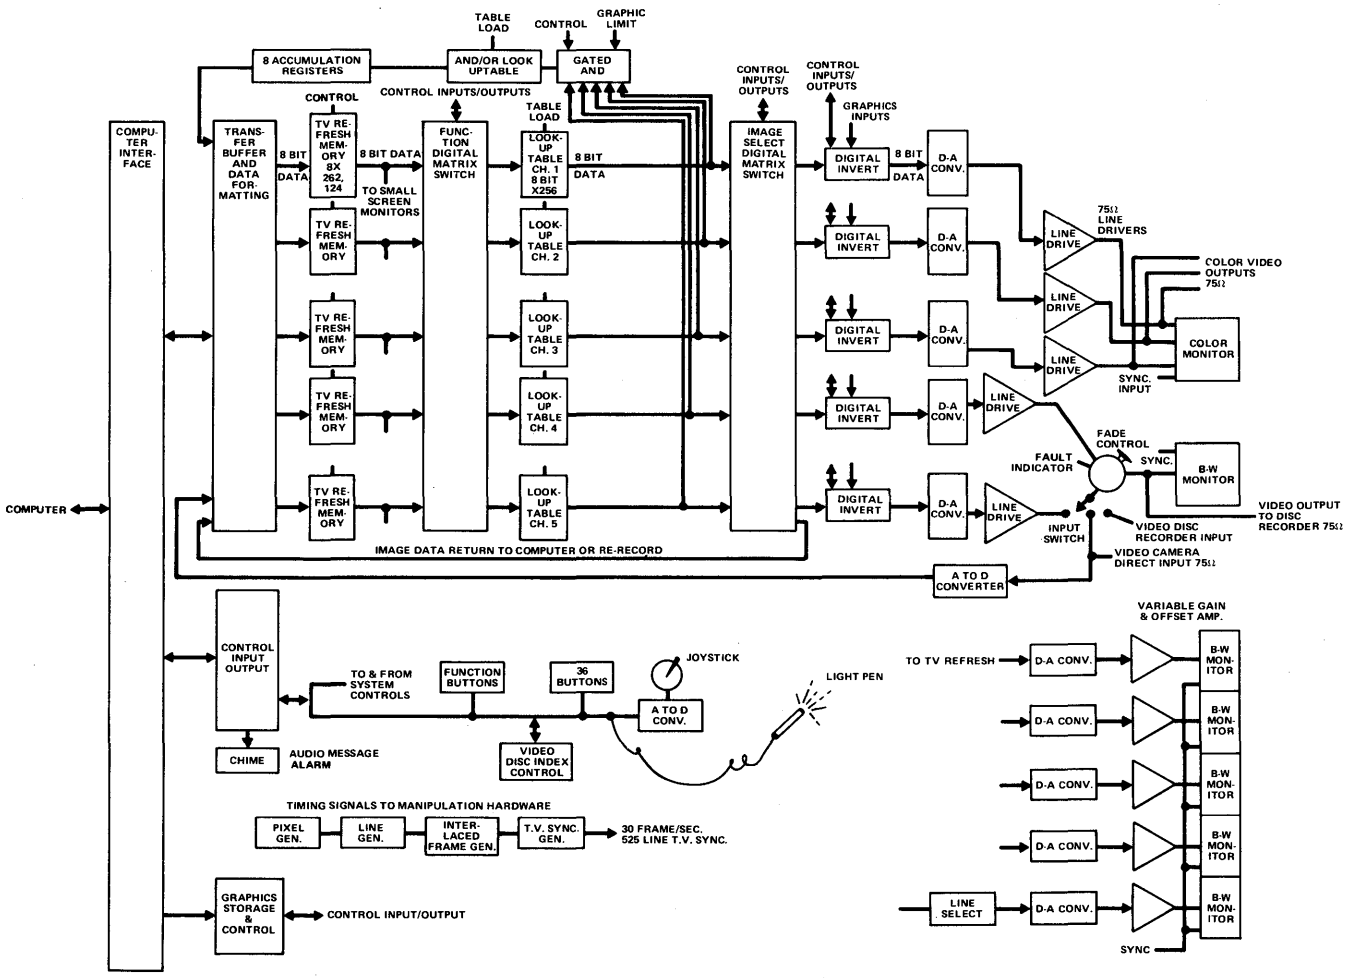

Figure 6—Terminal 2/3 logic diagram

- Scanner Input—A TV input scanner is utilized to digitize information and store it in any refresh memory channel.
- Video Transfers—All video signals can be transferred to or from the AOIPS video switching unit and the video disk unit.
- Direct Data Readout—Manipulated images and picture elements within a boundary may be transferred back to the PDP-11/70 computer for further analysis.
- Processing Control—A CRT keyboard display unit and an array of programmable function buttons are used to control the sequence of processing operations and to create new analysis scenarios.

The terminal hardware performs computer controlled image manipulation functions in real time while the user observes each operation. Image transfers from the computer to the terminal refresh memories occur at a rate of two images per second from disk units and at five images per second from the AOIPS High Density Digital Tape unit. Terminals 2 and 3 are fully interconnected to share resources thus allowing a user on either terminal to use up to 10 refresh memories to support data analysis operations.

Terminal 2 is used primarily for meteorological applications in support of severe storms research investigations. Terminal 3 is dedicated to information extraction technique development in support of severe storm forecasting investigations utilizing data from multiple satellite sensors and related surface truth measurements.

High Density Digital Tape (HDDT) subsystem

The HDDT unit is interfaced to the AOIPS PDP-11/70 and consists of a Honeywell Model 96 instrumentation tape recorder, a Martin-Marietta Data Converter, a Serial Controller Interface (SCI) fabricated by General Electric Company, and a DEC Model DR-70 Massbuss Adapter to operate the recorder on the AOIPS system.

The recorder uses one-inch wide magnetic tapes to record data on 10 of 14 data tracks. The remaining four tracks are

utilized for time tagging, audio, and two spares. The unit operates with data transfer rates of up to 20 megabits per second with bit error rates of 1 in 10^6, and provides for storage of approximately 1.4×10^{10} bits per 7200-foot reel of tape at a packing density of 20,250 bits per inch per data track.

Six playback speeds are provided, ranging from 120 inches per second to 3¾ inches per second. The unit will be operated at 7½ inches per second for playback of data into the AOIPS yielding an input data rate of approximately 1.5 megabits per second. A high-speed search capability is available at 120 inches per second; tape rewind occurs at 200 inches per second.

The Serial Controller Interface (SCI) provides the electronics needed to synchronize the serial input-output bit stream. The AOIPS SCI has been modified to subsample or average image data to allow selection of a portion of an image during data transfers to the AOIPS. This SCI capability provides options for obtaining subimages and reduced images from the full image data sets stored on high-density tapes.

SYSTEM SOFTWARE

Numerous software packages are available on AOIPS; some are geared to the specific requirements of an application and some are of a general support nature. Figures 7 and 8 present an overview of the major software packages available.

Both the PDP-11/45 (Terminal 1) and the PDP-11/70 (Terminals 2 and 3) operate under the DEC-supplied RSX-11D multiprogramming operating system. All AOIPS applications packages interface with the user through the previously mentioned hierarchical structure of menus.

Terminal 1 (the Image 100) was delivered with an application package (the Image 100 software system) designed

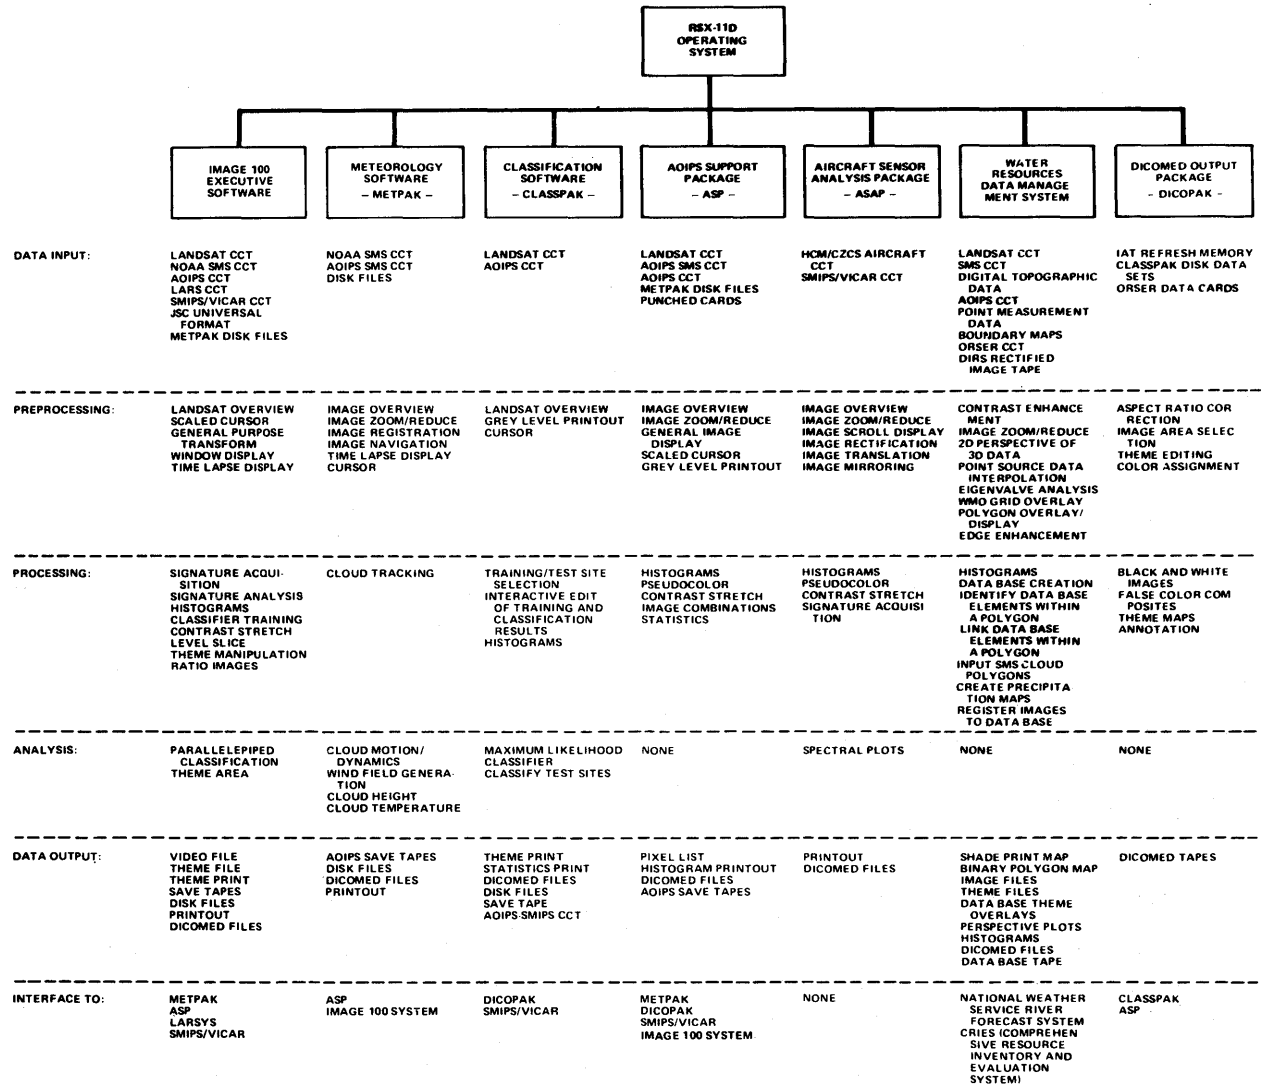

Figure 7—AOIPS Terminal 1 software overview

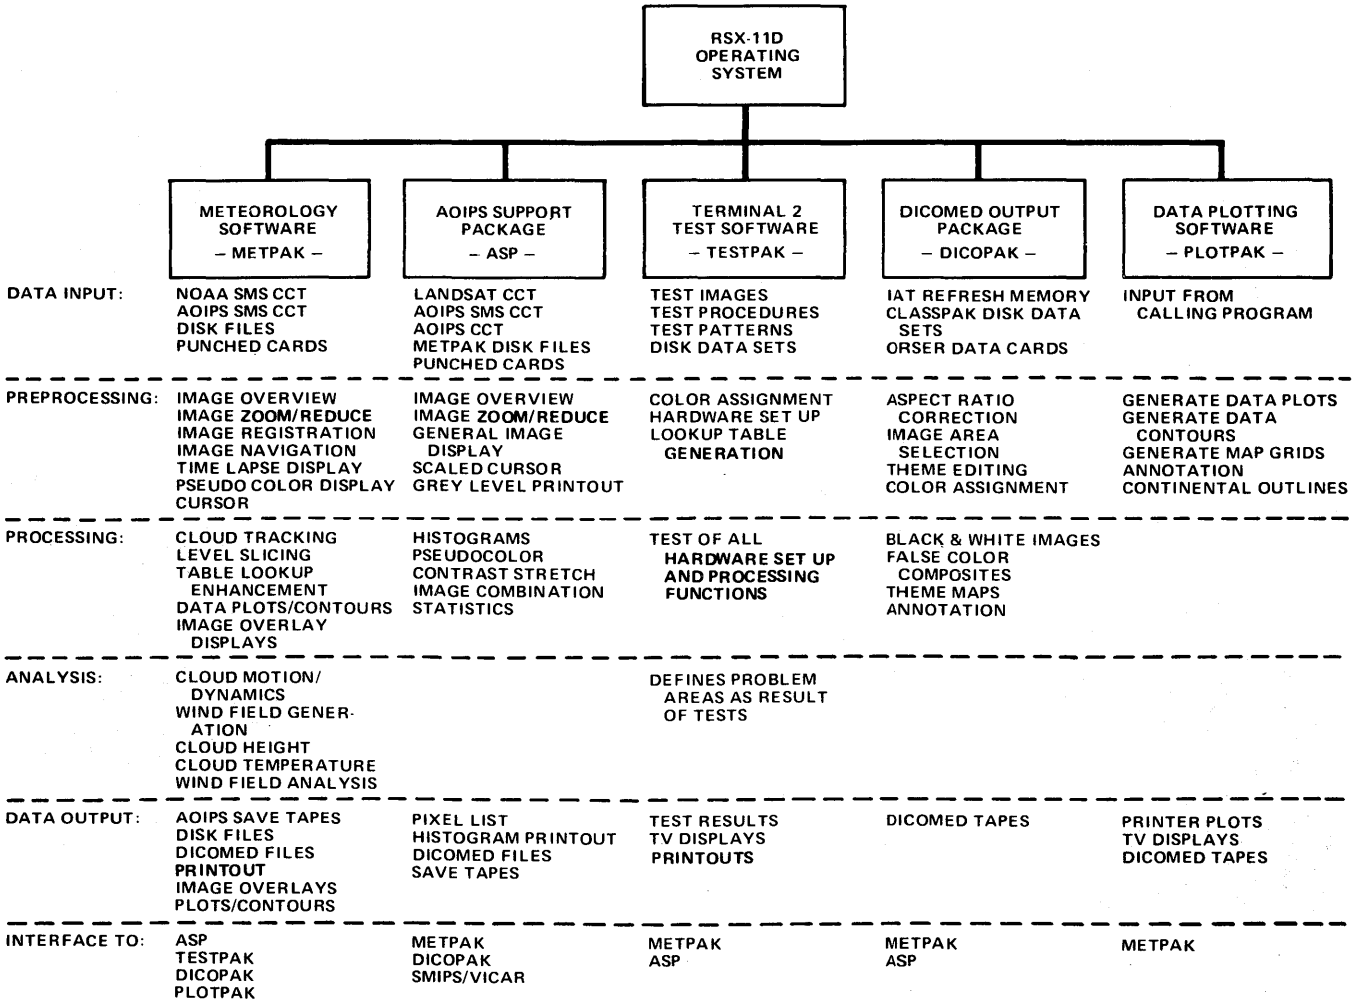

Figure 8—AOIPS Terminal 2/3 software overview

for interactive multispectral classification of Landsat satellite data. To support the varied requirements of system users, several additional AOIPS software packages were developed including:

METPAK—An interactive system which provides image navigation, registration and other functions required to support cloud motion studies, wind vector generation, and wind vector analyses. METPAK computes the cloud height and the displacement of selected clouds in a series of time lapsed digital images. It generates various analyses of the computed wind fields and displays TV and hard copy output products of images overlayed with plots and data contours of analysis parameters.

CLASSPAK—An interactive maximum-likelihood multispectral classification package. CLASSPAK accepts up to 24 channels of input data; provides for statistical analysis of the input data; and performs a classification using up to 8 selected channels. CLASSPAK provides a highly flexible, interactive environment for selecting, defining, displaying, editing, and combining training sites and training site statistics. CLASSPAK generates classification maps of up to 25 classes and displays of class correlation and covariance matrices as well as statistical analysis results.

Aircraft Sensor Analysis Package (ASAP)—An interactive software package for displaying, processing, correcting and enhancing multispectral aircraft scanner data. ASAP produces hard copy image output products and TV displays of processed aircraft imagery.

AOIPS Support Package (ASP)—An interactive system which provides general image display and manipulation capabilities. ASP performs histogram generation, contrast stretching, pseudo color enhancement, and image combination operations.

Figures 7 and 8 also list the capabilities of a number of other software packages used to manage AOIPS data bases and to generate final output products of image analysis results.

SYSTEM APPLICATIONS

During the past year, over 50 applications investigations have been supported on AOIPS. These investigations in-

Figure 9—Satellite interpretation of the dynamics of severe local storms

cluded research studies in meteorology, oceanography, hydrology, land use, forestry, geology, agriculture and related earth resources disciplines.

Reference 3 details the AOIPS capabilities used in support of severe storms investigations, particularly in the area of wind field generation and analysis. Additional system capabilities have been developed to analyze the dynamics of rapidly forming storm cells, to generate precipitation estimates from digital imagery, and to provide temperature profiles of selected clouds. These capabilities were used to produce the applications results illustrated and described in Figures 9 and 10.

The two primary earth resources applications supported on AOIPS include image enhancement for identification of ground features of interest and multispectral classification. Figure 11 describes one hydrological land use classification study conducted on AOIPS.

FUTURE SYSTEM ENHANCEMENTS

In early 1978, the AOIPS PDP-11/70 will be interfaced through a shared RP06 disk unit to another PDP-11/70 processor as shown in Figure 12. This second processor will be dedicated to deriving atmospheric temperature and humidity profiles from GOES-D VISSR Atmospheric Sounder (VAS) satellite data as part of the VAS Demonstration project. The shared disk link between the AOIPS and VAS 11/70s will provide the means of incorporating sounding data into severe storms analyses conducted on AOIPS.

The figure also illustrates plans for acquiring and processing SMS/GOES satellite data in near real time. These capabilities will allow investigators to detect and analyze severe storms as the phenomena occur in order to develop improved storm detection and prediction capabilities for the future.

During the next two years, several other AOIPS enhancements are planned for meteorological and earth resources applications including:

- Enhancing capabilities for monitoring the dynamics of cloud formation and severe storm development.
- Improving precipitation estimation capabilities using several estimation techniques.
- Developing capabilities for multispectral analysis of severe storm data.
- Applying multispectral classification techniques to severe storm analyses.

FIGURE 1: 21:08 GMT
SMS-2 OMAHA THUNDERSTORM

FIGURE 2: 21:28 GMT
SMS-2 OMAHA THUNDERSTORM

ENLARGED AREA HIGHLIGHTS THE CLOUD TOP TEMPERATURE STRUCTURE OF THE THUNDERSTORM CELL. BOTH THE 206°K AND THE 208°K AREAS HAVE INCREASED RAPIDLY. THE OMAHA TORNADO OCCURS AT 21:33 GMT.

INTRODUCTION

THE USE OF GEOSTATIONARY SATELLITE DATA HAS THE POTENTIAL OF BEING AN IMPORTANT COMPONENT IN THE DETECTION AND MONITORING OF THUNDERSTORMS AND OTHER FORMS OF SEVERE WEATHER. THE OBJECTIVE OF THIS RESEARCH IS TO DETERMINE IF THUNDERSTORM GROWTH RATES AND CHARACTERISTICS OBSERVABLE WITH SYNCHRONOUS METEOROLOGICAL SATELLITE (SMS) INFRARED DATA CAN BE LINKED WITH THE OCCURRENCE OF SEVERE WEATHER ON THE GROUND (TORNADOES, HAIL, HIGH WINDS). THESE SEVERE WEATHER EVENTS ARE HIGHLY CORRELATED WITH THE INTENSITY OF ATMOSPHERIC CONVECTION. BY ANALYZING SMS INFRARED DATA ON THE ATMOSPHERIC AND OCEANOGRAPHIC INFORMATION PROCESSING SYSTEM (AOIPS), PARAMETERS RELATED TO CONVECTION INTENSITY SUCH AS CLOUD TOP TEMPERATURE AND HEIGHT AND THE RATE OF VERTICAL GROWTH OF A THUNDERSTORM CAN BE IDENTIFIED.

AOIPS ANALYSIS

THE ATMOSPHERIC AND OCEANOGRAPHIC INFORMATION PROCESSING SYSTEM (AOIPS) WAS APPLIED TO ANALYZE SMS DATA TAKEN AT FIVE MINUTE INTERVALS BETWEEN 1803 AND 2208 GMT ON MAY 6, 1975 OVER NEBRASKA. A NUMBER OF SEVERE STORMS THAT SPAWNED TORNADOES AND HAIL DURING THIS TIME PERIOD CAN BE SEEN ON THIS SMS DATA. FIGURES 1 AND 2 ARE TWO IMAGES (20 MINUTES APART) EXTRACTED FROM THE TIME SERIES. THE THUNDERSTORM CELL THAT SPAWNED A TORNADO OVER OMAHA IS OUTLINED BY THE PURPLE BOX IN BOTH FIGURES WHERE IT IS ALSO ENLARGED 16 TIMES AND DISPLAYED IN COLOR TO HIGHLIGHT THE DYNAMICS OF THE CLOUD TOP TEMPERATURE STRUCTURE. THE GREEN AND BLUE REGIONS (208°K AND 206°K) INDICATE THE COLDEST OR HIGHEST PORTION OF THE THUNDERSTORM. THE INCREASE IN AREA OF THESE COLD REGIONS FROM FIGURE 1 TO FIGURE 2 IMPLIES STRONG CONVECTION AND A RAPID INCREASE IN THE HEIGHT OF THE THUNDERSTORM TOP.

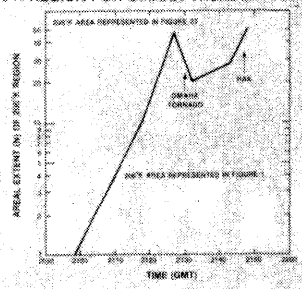
THE GROWTH OBSERVED IN FIGURES 1 AND 2 IS PRESENTED QUANTITATIVELY IN FIGURE 3 AS THE TIME INCREASE IN AERIAL EXTENT (N) OF THE 206°K REGION OF THE STORM CELL. THIS 206°K REGION INCREASES RAPIDLY JUST PRIOR TO THE OCCURRENCE OF THE OMAHA TORNADO AND AGAIN PRIOR TO OBSERVED HAIL. MOST OF THE OTHER SEVERE STORMS ANALYZED IN THIS STUDY EXHIBITED SIMILAR GROWTH PATTERNS IN THE CLOUD TOP TEMPERATURE STRUCTURE. THESE TRENDS ARE READILY RECOGNIZED WHEN PLOTTED AS AN INDEX OF SEVERE WEATHER AS IN FIGURE 4. IN THIS FIGURE, THE NORMALIZED RATE OF COLD AREA GROWTH $\frac{\Delta N}{N \Delta t}$ IS PLOTTED AGAINST CLOUD TOP TEMPERATURE FOR EACH OF THE 39 SEVERE AND NON-SEVERE CASES STUDIED.

A LARGE MAJORITY OF THE CASES STUDIED THAT FALL TO THE RIGHT AND ABOVE THE DIAGONAL DISCRIMINATION LINE ARE ASSOCIATED WITH SEVERE WEATHER WHILE THE CASES FALLING ON THE OTHER SIDE OF THE LINE ARE PREDOMINANTLY NON-SEVERE.

CONCLUSIONS

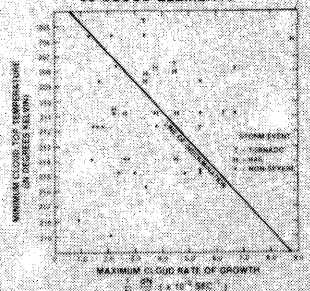
DIGITAL INFRARED DATA FROM A GEOSTATIONARY SATELLITE (SMS-2) WERE ANALYZED ON AOIPS TO STUDY THUNDERSTORM DYNAMICS IN RELATION TO THE OCCURRENCE OF SEVERE WEATHER ON THE GROUND. AN EXAMINATION OF 39 CLOUD ELEMENTS INDICATED THAT PARAMETERS DERIVABLE FROM SMS SHORT INTERVAL DATA ARE CORRELATED WITH THE OCCURRENCE OF SEVERE WEATHER. THESE PARAMETERS INCLUDE THE CLOUD TOP MINIMUM TEMPERATURE AND RATE OF VERTICAL GROWTH. THEREFORE, IT APPEARS THAT SHORT INTERVAL INFRARED DATA FROM SMS MAY BE USEFUL IN CALCULATING PARAMETERS RELATED TO THUNDERSTORM INTENSITY AND THE OCCURRENCE OF SEVERE WEATHER ON THE GROUND.

FIGURE 3: PLOT OF AREAL EXTENT OF THE 206°K REGION FOR OMAHA THUNDERSTORM



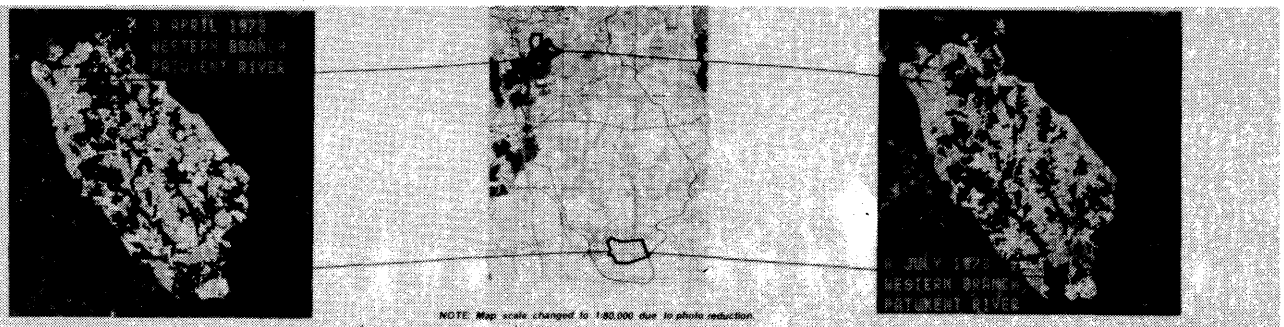
RAPID GROWTH OCCURS PRIOR TO BOTH THE OUTBREAK OF TORNADO AND HAIL EVENTS

FIGURE 4: PREDICTION INDEX PLOTTED FROM STUDIES OF 39 CLOUD ELEMENTS



A MAJORITY OF THE SEVERE WEATHER OCCURRENCES FALL TO THE RIGHT AND ABOVE THE DIAGONAL LINE OF DISCRIMINATION

Figure 10—Thunderstorm intensity parameters viewed from satellite



Imagery from Landsat-1 has been analyzed for hydrologic land use classification using the GSFC Atmospheric and Oceanographic Information Processing System (AOIPS). The upper portion of the Western Branch subbasin of the Patuxent River watershed served as a test site for classification. The boundary of this subbasin is identified on the 7½-minute USGS topographic map. The classification of Landsat image 1260-15201, 9 April 1973 and that of Landsat image 1350-15192, 8 July 1973 each resulted in cover type identification of greater than 90 percent of the watershed surface. These classifications (relative to the watershed boundary) are being used by the Hydrology and Oceanography Branch as input to hydrologic models for stormwater runoff estimation.

The AOIPS is a user-interactive computer system designed for analysis of remotely sensed earth resources information. Capabilities include various types of classification packages applicable to interpretation of data from ATS, Nimbus, GOES, ESMR, HCMM, side-looking radar, aircraft multispectral scanners and digitized photography as well as Landsat. The system rapidly analyzes Landsat and other imagery with results of each 'training', or data sample classification, being displayed within seconds on the cathode ray tube for user evaluation and modification. Each of the final watershed classifications shown here was completed within twenty hours of system operation.

CLASSIFICATION RESULTS

CLASS	APRIL		JULY	
	Hectares	Percentage	Hectares	Percentage
Agric fields	1116.8	15.5	2421.4	33.6
Construction	a		153.2	2.1
Water	23.0	0.32	18.7	0.26
Woodland	3194.9	44.5	2989.7	41.6
Residential	864.1	12.0	809.5	11.3
Urban	18.1	0.25	35.5	0.49
Bare fields	1297.2	18.1	261.4	3.6
Total classified	6495.6	90.7	6709.4	93.3
Watershed	7168.0		7168.0	

a No classification for construction sites was attempted on the April image.

The table at the left contains area measurements for each of the landcover classes identified within the Western Branch subbasin. Also given is the percentage of the subbasin covered by each class. Note that the major difference between the two classifications is due to seasonal vegetation coverage changes. April's 'bare fields' are classified as 'agricultural fields' in the July image. The growth in riparian vegetation has caused a slight decrease in the surface of water exposed. Except for the fact that some of the urban surfaces were left unclassified in the April scene, there is a high degree of precision between the AOIPS classifications from two different images.

Figure 11—Hydrologic land use classification of Landsat imagery

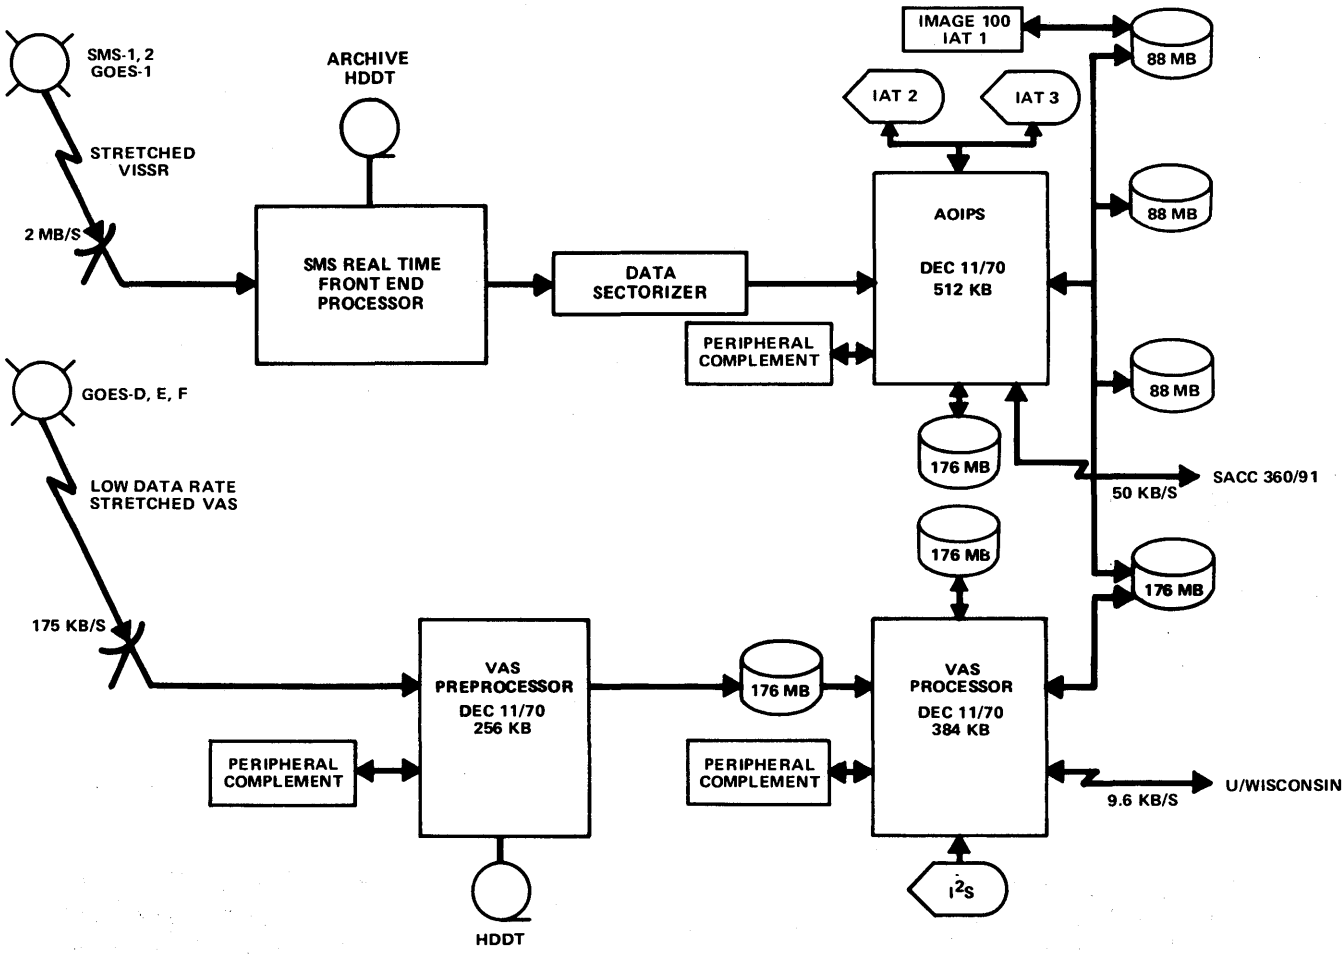


Figure 12—AOIPS—VAS system configuration

- Incorporating a wider range of nonimage surface truth and ancillary information into AOIPS information extraction operations.
- Providing capabilities for registering image and nonimage data from multiple sources.
- Establishing integrated data bases for storage, comparison and correlation of multisource/multitime image and nonimage data.

An array computer called the Massively Parallel Processor (MPP) will also be interfaced to AOIPS in 1981. When completed, the MPP will utilize an array of 128×128 primitive processing elements (i.e., elementary central processing units) to perform image processing computations on 16,384 picture elements simultaneously. The MPP has been designed to operate at speeds of over 5,000 million additions per second and over 1,000 million multiplications per second on eight bit integers. The system will be fully programmable and capable of handling variable word lengths and floating point computations.

An 8×8 breadboard version of the MPP has been successfully tested and is scheduled to be interfaced to AOIPS in April 1978. Reference 4 provides detailed information on the design and functional characteristics of the MPP.

SUMMARY

This paper has discussed the configuration and processing capabilities of the AOIPS interactive image processing system. Unique subsystems for displaying, analyzing, storing and manipulating digital image data were presented. Applications of the AOIPS to research investigations in meteorology and earth resources were highlighted.

Our experience to date indicates that future progress in relating remotely sensed measurements to earth based phenomenon is heavily dependent on an investigators ability to interact with his data and to combine multisensor/multitemporal data sets in integrated analysis data bases. In most cases, this interaction must take place within hours or days of the occurrence of an event to preserve the value of the information content in the data and to maximize the realizable benefits.

Remote sensing program in earth resources

by FREDERIC C. BILLINGSLEY
NASA Headquarters
Washington, DC

and

DONALD T. LAUER
U.S. Geological Survey
Sioux Falls, South Dakota

THE EARTH RESOURCES SITUATION

Population growth and demands for higher standards of living are creating pressures which affect all aspects of our society. The global population, currently near 3900 million, is growing at a rate of 75-80 million/year.

Coupled with population growth, and magnifying the effect, are rising demands for a more equitable sharing of the products and benefits of technology. The products and benefits derive from the consumption of natural resources. As societies develop and technological advancement begins, individual demands increase resulting in a more rapid rate of consumption of resources. Information is necessary to enable prudent decisions regarding the management of resources. But understanding alone will not lead to solutions on a long-term basis. Knowledge must be current, necessitating continuing inputs of fresh information. The most practical and economical manner of acquiring repetitive global, Earth Resources information is by means of a satellite-based remote sensing system.

REMOTE SENSING DATA SYSTEM

1. *General*

A total remote sensing data system (wherever the components are located and whatever the sophistication) comprises four distinct operations:

- Physical data acquisition and preprocessing
- Archiving for bulk retrieval
- Production and dissemination of individual products
- Extraction of the required information from the data

2. *Data Acquisition*

Mechanisms for data acquisition are the same for most applications. Global, repetitive, timely, and accurate information is a key element. Landsat addresses, and to a considerable extent, can satisfy the requirements for information. For this reason, the discussions will concentrate on Landsat data, although recognizing the presence of other sensor platforms in the NASA program. Not part of the system considered here, but often critical to successful solution of a given problem, is the inclusion of data from many other sources, such as maps or socioeconomic data. It is the task of the data analyst to blend all necessary data, from whatever source, to extract the desired information, and to present the results to the decision maker in the most optimum form.

As Landsat data are received by the data collection stations, they are forwarded to Goddard Space Flight Center (GSFC). Until July 1978, GSFC will apply radiometric and geometric corrections in making 70mm film masters, which are sent to the data archive at the Earth Resources Observation System (EROS) data center (EDC) in Sioux Falls, South Dakota. GSFC can also produce computer compatible tapes (CCT) on special order (through EDC) in which radiometric correction has been applied. Beginning in 1978, GSFC will deliver digitally corrected digital data to EDC on high density bulk tapes as the standard NASA product.

3. *Archiving*

All data are archived at EDC, where they are available for reproduction upon request of orders from users. A customer service and catalog function is available at EDC to assist users in locating required data.

4. *Availability of Landsat data*

Landsat data are currently reproduced and distributed to users by three Federal Data Centers operated separately by the U.S. Department of Interior's Geological Survey (USGS), the U.S. Department of Agriculture (USDA) and the U.S. Department of Commerce's National Oceanic and Atmospheric Administration (NOAA). Data products provided by the three centers are similar in scale, format and type. By mid 1978 a new all-digital system for handling and processing Landsat data will be in operation and will be providing improved products to data users. A processing

system will be implemented whereby the National Aeronautics and Space Administration (NASA) will provide Landsat high-density digital tapes (HDTs) to the USGS's EROS Data Center (EDC) which will be the nation's federal dissemination facility for original Landsat data products.

The Landsat high-density digital tapes routinely received at EDC from NASA's Goddard Spacecraft Center will be radiometrically restored (for detector gain and offset) and geometrically corrected (to a Space Oblique Mercator map projection) using a cubic convolution resampling algorithm. By means of retrospective user orders, NASA will provide EDC Landsat data which are corrected to the Universal Transverse Mercator or the Polar Stereographic (over 65° latitude only) map projection, resampled with a nearest neighbor algorithm, or in an uncorrected high-density tape format (i.e., radiometrically restored but not geometrically corrected).

The digital processing system at EDC has the flexibility to produce a brightness-frequency histogram showing brightness value distribution for each Landsat scene, and perform contrast and edge enhancement functions which are based on the brightness value distributions. When placing an order, a user may select or omit these enhancement functions. Film and digital tape products, from the multispectral scanner (MSS) and the return beam vidicon (RBV) camera, will be available from EDC. Negative film working masters in a 241mm format will be made on a high resolution laser-beam film recorder. Customer products made from the film masters will include second generation positive film transparencies, third generation negative film transparencies, black-and-white or color composite prints at various scales of enlargement, and 70mm film products. Computer compatible tapes (CCTs, 800 or 1600 bits per inch) generated from high-density digital tapes will include RBV data in subscene sequential format, or MSS data in band sequential or line interleaved formats. Pixel interleaved format will no longer be available. Specified images may be selected and specially ordered in an HDT format.

More information concerning these data products may be obtained from:

User Services
EROS Data Center
U.S. Geological Survey
Sioux Falls, SD 57198

5. *Foreign Ground Stations*

In addition to the data returned to the United States and available through EDC, several countries have elected to install their own receiving stations. At the present time, these are Canada, Brazil, and Italy. In addition, agreements have been reached with Iran (station under construction), India, Argentina, Zaire, and Chile (the latter two are not yet funded).

NASA and the U.S. climate program—A problem in data management

by JOHN J. QUANN
NASA/Goddard Space Flight Center
Greenbelt, Maryland

INTRODUCTION

Climate can be thought of as the average of weather. Whereas fluctuations in weather on a daily basis are essentially unpredictable, fluctuations in weather over longer time scales are part of climate and may well be predictable. The goal of the U.S. Climate Program is to help the nation respond more effectively to climate induced problems by enabling its government to be aware of or to anticipate climatic fluctuations and their domestic and international impacts and to identify the real and potential impact of man on regional and global climate.[1]

In order to deal with the many aspects of climate, NASA developed an agency plan, which defines the NASA contribution to the U.S. Climate Plan. In it, NASA chose to divide climate into four separate but related activities:[2]

1. Climate A deals with the current state of the climate. The goal is to provide timely information in a usable form on the current state of the climate and to provide for the analysis of this information.
2. Climate B deals with regional climate on time scales longer than a month but shorter than a decade. The goal is to predict fluctuations in climate over individual regions of several hundred kilometers square.
3. Climate C refers to climate which occurs on time scales of a decade and beyond. The goal is to understand the causes of natural changes in the global climate.
4. Climate X deals with the climate as it is affected by mans activities on all temporal and spatial scales. The goal is to understand and anticipate the impact of man so that appropriate action can be taken.

Currently, programs related to the analysis and modelling of climate are limited and dispersed throughout many agencies in the government. The National Oceanic & Atmospheric Administration (NOAA), The National Science Foundation (NSF), The Department of Defense (DOD), and the National Aeronautics & Space Administration (NASA) are but some of the agencies and institutions in which research into climate is being conducted. However, there is no central focus at the present time. No group is responsible for establishing and maintaining a comprehensive program dealing with the many aspects of climate. This situation will change with the establishment and implementation of a national climate plan which will be integrated not only among domestic agencies but among many nations having related programs. At present the major agencies involved are developing, in parallel, the plans for their respective agencies to participate in the overall program. NASA's role in the achievement of the objectives of the National Climate Plan relates primarily to satellite based instrumentation, the development of climate required parameters on a global scale, climate modelling and assessment, special studies, and data management.

DATA MANAGEMENT

The objective of the climate data management system is to permit effective use of a global data base for climate research. Information contained in the data base must allow researchers to answer a variety of questions on climate . . . questions related to the impact of climate variations on crop yields, energy, land use and water resources; questions relating to the determination and effect of gas and particle loading in the atmosphere; questions concerning the variability of climate and the relationship to the earth's energy budget, distribution of cloudiness, snow cover etc.

The global data base must facilitate research on a wide range of time and space scales. It must be able to aid in the development of climate models and provide data for their verification. It must support diagnostic studies that investigate the structure of climate changes and facilitate assessment studies as the effect of climate change on food and fiber production.[3]

NASA'S ROLE

Forty (40) parameters have been identified as key variables requiring observation from space and having a direct effect on climate (Table I). NASA's contribution to the total climate data base will be to produce climate data sets from its experimental space observing systems and to maximize the value of this data for climate analysis and prediction. Validated data sets will be provided to NOAA for inclusion

in their overall diagnostic data base. NOAA will, in turn, provide NASA similar data sets from both conventional data sources and operational space observing systems. Standard weather parameters such as surface temperature, surface pressure, temperature profiles, wind velocity and humidity will be acquired through the operational observations of the World Weather Watch (WWW) Program and will be stored and accessed through NOAA's Environmental Data Services (EDS). NASA and NOAA space observation data has been reviewed and a decision made that the starting point for a climate data base would be January 1973 which coincides with the launches and data availability from the NASA Nimbus 5 and the NOAA-1 satellites. The sources of data from existing and planned satellite programs required for Climate B are summarized in Table II. Additional sources for Climate C and X are given in Table III. It is unlikely that full extraction of climate parameters can be afforded from all sources. As an example, the Scanning Radiometer on the NOAA satellites is the most consistent source for global cloud data at the present time. Cloud information could also be obtained from the Nimbus and Landsat satellites but the data coverage is insufficient. Another potential source for a cloud data set is the geosynchronous SMS (Synchronous Meteorological Satellite) and GOES (Geostationary Operational Environmental Satellites). When all geosynchronous spacecraft are in place only the polar regions will not be covered. It may be feasible at that time to extract only the polar regions from polar orbiting spacecraft.

DATA BASE

The information contained in the data base will be accessible at four different levels of processing. Level O is raw data as telemetered from the spacecraft. Level I consists of data which has been calibrated into engineering units, e.g., radiances, microwave brightness temperatures, and located with respect to time, orbit, and attitude. Level II refers to climate parameters, e.g., sea surface temperature, percent sea ice, soil moisture, at full spatial and temporal resolution.

Acronyms

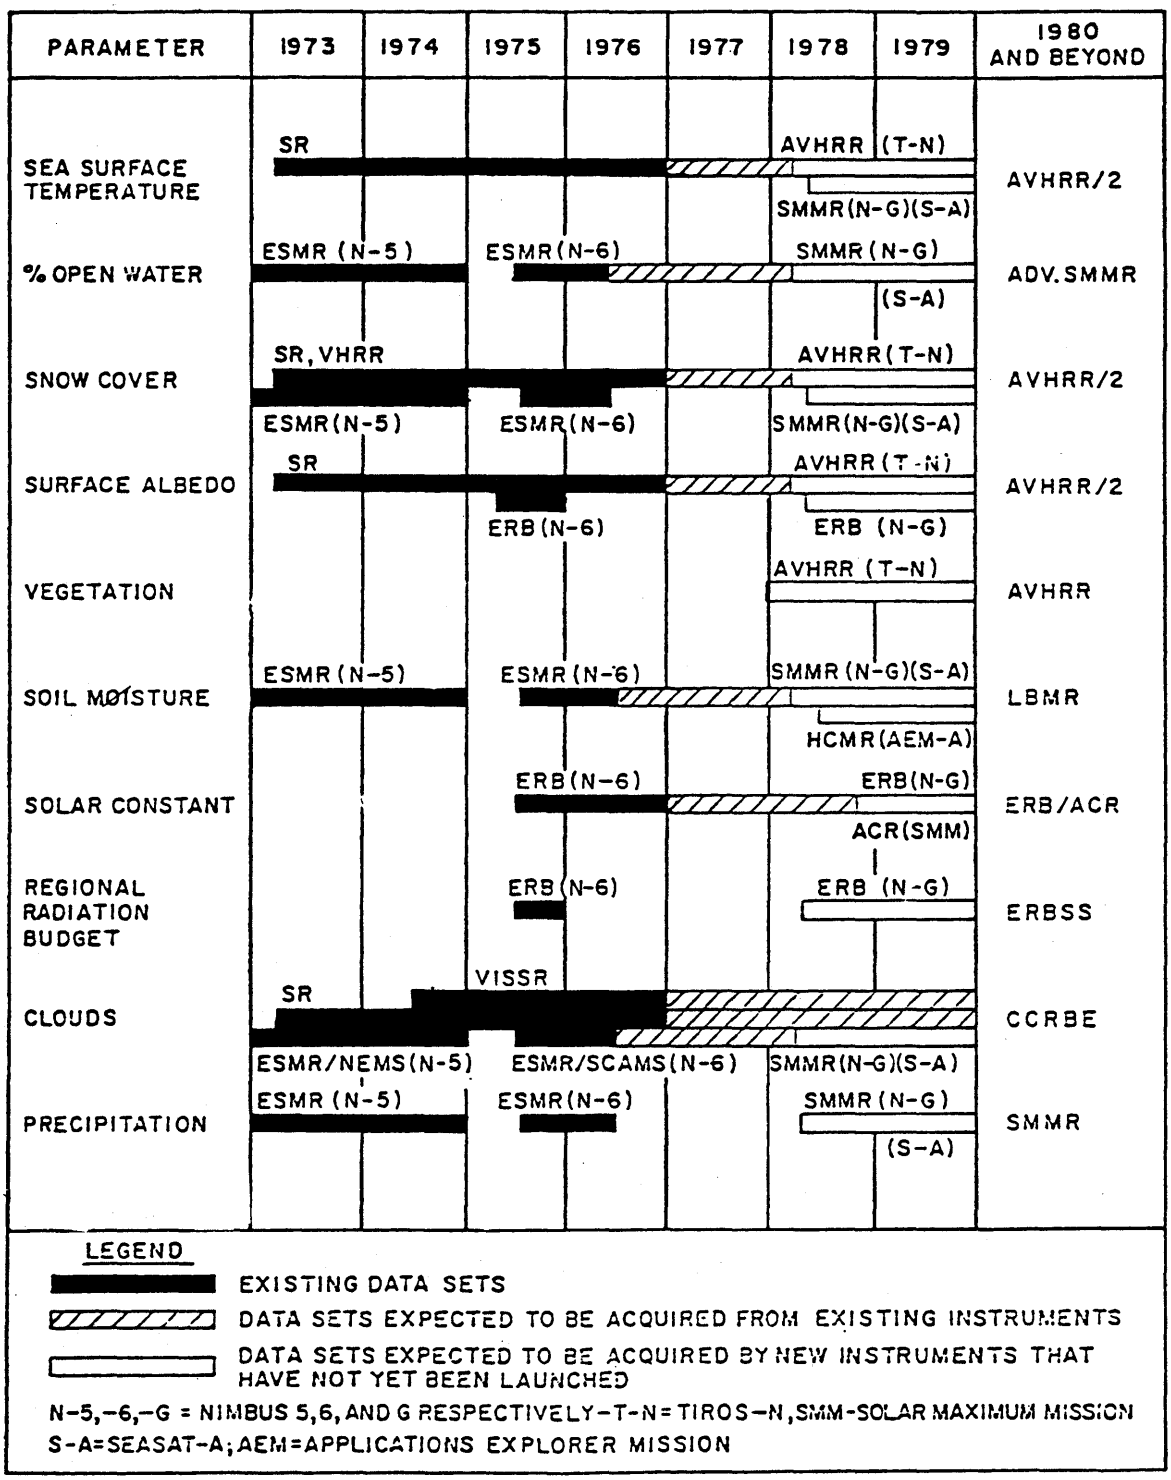
1. ACR	—Active Cavity Radiometer
2. AVHRR	—Advanced Very High Resolution Radiometer
3. CCRBE	—Cloud Cover Radiation Budget Experiment
4. ESMR	—Electrically Scanning Microwave Radiometer
5. ERB	—Earth Radiation Budget
6. HCMR	—Heat Capacity Mapping Radiometer
7. LBMR	—L-Band Soil Moisture Radiometer
8. LIMS	—Limb Infrared Monitor of the Stratosphere
9. LRIR	—Limb Radiance Inversion Radiometer
10. SAGE	—Stratospheric Aerosol & Gas Experiment
11. SAMS	—Stratospheric & Mesospheric Sounder
12. SAMII	—Stratospheric Aerosol Measurement
13. SBUV	—Solar Backscatter Ultraviolet instrument
14. SMMR	—Scanning Microwave Multichannel Radiometer
15. SR	—Scanning Radiometer
16. VISSR	—Visible & Infrared Spin Scan Radiometer

Level III consists of climate parameters which have been spatially and temporally averaged.

Functionally, the climate data management system must:

1. Acquire raw telemetry data from the applicable NASA sensors.
2. Catalog, store, and retrieve all information archived in the NASA data base at any level.
3. Calibrate, locate, and extract climate related parameters from the raw data.
4. Facilitate the validation and analysis of information.
5. Manage and give easy user access to a complete, current NASA data directory.
6. Grid, register, spatially and temporally average climate parameters.

TABLE II—Basic Data Sources for Climate B

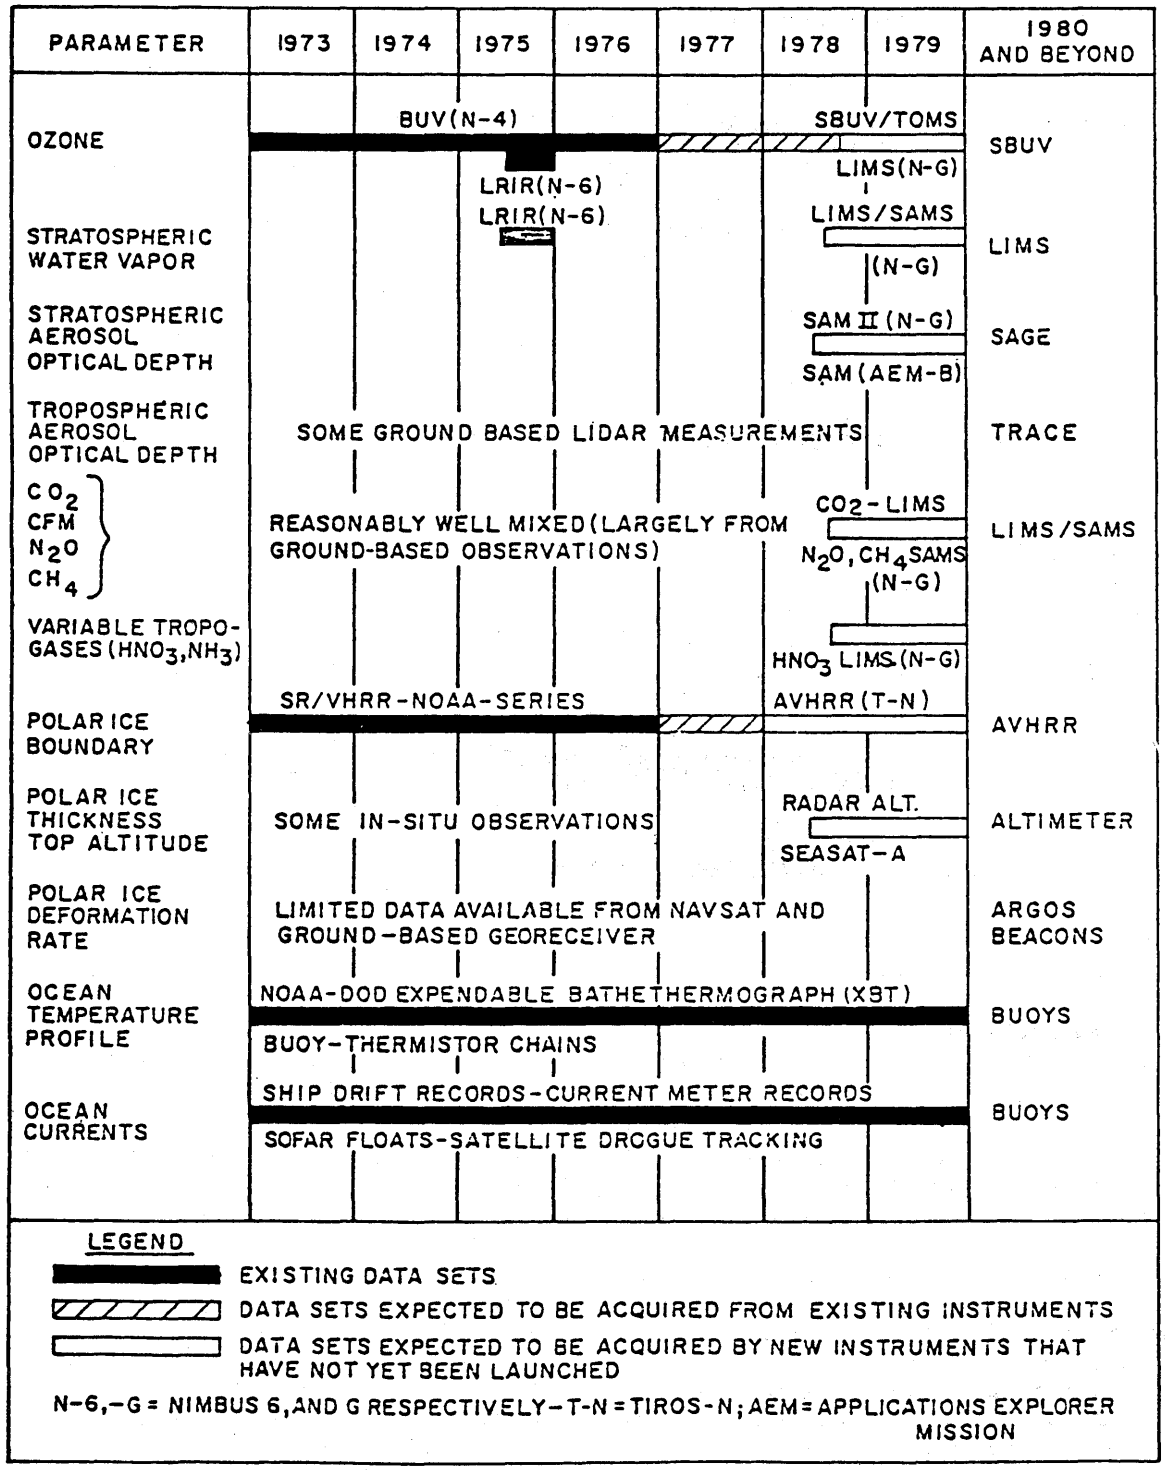


7. Provide information to users in pre-selected formats or as experimental data sets in non-standard form.
8. Provide a central interface with NOAA for access to and exchange of climate data sets outside of NASA.
9. Provide a centralized access to climate data sets in a manner which is functionally transparent to the user.
10. Provide acceptable response time to the user.

Figure 1 presents a functional overview of the NASA climate data management system. NASA Goddard will be responsible for receiving all raw spacecraft data from NASA missions and maintaining a central end to end data directory. The functions associated with the transformation of the raw data into the Level I data base is the responsibility of the NASA center managing the particular payload. As an ex-

ample the Earth Radiation Budget (ERB) Satellite is managed by Langley Research Center. Langley, therefore, would be responsible for the Level I processing and archival functions. The processing of information into individual climate parameters, i.e., Level II, is the responsibility of the NASA Center charged with development of the particular climate parameter. As an example, although Langley may have the responsibility of processing the ERB data into the Level I data base, another NASA Center, Goddard for example, may have the responsibility of processing the Level I data into a measurement of the solar constant which is a Level II climate parameter. Level II data, therefore, will be a distributed data base. Each Center has the option to maintain its own local data base for the Level II climate param-

TABLE III—Basic Additional Data Sources for Climate C&X



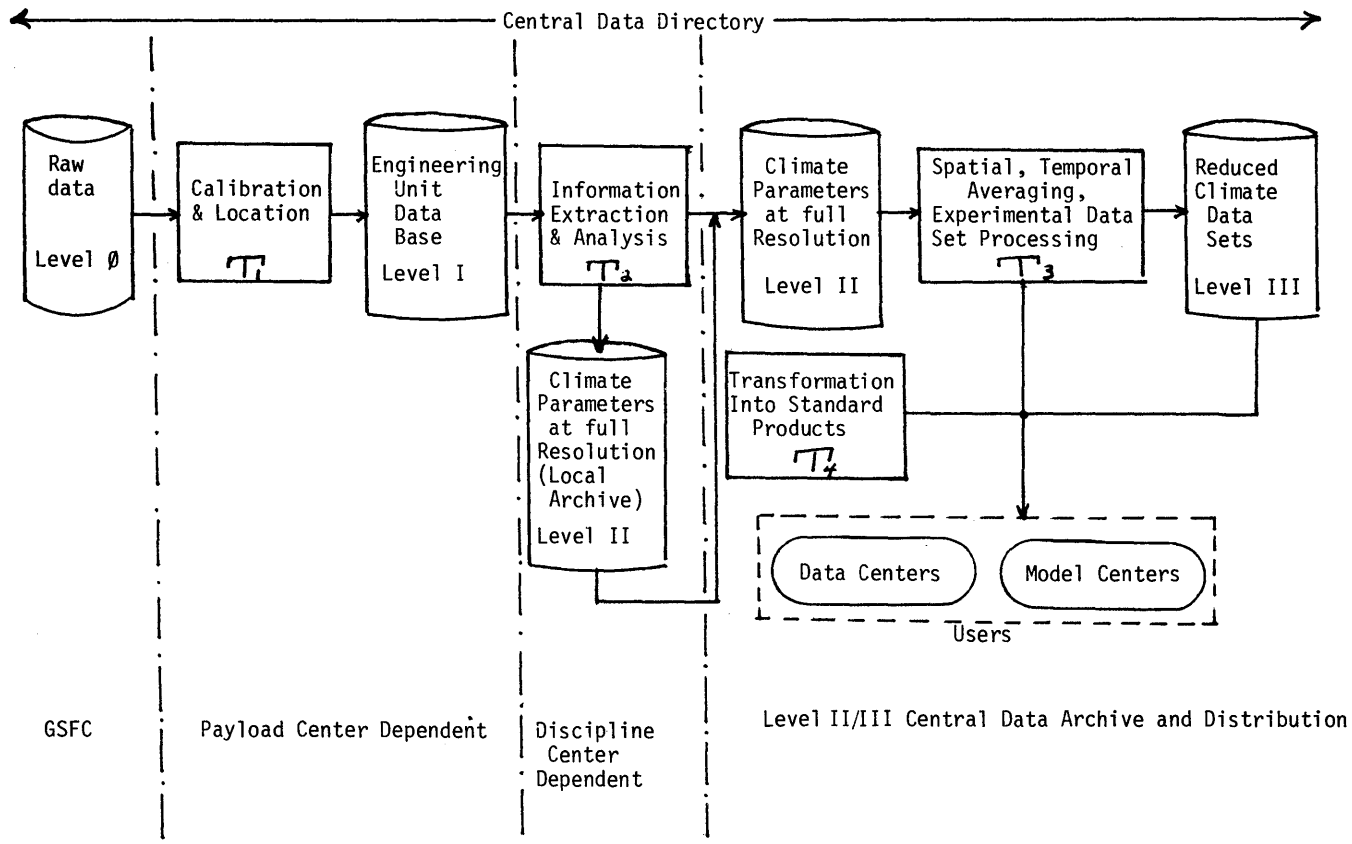


Figure 1—NASA climate research program data management

eter for which it has the responsibility of developing, or submit the data to the central data base maintained at Goddard. If the former course is chosen, the local data base must be accessible by the Goddard data management system. Regardless of where the Level II data is archived, all information concerning its availability will be maintained in the central data directory at Goddard. Level III data will be centrally archived and distributed by Goddard. In addition to maintaining the NASA data base the data management system must be able to interrogate, access, and retrieve information from the NOAA data base in order to integrate data sets in terms of temporal and spatial resolution.

SUMMARY

The Climate Program is not short term, but is anticipated to extend over decades. To catalog and manage global data in all its forms, to facilitate retrieval of large integrated and distributed data sets upon user demand, simply to store, and access the equivalent of 10^5 digital data tapes, are typical problems illustrative of the scope and magnitude of Climate data management. It will be the largest, most complex data management system ever developed by NASA. But the analysis of climate is complex and requires such a system if it is going to be effective, and effective it must be if man is to benefit.

What good is all this data if we can't use it?

by GEORGE J. McMURTRY
The Pennsylvania State University
University Park, Pennsylvania

One of the most disappointing aspects of the Landsat program to date has been the relatively slow acceptance and use of this remote sensing data by federal, state, and local agencies. In order to attract a greater number of users of remotely sensed multispectral data, several conditions must be satisfied. The user must be convinced that he has the resources and capability of acquiring, processing, and interpreting the data and that information extracted from that data will be helpful to him in satisfying the requirements of his particular job. The final processed results must provide the desired information in an understandable and attractive format. Furthermore, the user must be able to obtain the final result more cheaply, quickly, and/or easily than by conventional methods. Finally, he must be able to integrate the data and/or the processed results with other pertinent data.

In the session on Image Processing System Design, two interactive systems have been described. The word "interactive" itself implies an intimate involvement of the user. This type of analysis tends to require a more technically sophisticated user. This in turn implies that user agencies will require highly skilled and trained personnel who can interact with the appropriate processing system. Even so, there will still be a need to have interactive systems with which a user may interact "in English" using menus, etc., i.e., an input-output format which makes the system appear to be not only accessible but attractive and easy to use. If these conditions are satisfied the user must then decide which specific set of hardware and software he should purchase for installation in his own facility. Another alternative is for the user to purchase time and perhaps services at some other facility.

In addition to the papers on interactive analysis systems, we have heard a description of the design of a large pipeline system for handling large quantities of data routinely and quickly. The emphasis in such a system is to process a large volume of image data with a high through-put for distribution to a wide community of users. Such a system has additional requirements for reliability, special processing, and accuracy. It must take into account the needs and desires of a wide variety of users. In determining the types of processing available in such systems several questions are pertinent. Is it cost effective for NASA to provide the special processing required by the user? Or would it be better for the user to obtain raw data and to process that data according to his own needs? To answer these questions one must determine whether it is reasonable to expect the user to have the capability to perform such processing. Many users will not. This may suggest that if the principal objective is to increase the number of users, then any pipeline system should be designed for the needs of many relatively small users who would not be expected to have sophisticated processing capability rather than to design the system for the user with the more highly sophisticated equipment and software, even though the latter user may be the recipient of a much larger volume of data. In general, the user of whom we are speaking will need a product that has been both geometrically and radiometrically corrected and referenced to a common coordinate system. As the user community grows, the users' needs and capabilities will change and any pipeline system must be flexible and be adaptable to such changes.

The authors of the two papers on interactive systems have stated that there is a need "to combine multisensor/multitemporal data sets in integrated analysis data bases" and for "registration of the existing geocoded data bases with Landsat imagery . . . if the Landsat data is to be truly useful to the user community." This implies that the output of a pipeline system should consist of corrected data, fully processed to a standard geodetically defined grid and it has been suggested that this data should be specifically designed to overlay groups of 7.5 minute topographical quadrangle sheets (1:24,000). Many different projections have been recommended including SOM, Lambert Conformal Conic, Polyconic, state plane coordinates, equal area, and lattitude/longitude. Taking into account user needs, conformality, zone boundary problems, and ease of mechanization, a conformal projection such as UTM should be used. The header format on data provided to users should include the following kinds of information:

1. Geometric
2. Radiometric
3. Historical
4. Statistical, including reliability and accuracy estimates.

The format should provide a structure which will handle ancillary information in the form of either cellular data, numerical lists, or alphameric lists. Interleaving of bands by

pixels or by lines should be determined by the needs of the users with less sophisticated facilities. If the data demand is sufficient, both types of interleaving could be available as standard products. Most non-research users will probably not be concerned about the types of sampling techniques used in correcting the data but they should be informed about such techniques and their possible consequences. The more sophisticated user may wish to acquire the raw data and perform his own sampling and correction for purposes of incorporating the data with a particular geobase information system. Since inventory, monitoring, and change detection are expected to be among the principal applications of Landsat data by user agencies, it is important that the registration of this data with other data sets, or images, be well within one pixel. In addition, the user should be able to order small segments of data rather than a large standard frame. For example, many users work with areas corresponding to single or a few 7.5 minute quad sheets and much local processing time could be saved if they could obtain Landsat data covering only the area of their interest. To facilitate this type of archive retrieval it has been suggested that full geometric and radiometric calibration be performed by swath.

There are many other data features and processing considerations which could make the Landsat data more attractive and accessible to the potential user community. It would be extremely helpful if users were able to identify and have access to persons or facilitites in their local region who/which could provide the user with information and assistance in obtaining and using Landsat data. Many potential users today have the need for, and the interest in using, Landsat data but are limited in their hardware and software capabilities. There exists a need to provide modified versions of existing software packages which would fit on the smaller computers often available to these users. One of the most pressing needs today is the availability of a relatively inexpensive method of producing a permanent and attractive display of a processed final product. For most user agencies a black and white character printout is not an adequate final product. The user frequently desires a product in a color film format which is inexpensive and which preferably can be obtained locally.

Electronic fund transfer systems

Electronic funds transfer systems (EFTS) were considered for several years to present significant cost savings opportunities to financial institutions. Ideally, their wide scale introduction and acceptance would cut down paper work and enhance the market shares of those participating. Retailers offering services provided by financial institutions would also benefit directly by reduced check costs and possibly by attracting new customers through the convenience of banking facilities at their locations.

For several years, reports of varied systems designs, their promises for acceptance and the favorable impact on their sponsors were widely circulated. However, more recently the pattern of comments has become less optimistic. Now several key areas of concern are emerging:

- What are the roles of financial institutions and retailers as EFT alters the types of locations and of services which they can provide?
- What is the role of government in providing services, particularly when the services might not be a natural monopoly?
- What are the technological impacts of systems which allow for a high degree of concentration of information regarding an individual and his transactions.
- What legal modifications must be enacted due to the consumerist, anti-trust, and institutional changes which are brought about by EFT?

The last few years have demonstrated that the design and development of systems to achieve EFT's objectives may be the easiest part of EFT. Complexity arises because individuals and institutions are less willing to accept change than had originally been contemplated. Institutions often find more significant disruptions to their business activities than they had expected. Technological change is easier to design than to implement.

The National Commission on EFT, organized to review the societal ramifications of EFT, did not produce a report which could be easily implemented legislatively. Instead, there is still a significant polarization of interests coupled with diminished excitement about projects—most less successful than anyone had anticipated.

However, long term expectations are that certain phases of EFT still have significant promise:

- Automatic teller machine costs are declining rapidly and with more effective marketing, their installation will be more widespread.
- The automated clearing house had to achieve a stage of national interchange before it could truly have an impact on corporations. That has now been achieved.
- Designs of systems used at the point of sale still search for the formula which provides financial feasibility. Success here will be more difficult to achieve.

Meanwhile, financial institutions will explore other techniques, both technological, such as image retention and operational such as truncation, to reduce the costs of offering services. Retailers will make more extensive use of their internal point of sale systems for more economic transaction processing.

Systems auditability and control in an EFTS environment

by RUSSELL DEWEY
SRI International
Menlo Park, California

INTRODUCTION

Losses from accidental and intentional acts involving computers and data communications in financial institutions are growing. The current estimate of losses from credit card fraud alone is $500 million and could rise to $6 billion to $10 billion by 1986. Of greater concern than this problem is the growing potential for single instances of massive losses as EFTS grows and participants become highly dependent on continuously available computer services where most of their assets are stored in electronic form.

There is obviously a need to apply the principles of secure systems to the emerging development of EFTS, and much work has already been completed and published (See References 1 through 9). Most of this work has been focused primarily on the technology of security, such as: Personal Identification Numbers, Plastic Card Security, Cryptography, Physical Security, and Operating System Integrity.

On the other hand, there is also a growing awareness that EFTS security is a "people" problem. The risks, threats, and vulnerabilities to EDP systems derive primarily from the activities of individuals, either accidental or deliberate.[7,10] In the EFTS environment, individuals may be employees of the financial institutions, merchants, telephone company, hardware and software vendors, maintenance personnel, computer service bureaus, security personnel, and auditors.

Between the two orientations—technology and occupation—a body of information is emerging regarding audit techniques, and system application controls that, if implemented, could help reduce the potential for significant loss.[5] The purpose of this paper is to review and summarize the state of that art within the context of the EFTS environment.

THE EFTS ENVIRONMENT

The number of financial terminals being installed in remote locations to automate all or part of the transfer of credits and debits is increasing. By 1980 there may be over 100,000 terminals providing a variety of EFTS services, including:

- Deposits
- Withdrawls
- Transfers of balances between accounts
- Direct Debits for purchases
- Balance inquiries
- Check authorization and guarantee
- Credit card authorization and data capture
- Corporate cash management
- Funds concentration
- Corporate to corporate wire transfers

During the last few years, components of EFTS technology have begun to be implemented in a variety of different configurations, including shared access networks. A shared access network is one which allows for the switching of EFTS transactions to more than one possible destination, regardless of ownership considerations. Since this environment is more complex than single institutions dedicated to EFTS, we will focus on shared access networks for this paper.

The likely evolution of such shared access networks may be described by its principal components:

1. Remote Terminal—The terminal may be operated entirely by one person, such as an Automated Teller Machine (ATM), check guarantee terminal or cash management terminal. They may also be operated by an intermediary, such as a financial institution teller or merchant sales person.
2. Communications—The terminal may be connected to a computer located at a merchant, corporation, or potentially a government facility. In this case, the originating computer must be connected to the destination computer through intermediate computers and telephone communications facilities. Depending on the complexity of the local environment, the number of institutions participating, and economic considerations, the terminal may optionally be connected directly to a local financial institution, directly to a joint

venture shared EFTS switch, or through common carrier facilities directly to the destination.

3. Files—EFTS files take several forms and may be found in several discrete locations:

   - At the remote operator (merchant, corporation, government agency) there may be audit trails of EFTS transactions passing through, or decision parameters to control the processing of transactions when the remainder of the network is down. There are likely no balances, account data, or financial institution programs.
   - At the acquiring financial institution there may also be audit trails, but also balances and account data for its merchants and corporate customers and for transactions that do not need to be switched, such as an "on-us" debit. The acquiring financial institution may also have decision parameters to control the processing of "not-on-us" transactions when the remainder of the network is down.
   - At the EFTS switch there may be audit trails and decision parameters for any destination facility that may be down. There are likely no financial files, other than reconciliation totals and settlement amounts between institutions.
   - At the destination financial institution there may be audit trails, memo-post master file balances, transaction files with backup and off-line master files with back-up.

4. Communication Equipment—Each computer site will have specialized hardware to interface the EDP system to the external communication lines.
5. EFTS Software (Program Logic)—Each computer that is expected to participate in such an EFTS network must have specialized programs developed. These include:

   - Terminal protocols
   - Message format conversions
   - Switching and routing logic
   - Interface logic/protocol to other computers
   - Interface to existing financial software, such as:

     — Demand deposit accounting
     — Savings account accounting
     — Customer information data bases
     — New account processing

   - Specialized audit techniques and application controls

EFTS APPLICATION AUDIT TOOLS AND TECHNIQUES

The transition from traditional financial institution recordkeeping to today's EFTS application systems—characterized by large on-line master files, lack of manual intervention, and remote terminal entry—has brought with it design concepts that cannot rely on traditional manual control procedures. The accuracy and reliability of EFTS application processing is becoming more dependent on the incorporation of automated application controls (discussed in the next section). The purpose of the EFTS audit tools and techniques is to evaluate those controls, verify processing accuracy and continued compliance with processing procedures.

Some of the key audit tools and techniques that apply to the EFTS environment and verify the correctness of processing logic and controls include the following:

- *Base Case System Evaluation*—Execute application programs against test transaction data, entered through a "test mode" EFTS terminal, and compare results against pre-determined test results.
- *Parallel operations*—Execute new or revised application programs and existing application programs and compare results.
- *Integrated Test Facility (ITF)*—Enter test transaction data through live terminals commingled with live transaction data.
- *Parallel Simulation*—Live transactions are copied and processed against auditor programs that simulate processing logic. The simulation results are then compared to the live results.
- *Transaction Selection*—Systematically screening and selecting transaction samples entered through EFTS terminals for subsequent manual verification.
- *Embedded Audit Data Collection* (Sometimes known as *System Control Audit Review File: SCARF)*—Audit subroutines are embedded in the application programs to screen and select internal generated messages between EFTS logic modules that result from the original terminal transaction.
- *Terminal Audit Software*—Direct access to inspect live files during actual operation of the EFTS. The auditor will want to examine terminal polling lists, routing tables, merchant codes, floor limits, and default authorization tables.
- *Snapshot and Trace*—Secure documentary evidence of logic paths, control conditions, and processing sequence of a specific transaction. This is done by continuously recording transaction status for some selected transaction as it passes through the system.
- *Job Accounting Data Analysis*—Select, extract, and display job accounting data to monitor access to sensitive data files and on-line libraries.
- *Code Comparison*—Use of an off-line program to compare two versions of an application program to identify differences in coding.

EFTS APPLICATION SYSTEM CONTROLS

The purpose of the EFTS Application System Controls are to assure the accuracy and completeness of the processing results, the security of the environment in which the EFTS transaction is effected, and the effectiveness of the overall computer design and operations.

The controls described in the following sections are some of those likely to be beneficial in the remote terminal EFTS environment. They are grouped according to five phases:

- Transaction Origination and Data Entry
- Data Communications
- Computer Processing
- Data Storage and Retrieval
- Output Processing

TRANSACTION ORIGINATION AND DATA ENTRY CONTROLS

In developing controls within this phase, an organization may wish to implement:

- *Special-Purpose Forms*—At merchant operated or teller operated terminal locations. Proper form design encourages completeness and accuracy of data. In the cardholder operated terminal environment, Video Display Units (VDU) may be used for pre-formatted and/or interactive input.
- *Transaction Identification Cross-Reference and Source Document Numbers*—This control calls for sequentially assigned source document numbers (or sequential screen numbers) which are transmitted to the EFT processor as part of the transaction identification.
- *Sequence Log*—An internal log of which sequence numbers have been assigned to which merchant/teller locations or cardholder operated terminal location.
- *Signatures*—In the EFTS environment this control consists of appending a series of endorsements to each transaction as an audit trail of each node that handles it. It also serves as a "return destination" for undeliverable messages. The first endorsement is the terminal I.D.
- *User Identification*—A unique identification by class of user (cardholder, merchant, teller, bank supervisor) used to restrict the transaction to be processed as well as files that may be accessed.
- *Batch Serial Numbers*—Batches are identified by serial number to provide accountability of data, and to assist in the isolation of errors when an EFTS terminal cannot successfully reconcile at end of day (or other cut-off time).
- *Limit the Number of Transactions in a Batch*—This is done to simplify the reconciliation process.
- *Turn-Around Documents*—The source documents contain pre-recorded data in machine readable format. This will simplify processing in the event the on-line system is down and paper documents are used as back-up.
- *Retention Dates on All Transaction Logs*—This is based on legal requirements and management policy.
- *Source Documents Maintained at Origin*—In the EFTS interchange environment this means two things: (1) The paper documents (credit card vouchers, debit card vouchers, deposit slips, withdrawal slips) are maintained as closely as possible to the acquiring bank, to prevent unnecessary risk of loss through transportation, and (2) the electronic version of the EFTS transaction is also maintained at the acquiring facility until balanced at the end of the day. Subsequent settlement between banks, and actual movement of value data for posting can occur in batch mode at lower cost and higher reliability.
- *Error Logging*—Maintained by the acquiring facility to record and monitor the type of errors occurring at the terminal. Suspicious patterns of such errors could imply an attempt by an outsider to breech system security.
- *Verification of Re-Entered Data*—The data fields on resubmitted transactions are subjected to the same verification procedures as the original transaction.
- *Security of EFTS Terminals*—EFTS data entry terminals should be physically secure by placement in a lockable room, putting a keylock on the terminal itself, or by placing a lockable cover over the terminal device when not in use.
- *Terminal Logs*—Journals in the terminals to record all transactions.
- *Terminal Control Logs*—Journals in the terminal controllers to identify imposter terminals on the network (i.e. controller total of transactions should equal the sum of the legal terminals.)
- *Built-In Terminal and Terminal Controller I.D.'s*—These devices are provided with electronic identification that can be queried by the computer; used to validate proper terminal authorization.
- *Editing and Validating Routines*—These may be partially performed in the terminal itself, given anticipated hardware capabilities.
- *Passwords*—Used to verify that the input is being received from an authorized source. Likely to be the Personal Identification Number (PIN), although other techniques are being actively explored.
- *Unauthorized Access Attempts*—An immediate report is produced of unauthorized attempts to access the system. After a threshold of repeated attempts the system shuts down the terminal in question and allows access from that terminal only after intervention by security personnel.

DATA COMMUNICATION CONTROLS

In developing controls within this phase, an organization may wish to implement:

- *Secure Phone Equipment Rooms*—Locks and alarms are used to control access.
- *Network Configuration Polling Table*—No open addresses for unauthorized terminals to gain access.
- *Communication System Control Log*—To detect any unauthorized changes to the network done through network supervisor terminals.
- *Communication Line Routing*—Data communication lines are not put through public switchboards (PBX).
- *Local Loop Security*—Between the terminal, or termi-

nal controller, or computer, and the telephone company branch office.

- *Encryption Techniques*—Such as the National Bureau of Standards (NBS) Algorithm. For an excellent discussion of encryption techniques, see Kaufman and Auerbach.[1]
- *Forward Error Correction (FEC) and Automatic Request for Retransmission (ARQ)*—Common types of link control; to control transmission errors on each segment of a transaction path through the EFTS network to the cardholder data base and back to the terminal.
- *Message Sequence Number*—Each transaction at an EFTS terminal may generate several messages (terminal-to-acquiring CPU, acquiring CPU-to-switch, switch-to-cardholder CPU, etc.). This provides a traceable log to match inquiry with response, detect lost messages, or detect imposter messages.

COMPUTER PROCESSING CONTROLS

In developing controls within this phase, an organization may wish to implement:

- *Monitoring of Internal-Generated Messages*—Internal generated messages (such as an authorization request to the issuer on an interchange withdrawal transaction) should be uniquely identified and cross referenced to the external transaction that spawned them.
- *Control Totals*—Reasonableness checks and internal control totals between program modules.
- *Default Option*—Each level in the system hierarchy may need to make decisions in default when the rest of the system is down, or when it is uneconomical to do so (e.g., the merchant bank may authorize a $3.00 transaction against a negative file instead of requesting authorization from the issuer).
- *Dual Fields*—All entries should be carried as a credit against one account and a corresponding debit against another, throughout the life of the transaction.
- *Arithmetic Accuracy*—Techniques such as double arithmetic and arithmetic overflow checks are placed in critical points in the application.
- *Destructive Update*—Debit and credit type entries are used to correct error conditions, not delete or erase commands.

DATA STORAGE AND RETRIEVAL CONTROLS

In developing controls within this phase, an organization may wish to implement:

- *File Classification*—Each file is classified by security level, and access is restricted by level.
- *Data Base Control Table*—No data base access is allowed unless it comes from an authorized program module.
- *Program Linkage Control Table*—These tables control the authorized module linkage between programs.
- *Dormant Files/Accounts*—The system reports on dormant files/accounts that suddenly have activity on them. Many attempts at EFTS fraud try to make use of dormant accounts.
- *Excessive Activity*—The system reports on records and data fields that have excess activity over a certain threshold. It could mean that a lost or stolen card is being used.

OUTPUT PROCESSING CONTROLS

In developing controls within this phase, an organization may wish to implement:

- *Reconciliation*—The response to an EFTS request is matched up and reconciled with the original request before completing the transaction.
- *Transaction Log*—The central transaction log is periodically matched against the journal tape in the EFTS terminal. These totals are also verified against individual application control totals.
- *Output Activity Review*—Real-time statistics such as the number of terminals on-line, transaction quantities, and circuit traffic are reviewed by the appropriate management. System generated subjective judgments, such as default authorization, are reviewed by user departments.
- *Device Verification*—EFTS devices whose action such as imprinting a card or dispensing cash is controlled by the application programs will send a status report back to the host computer to verify completion of the requested mechanical operation.

CONCLUSION

Any remote terminal-based interactive system will face a variety of threats. EFTS, in particular, because of the electronic movement of funds and value, will be particularly vulnerable. Fortunately, a number of system audit techniques and application controls are available to the system designer; and more are under development. Depending on the particular system design, careful implementation of these audit techniques and application controls is likely to diminish the vulnerability to those threats.

Electronic fund transfer systems and quality of life

by ROB KLING
Information and Computer Science
University of California
Irvine, California

SOCIAL MEANINGS OF ELECTRONIC FUNDS TRANSFER SYSTEMS[1]

Electronic funds transfer technologies are rapidly emerging. The many different technologies, collectively called EFTs, provide for the transfer of credits and debits and for a variety of related information services. They are likely to be widely used and may easily penetrate our everyday lives. If they become pervasive, they can alter the texture of our society with an intensity similar to that of the radio, automobile, jet plane, electricity, telephone, and television.

In their early years, new technologies offer tremendous promises to increase the quality of life for their consumers. However, when high technologies are adopted on a large scale, they often lead to social problems as small problems magnify in size. For example, cars were an optional novelty and recreational vehicle in the horse and buggy Los Angeles of 1900. Today they dominate the social architecture through freeways which link sprawling suburban tracts, regional shopping centers, and widely scattered workplaces.

Most complaints about modern "industrial technology" focus on large scale, relatively inflexible technologies with centrally managed infrastructures. Thus, the automobile, television, jet planes, and nuclear power raise troublesome problems. On the other hand, individually controllable technologies such as the telephone, cameras, stereo systems, pocket calculators, sewing machines, electric typewriters, and photocopiers have been applauded or silently accepted. It is not "technology" per se, but the social institutions that develop around a technology, that result in praise or mistrust and complaint.

Research studies can shed light on the impacts of different EFT arrangements. But investigators make important assumptions when they select particular social patterns and values to study. It is easiest to select "dominant social trends" such as increasing affluence, urbanization, market concentration, and levels of social integration which have characterized American life during the postwar years. However, the criteria for selecting some trends rather than others are rarely made explicit. *Which* trends will characterize our futures often lie in the eye of the beholder.

Trend analyses often obscure the possibility of important social choices. If the banking industry has been marked by increasing concentration in the last two decades, need that continue? Is it necessary or desirable that all EFT arrangements support that "trend"? While most EFT arrangements are promoted in a way which is consistent with a consumption-oriented growth economy, are any EFT arrangements particularly consistent with a steady-state economy?[2] Such questions are hard to ask, let alone answer with casual trend analyses. This paper provides an alternative form of analysis by explicitly using a theory of social life and a design space for EFT arrangements.

QUALITY OF LIFE

We experience our social worlds and define the quality of our lives in very concrete terms: enjoying coffee with a friend, being frustrated over the noise of a radio or plane, or being disappointed in love, tense over the prospects of losing a job, or amused while watching a child play with a cat. "Quality of life" denotes the subjective meanings we place on our experiences and opportunities. In general, analysts define a good quality of life both by expressed personal satisfactions of people and by the absence of discernible social problems such as crime and unemployment.

Although, there are growing bodies of empirical research about perceived quality of life,[3] *theories* of "quality of life" are rare. Gerson,[4] however, has developed a position which merits serious attention. It emphasizes the relative power of participants in social settings as well as their relative social resources and satisfactions. Gerson's theory forms the basis of the analysis presented here.

We begin with a concept of social order which develops in and through a process of ongoing negotiation.[5] In Gerson's perspective, the problem of reconciling the good of individuals with the good of the largest social group in which they act is that of "creating and managing a pattern of negotiations which is viable throughout the range of (social) scales at which it takes place."[4]

This conception of social life emphasizes joint participation in multiple settings. The subjects of negotiation in each setting are flows of resources and constraints upon them. Resources include both *material goods* such as time and money, and *social goods* such as skills and sentiment (pride, embarrassment, state of mind, etc.). The quality of life of a

participant in a specific setting increases with:

- the resources at his disposal;
- his ability to negotiate new resources.

EFT arrangements may influence the quality of life for participants of a social setting on two different levels. First, they may influence the resources available to *individuals in everyday life* and the ability of *individuals* to negotiate with each other and with organized groups. Secondly, they may alter the resources available to specific organized *groups* and influence their ability to negotiate resources and commitments. In the next section, we will develop six categories for describing patterns of resource distribution and negotiating ability.

CHARACTERIZING QUALITY OF LIFE

We need a systematic way to think about the influences of alternative EFT arrangements upon the *quality* of social and institutional life. We emphasize six characteristics of social settings.

Resource Distribution

- *Opportunity*: the kinds of resources that an EFT arrangement adds to a particular social setting.
- *Ecology*: The extent to which specific EFT arrangements save or consume disproportionately large amounts of scarce non-renewable resources.
- *Coordination*: The extent to which specific EFT arrangements alter the ease with which a party can manage his activities across all the settings in which he participates.

Negotiating Ability

- *Intelligibility*: The extent to which social, organizational, or technical arrangements can be understood by the participants in a specific setting.
- *Dependency*: The extent to which the participants in a specific setting can choose to use or not use specific EFT arrangements without bearing "excessive" costs in resources such as money, time, sentiment, etc.
- *Agency*: The extent to which participants in a particular setting can influence the social, organizational, or technical arrangements in force.

In an ideal world, EFT arrangements would increase opportunities for all parties, and be ecologically efficient; relative to current arrangements, they would be more intelligible, increase all party's sense of agency, and generate so little dependency that consumers could choose to get on and off with negligible costs. In actuality, these values trade-off against each other.

This paper analyzes the ways in which alternative EFT arrangements influence the six aspects of negotiated social life. However, first we need to characterize different EFT arrangements.

CHARACTERIZING EFT TECHNOLOGIES

Most analyses of EFTs are developed in terms of either specific EFT arrangements (e.g., point-of-sale networks, automatic tellers) or specific services (e.g., debit cards, preauthorized payments).[6–10] However, for shaping public policy, it is important to be able to *distinguish between* EFT arrangements (technologies and their associated social organization) that have different abstract features.[7] For example:

- A point-of-sale (POS) network which serves the major department stores to help them improve their cash management may be more effective if it is national rather than regional in scope;
- A national POS network may be much more convenient for people who travel cross country than would a set of regional networks;
- The disruption caused by an unreliable POS network would be less severe if it were regional in scale rather than national.

Many discussions of the opportunities offered and problems posed by different EFT arrangements are *reasoned* through in terms of certain properties of EFTs. For example:

- Discussions of the accessibility of EFT arrangements to smaller banks focus on different ways of *sharing* facilities;[9]
- The impacts of different EFT arrangements on personal privacy are discussed in terms of the *richness* of the data they contain and the extent to which people access such systems;[11]

Analyzing alternative EFT arrangements can be facilitated by developing an appropriate set of attributes to characterize them. In this analysis we propose seven "internal" features:

- *versatility*: denotes the variety of services provided with a particular EFT arrangement.
- *scale*: denotes the number of points of contact and people served by a particular EFT arrangement.
- *coupling*: denotes the extent to which EFTs that provide separate classes of service or which could be factored to serve separate geographical regions are joined together.
- *reliability*: denotes the extent to which specific EFT arrangements are trustworthy, e.g., that the equipment will not fail and that data or funds will not "leak" unexpectedly from the system.
- *richness*: denotes the volume and variety of data in a specific EFT that can be linked to a particular account holder or class of transaction.
- *accessibility*: denotes the ease with which people or organized groups may gain access to the services or

data which are collected or provided by a specific EFT arrangement.
- *production costs*: denote the costs of fabricating, administering, operating, and maintaining a particular EFT arrangement.

These features can characterize a variety of EFT arrangements. For example, under current arrangements, automatic teller machines provide a few specialized services, are not very versatile, operate on a small scale, are not highly coupled, are relatively reliable, are data poor, and are relatively accessible to bank customers. In contrast, national automated check processing networks would be more versatile, operate on a large scale, may or may not be coupled with other services, are of uncertain reliability, would be data rich and very accessible.

This set of characteristics can be used to compose many important characteristics of EFTs. For example, convenience increases with ease of access, reliability, and versatility. Similarly, Rule's[11] concept of "surveillance capacity" combines our concepts of *richness, scale,* and *accessibility*. These features are not completely independent. For example, the *coupling* of two diverse EFT operations (such as a POS network and a credit-card transmission system) could lead to a more *versatile* system.

These "internal" features characterize EFTs independently from the world in which they reside. We also need to consider the "fit" between specific EFTs and the social, legal, and economic world in which they are embedded. For example, automated checking systems will be substantially more convenient if electronic records are accepted as proof of payment. This motivates our sole "external" characteristic:

- *fit*: an EFT arrangement has a better fit with a given social, legal, political, or economic arrangement to the extent that the conventions of the two coincide.

ASSESSING EFT IMPACTS

The last two sections developed a design space for EFTs and a specific set of features to describe the quality of life in specific social settings. The analyses developed here will be clustered under each of the six aspects of quality of life developed earlier: opportunity, intelligibility, dependency, agency, ecology, and coordination. Each of these six aspects will be considered from the perspectives of (1) everyday life of individuals and (2) institutional arrangements.

Opportunity

Increases in "opportunity" are the raison d'etre of EFT developments. While EFTs may increase opportunities for some people, they may diminish opportunities for others. Presumably, many individuals would gain access to new financial and related services.[10] Yet, some EFT arrangements might endanger the existence of unpopular political groups by enabling abusive surveillance and harassment.[6,7]

Most EFTs have been developed by private businesses which seek to open new markets and increase operating efficiencies. And they have been supported by public agencies such as the Federal Reserve Board which seek to enhance their institutional efficiency and effectiveness. Since most accounts of EFT arrangements emphasize the enhanced opportunities the technology provides, they will not be elaborated here.[9,10,12] In general, EFT arrangements will offer greater opportunity to larger institutions with increasing levels of *scale, coupling, diversity,* etc.

Intelligibility

The National Commission on Electronic Fund Transfers argues that EFT developments should be fostered so as to maximize the number of available kinds of EFT-based services.[9] Yet, different EFT arrangements can alter the coherence of people's business relations in two primary ways:

- They can simplify or complicate specific transactions and financial contracts;
- They can alter the demands made upon people to understand available products.

As personal choices increase, so do the demands upon them for understanding the array of options available and the relative benefits of each. We have little understanding of the conditions under which people experience increased choice as bewildering.

Some leads may come from research on human memory. Twenty years ago, George Miller publicized his famous finding that people could retain "seven plus or minus two" chunks of information in short term memory; the number of distinct things that people can remember and compare depends upon the ways in which their characteristics are coded. It also appears that individuals cannot easily remember or cope with the details of an arbitrarily large number of choices.[13] In economic terms, the "information costs" borne by consumers may increase as additional EFT arrangements become available.

A second issue is the complexity of particular financial transactions. Altering the complexity of a few routine transactions, such as paying a utility bill, has minor ramifications. In this case, authorized pre-payment schemes may have mixed effects: they may simplify routine payments, but make it more difficult for consumers to detect and correct foul-ups. However, if EFT arrangements become so widespread that they become the medium for most routine payments for essential services, then individual consumers may find the technology not altogether "labor or attention saving."

One societal arrangement is preferable to another *if* it can be easily comprehended by lay people as well as by specialists. Versatile EFT arrangements which provide a myriad of related information services (such as funds transfer, accounting, electronic mail, etc.) to a variety of institutions

can easily boggle the minds of most people. Large scale EFT arrangements should be judged by a criterion of "manageable complexity." This means both:

- that people can understand the contours of an EFT system;
- that EFT arrangements should not confuse the regulatory distinctions between banking, communications, etc. and the domains of the regulatory agencies such as the FCC, FTC, etc.

EFTs become less coherent as they increase in versatility, scale, and coupling. Precisely those features that increase the "opportunities" provided by EFTs to some parties can render them incomprehensible to the people who are authorized to act on behalf of the public.

"Intelligibility" is also influenced by purely technical issues. As Weizenbaum[14] points out, very large computer programs develop in such a way that they cannot be easily understood by their designers or implementors. This issue has many difficult aspects. Some concern the limited ways we have of representing the design and behavior of computer programs. Users and auditors of computer programs have occasion to ask very different questions about a set of computer programs and the hardware on which they run:

- what computations (tasks) can these programs perform?
- What kinds of computing resources will they consume in the course of carrying out a specific computation?
- Under what conditions will these programs fail to operate properly?
- Under what conditions will data "leak" from one path in these programs to another path in these programs?

Currently, computer specialists have very few means of representing system specifications. These difficulties are compounded by the ways in which large software systems are developed; on such projects, many architectural details which are unspecified in a grand design are resolved (or altered) by specialists who are working on complicated subproblems. The net effect is that it is common for many programmers to introduce minor but significant design details which are essentially undocumented.

The quality of available documentation is also strongly influenced by the widespread distaste many professional programmers feel for documenting their work. While different strategies for organizing software production and document preparation are being developed to help minimize these difficulties, there are, in general, no clear and reliable solutions today.

Dependency

To the extent that people depend upon a particular arrangement, they may lose their power to negotiate alternatives later on. Benign technologies provide people discretion in their decisions either to use them or drop them should they choose to.

Dependency means both reliance upon a particular good or service or reliance upon a single or small set of suppliers. While all social life is based on complex patterns of mutual dependency, "good" social relations allow some parity between parties.

New technologies such as computing, in general, and EFTs, in particular, attract many consumers because they extend their "reach." The same can be said for electricity, automobiles, and the telephone. Problems emerge when we develop complex forms of social organization which are dependent upon the reach provided by a single technology or system. Thus, the Northeast power failure of 1965 and the New York failure of 1977 were particularly disruptive because people had few alternative energy sources for illumination and appliances.

Not all pervasive technologies are essential. Plastic wrap could disappear, or even television could be discontinued without a major national emergency. However, we would have a tougher time cutting back telephones, electricity, and automobiles. To the extent that EFT services *replace* current means of payment, they will become more like electricity than like plastic wrap.

Particular individuals may organize their lives so that they are more or less dependent upon a given technology. Thus, in Southern California, some individuals insist on driving their cars even one city block, while others make elaborate arrangements so they can bicycle to work amidst a maze of freeways and boulevards. It is a quite different question whether a social collectivity can easily switch from one technology to another.

Payments mechanisms are an essential part of a social infrastructure. In that, they are like transportation and personal communication. Once an attractive new technologically based capability is developed, many institutions can alter their style of business so that they effectively depend upon it.

Large scale, specialized, complex technologies take a long time to plan and implement. In the course of developing a plan, thousands of people may become involved. Thus, even "feasibility plans" develop tremendous inertia. Even when major design flaws are found, it is difficult to redesign or retrofit large scale systems. The BART system in the San Francisco Bay Area provides a particular object lesson here.[15]

In general, the larger the *scale, versatility,* and *accessibility* and the less *costly* an EFT service becomes, the more likely we are to become dependent upon it.

Agency

In the western liberal tradition, personal influence is a central moral and political value. In the American political system, in theory, the voter is sovereign. And in the neoclassical theory of the free enterprise system, the consumer is held to be sovereign.[16] Social and technical arrangements should be valued to the extent that they enhance the sovereignty of individuals. To the extent that they enhance the

influence of already powerful groups over weaker groups, they should be viewed with caution.

We have little understanding about the ways in which different EFT arrangements alter the influence of people in their daily dealings with business enterprises and government agencies. EFT technologies can enhance the control of either individuals or EFT-using institutions. The actual patterns of control that emerge have less to do with technical capability than with institutional prerogatives. For example, while it is easy to implement "stop payment" mechanisms in automated check processing systems,[6] proposals for such systems usually neglect these features. In fact, studies of consumer preferences seem to show that most people who use some combination of cash, checks and credit cards are satisfied with the sense of control over their finances that these payment media offer.[9]

One may wonder whether particular EFT arrangements alter the ability of the polity to act as a collective agent on its own behalf. The recent court cases brought by the U.S. Department of Justice against IBM indicate that it is easy for a corporate giant to overwhelm the resources of a federal agency. Specific EFT arrangements may lead to an even weaker balance of power between Federal or state regulatory agencies and large EFT using institutions. This may happen by:

- certain EFT arrangements fostering further concentration of capital in selected sectors of the economy.[12,17] The emergence of "superbanks" would be one such development. While there are over 14,000 commercial banks in the U.S., over 70 percent of all deposits are controlled by the 100 largest banks.
- EFT arrangements becoming so complex that EFT operations could not be easily influenced by focused collective action such as Federal legislation or regulation.

These observations don't lead to easy policy positions since federal regulatory agencies have also been an imperfect device. They have been criticized for both insensitivity to the public, and for being whimsical agents for businesses to deal with.[17,18] In general, the larger the scale, the more versatile and the more highly coupled EFT operations become, the more they are likely to foster large enterprises on one hand, and demands for Byzantine regulatory devices on the other.

Ecology

In a period of limited resources, we must emphasize technologies which are energy and resource efficient. Projections about energy and resource efficiency and conservation have to be carefully assessed for specific technologies in specific settings. For example, narrow estimates of the paper-saving efficiency of photocopiers would focus on the amount of carbon paper saved. However, in most settings where copiers are used, paper and energy consumption has probably increased. This is not to say that photocopiers ought to be restricted; rather that projections for resource conservation need to be made based upon expected volumes of service rather than upon efficiency criteria alone.

On a larger societal scale, the resources consumed by particular EFT arrangements must include the costs of capital construction as well as the resources to operate them. In a recent analysis of the economics of mass transit, Lave[19] has argued that rail systems have lower *operating costs* than automobiles and buses; However, they have *higher overall costs* when one factors in the costs of constructing rails and vehicles. Is it possible (or likely) that the same patterns hold for large-scale EFT arrangements relative to their manual (paper-based) precursors?

An ironic development with some current EFT arrangements used by banks is that they are used to increase the volume of financial transactions generally.[10,20] Thus, a current side-effect of some "paperless" EFTs is a net increase in the net amount of paper flowing through the banking system.

If energy prices continue to rise, the relative attractiveness of EFT based services and its traditional alternatives will shift. If particular EFT arrangements are clearly conservative of resources, they might be promoted through positive public policy. On the other hand, those EFT arrangements that are relatively expensive in energy and nonrenewable resources might be discouraged.

Coordination

It is an open question whether specific EFT arrangements increase or decrease the ease with which users and others can manage their social and business relations. It is a commonplace observation that "labor saving" devices seem to have exacerbated the plight of the "harried leisure class."[21] While EFT advocates proclaim the array of "conveniences" that EFT arrangements may provide, these claims seem to be oddly isolated from the overall problems that they may induce. When they work well, some EFTs may lead to small increases in convenience for consumers. In addition, new information services, such as accounting-like payment summaries, may help people organize their business affairs. However, when payments records are in error, the "costs of coordination," e.g., correcting errors, may increase. Generally, people can spend less effort coordinating their lives in a society that depends upon a large variety of EFT-related services to the extent that they lead to greater *intelligibility*, greater *agency*, and less *dependency* for people.

In a recent article, Rose[12] suggests that small and large businesses may be able to increase their fiscal control through bank-related cash-management services. In theory, the same characteristics of EFTs that lead to lower costs of coordination for individuals and larger institutions should be identical. In practice, the larger institutions can "purchase" greater expertise than smaller businesses and individuals. Thus, we expect larger institutions to gain more from EFT-based information services when they work well. However, organizations, large and small, will ease their burdens of coordination to the extent that EFTs grow in *versatility, richness,* and *reliability*. In addition, enterprises with geo-

graphically dispersed activities—already a large and growing fraction of private enterprise and public agencies—will benefit from increases in the *scale* of EFT arrangements.

EFTs and broader social patterns

This paper has developed a design space for analyzing different EFT arrangements. It appears that certain EFT designs (e.g., *smaller scale, less coupled*) present fewer potential social problems that EFTs of alternative design.

Despite these normative considerations, EFT developments are rapidly emerging in the current industrial system[22] and the existing legal and regulatory arrangements. Growth is a dominant feature of large enterprises; both the computer and financial industries are highly concentrated.[23,24] For expansion seeking suppliers of computing equipment, EFTs offer a lucrative new market. For financial institutions, EFTs offer strong potential for increasing their market share. Firms in both industries may gain from large scale, rich, and versatile EFTs.

As EFT services spread, failing to integrate several related services that are manually linked by different users or consumers may appear oddly "inefficient." Thus, the integration of large scale, highly versatile EFTs may be less the product of a grand design than the by-product of many small "locally rational" decisions. Unfortunately, the "tyranny of small decisions" easily leads to an overall arrangement which no one would have sought had the long run designs been made explicit early on.[25]

It is commonplace to notice that some values trade off, that others are mutually supportive, and that some design values and social values conflict. More reliable technical systems often have higher production costs. Larger scale and more versatile EFTs which provide more opportunities for users and consumers. But they are also likely to be less intelligible and diminish agency when compared with less expansive EFTs.

Whether one speaks of value conflicts or "tradeoffs," the social choices we face are no longer very simple.[26] There is a cartoon caption that reads:

> There's a price tag on everything. You want a high standard of living, you settle for a low quality of life (quoted in reference 27).

In order to help make our choices less grim, I believe that we should have clear answers to several questions. These are elaborated in the next section.

RESEARCH AGENDA

The analyses of this paper indicate some of the social dilemmas posed by EFTs. EFTs are not all alike. Some, such as automated tellers, may be more amenable to small scale operations than, say, automated check processing.[6] To the extent that EFTs increase the intelligibility of social arrangements, ease of coordination, and social agency, while decreasing dependency for the public, they may be thought of as especially benign technologies. These hopes may be problematic at best and naive at worst. Studies which need to be done include those to:[28,29]

- Examine the market structure of firms which use and provide EFT services to determine which EFT arrangements foster increased concentration amongst a few firms and which arrangements support a diverse array of smaller scale businesses.
- Identify important social costs and develop ways to internalize them into pricing schemes for EFTs. Many of the social costs of EFTs suggested in this paper and elsewhere[6,7] are intangible. Furthermore, they may appear only after EFTs reach an advanced form of development and widespread use.
- Understand what it means for consumers to have "perfect information" about the choice of EFT services. If social costs cannot be internalized into EFT pricing, as is likely, determine how the public can be best informed about what they are.
- Develop stronger forms of consumer sovereignty in oligopolistic markets. It is easy to assume and difficult to demonstrate the sovereignty of consumers in complex business and financial markets. The structural role of consumers relative to EFT providing institutions ought to carefully investigated.
- Understand which EFT arrangements are most consistent with a low growth rather than high growth economy.
- Understand how to develop EFT technologies and their associated social arrangements so that they are easy to roll-back, if necessary, without major social upset.

Effective public policies to resolve many of the dilemmas raised by pending EFT developments must foster broad consensus among social groups with conflicting values and interests. In setting a research agenda, we should be fully aware that by selecting important values for study, we may superficially threaten active interests. This is a problem of doing serious research in a highly charged setting.

Special purpose terminals

This technical area focuses on the current state of the art in Special Purpose Terminals and provides a forum for discussion of the future trends in Special Purpose Terminals. The sessions are balanced to provide sufficient definition, by contrasting the Special Purpose Terminal with the General Purpose Terminal, along with special aspects of terminal operations such as voice input.

The criteria associated with planning a special purpose terminal for a given marketplace is explored. The major influences exerted by Engineering, Marketing, Manufacturing and competition are examined and placed in perspective. It gains this perspective by examining basic trade-offs on cost, performance, implementation, marketplace, competitiveness and profitability.

The areas of market and product existence, product salability, and administrative analysis are examined with details on decision steps required to complete the product planning. It highlights the decision criteria and planning process by walking through a special purpose terminal that was designed to displace a general purpose terminal.

Making a special purpose terminal work in a general purpose system environment complements the decision to produce a special purpose terminal. Labor costs for factory operation along with the need to reduce inventory costs have been a strong motivator for the special terminal in the factory. Most factory oriented special purpose job oriented terminals need to directly communicate with large scale general purpose data processing systems. This technical area presents the system implementation used to connect an interactive factory data collection system on line to a large scale IBM data processing system operating in an IMS data base environment.

The factory terminal system has many requirements which include both general purpose and special purpose parameters: Time and Attendance (Special Purpose), Last Job Checkout (Special Purpose), Inquiry (General Purpose), and Material Tracking (General and Special Purpose).

The method chosen for interfacing the complete system was to emulate a general purpose network of IBM 3270 type CRT terminals. The emulation technique provides for many on-line different modes of operation including the following: 3270 Emulation in the remote communications mode, 3270 Emulation with direct channel attachment, Transparent mode of operation, Data collection

mode of operation, and Interaction with both main data base and fast response local files.

The future of Special Purpose Terminals is broadly covered with emphasis on input devices that complement the environment that we find in the special purpose terminal. "The Future of Special Purpose Terminals" examines current trends in computer terminal development and extrapolates these into 1978-1988 time period, with special emphasis on the transition from large scale integration (LSI) to very large scale integration (VLSI). This session offers projections concerning the demands for special purpose terminals and on the ability of the industry to respond to these demands. Additional explorations are examined in more detail by the panelists who have chosen to concentrate on specific technology areas as well as on the extent in which future advances in technology are likely to affect terminal systems presently in use.

One point of view that will be presented asserts that the single most important attribute of the interactive computer terminal of the future is that it contains a general-purpose computer with the approximate characteristics of a present-day mini-computer. Another point of view points out that voice data entry, long recognized as an ultimate step towards simplifying communications between a human and a machine, is now a reality. Over 200 voice terminals are currently in operation in a variety of industrial and commercial applications in eight countries around the world. New speech input terminals using microcomputers have been introduced which can replace and/or complement intelligent CRT/keyboard stations by enabling the user to enter data by voice.

The potential applications of voice data entry are determined by the economic advantages of voice input as compared to other alternative data entry devices and/or techniques. As the cost of voice data entry terminals decreases, more justifiable applications will arise, particularly when the true costs of data capture are considered. In some cases, voice input offers advantages which far outweigh the direct labor savings and permits certain operations to be achieved which could not easily be accomplished using alternative data input techniques.

A third point of view addresses the impacts of technology advances on current data entry terminals and their use. How long does it take for an incumbent industry or profession to yield to the onslaught of new advances? It observes that keyboard data entry is supposed to have been "dying" for over 20 years, ever since the introduction of optical character recognition (OCR). Each time a new device is developed the cry "keyboard data entry will become obsolete in five years" is heard again. Yet through all of this, there are more data entry keyboards of some type in use today, and more are projectd for the future.

Decision criteria in terminal product planning

THE SPECIAL PURPOSE TERMINAL VS. THE GENERAL PURPOSE TERMINAL

The concept of special and general purpose products is, to a great extent, in the mind of the end user. The application areas have the greatest impact on the definition of special purpose and general purpose. Products which address applications in many areas are considered general purpose. Also, products which address no specific application but can be adapted with additional software or hardware are considered general purpose.

The concept of the product incorporates the market or end usage of the product as special or general purpose also. A grid of special purpose and general purpose terminals and special purpose and general purpose applications emerges (Figure 1). In reality, any attempt to make clear line distinctions as shown in Figure 1 are not realistic, and the more general grid in Figure 2 shows the complexity of this graphic determination. For presentation purposes, only Figure 1 presentation will be used to denote:

A—A general purpose terminal used in a general purpose application.
B—A general purpose terminal used in a special purpose application.
C—A special purpose terminal used in a general purpose application.
D—A special purpose terminal used in a special purpose application.

At this level, some generalities can be abstracted, and some limits to the directions for this paper can be made.

First of all, the general purpose application with general purpose equipment (A) is the realm of the computer center or system user, where the manufacturers equipment or OEM equipment predominates. As a general application evolves, usually additional software is generated, and additional equipment is purchased. Special purpose terminals are difficult to support because of the increased software burden compared to manufacturer supplied system interface oriented terminals (Section C). This is an area in which the special terminals do not survive well. For the purpose of this paper, Section A will not be pursued again.

Section C, which shows special purpose terminals used in general applications, was briefly mentioned above. The special purpose terminals do not stand up well in a general application market. The major livelihood of this type of system results from a terminal addressing a large number of general applications, so that its product life can extend beyond a single level of application evolution. The identification of the general application markets and the development decisions will be discussed later in this paper.

Section B shows a general purpose terminal used in a specific purpose application. The typical environment contains one or more general terminals bound by special software, often with a dedicated minicomputer or microcomputer interfacing a computer system and the special purpose application. A heavy burden is placed on terminal support software to make the general terminals conform to the special requirements of the applications.

Section D shows the special purpose terminal satisfying a special application. The burden on application support usually resides in special hardware features or special microcoding. The trade-offs between Section B and D applications are the most easily understood. The basic problems are availability of components (including major OEM pieces), cost of hardware design, cost of software design, documentation, maintenance and training.

The user implementation aspects for these trade-offs and decision have been covered in numerous other papers and articles. The focus of this paper will be on the manufacturer rather than the user. Section B, C and D will be generalized as part of a larger problem of product planning in the next section, before bringing in examples of the decision making for applications.

THE BASIC INFLUENCES ON DEVELOPMENT OF A PRODUCT

The business units that form the product development group are:

- Administration
- Marketing
- Business Development
- Manufacturing
- Engineering (Hardware and Software)

The interaction of these units create the final product price and function, regardless of where the initial product idea

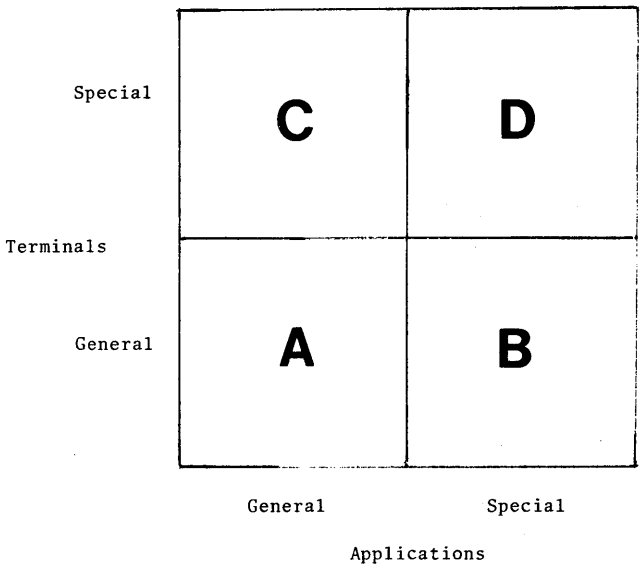

Figure 1—Sectional analysis of decision criteria

originated. Two basic outside influences complete the interactions:

- Customers/Market Place
- Competition

The interaction between all of these groups can be viewed as a feedback system using the approaches of Industrial Dynamics. Figure 3 shows a simplified feedback system for product function and Figure 4 shows a similar function for product price. Both price and function are inputs into each other's system interactions. In this simplified format the elements for Customer/Market Place and Competition are shown as constants but they have their own system dynamics which complicate this picture. For now these simple

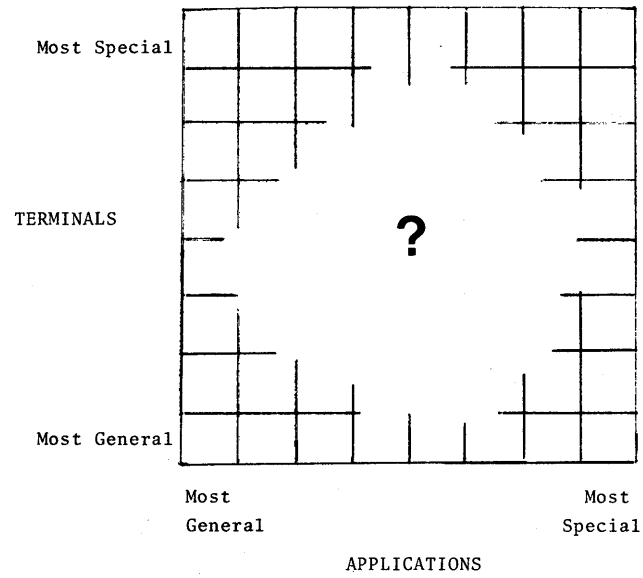

Figure 2—Sectional analysis for real world decisions

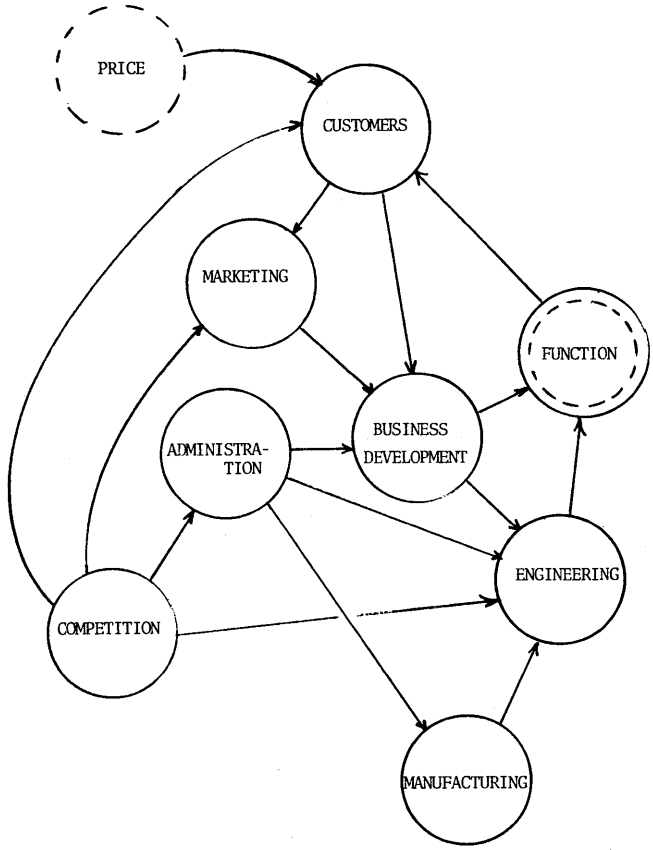

Figure 3—System dynamics interaction for function

techniques will be sufficient. The major intent is to simulate price and function determination in this feedback system until it stabilizes.

As each organization has its own management, department dominancies and interactions, there is no single system that solves how function and price will be determined. In the short run, the system described is likely to be astable. The non-linearities and administrative over-rides keep the real world stable. The major instabilities in the feedback model should be viewed as warnings, to help identify the failings and traps that occur in the process of product function and price identification.

The major problems of the product idea development are documented by many management oriented books and articles. Only a summary of problem areas will be covered in this paper.

- Dominance of a business unit—when all areas do not interact fully, an unbalance price/function decision may be made. Examples are:
  Manufacturing—An easily manufactured product may not have features required in the market place.
  Marketing—Features planned for good sales may cause poor system performance.
  Engineering—Design techniques may limit product utility or adaptability.
  Business Development—Long range goals may make the product initially unsalable.

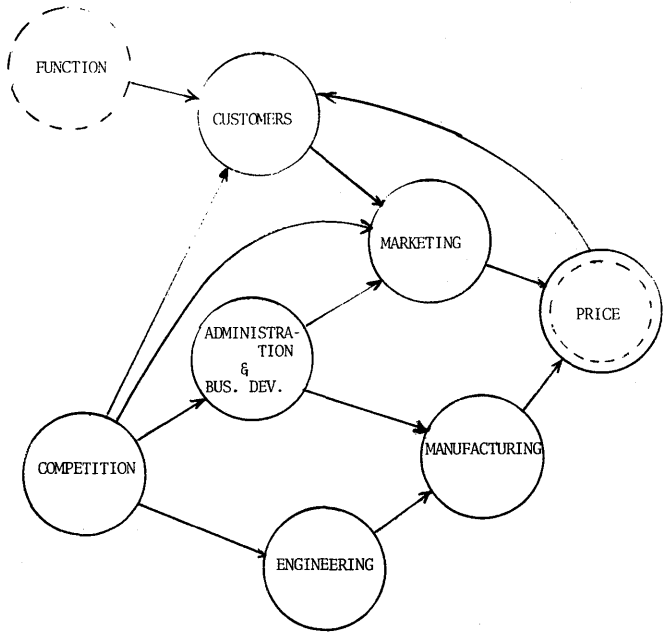

Figure 4—System dynamics interaction for price

- Inability to play "devil's advocate"—when a product idea is developed and all parties "jump on the band wagon," the balancing effects to round out a product may be missing.
- Communication problems may make all parties agree on the words used but have different concepts on the product usage, function and marketplace.

The "tales of woe" can run on indefinitely, but only a sample is necessary to realize that product planning is an art still rather than a science. The intention here is to skip this phase, and proceed to the business decisions in a terminal satisfying Sections B, C and D of the general purpose versus special purpose product.

PRODUCT TRADE-OFFS

For every user trying to decide which terminal to use and how to use it, there is a producer looking at that same problem. The producer has already finished his decision making, armed with the tools of market analysis and statistics. The producer also has his judgment and best guess working for him. When he produces a terminal product, the following factors lead to the general purpose versus special purpose trade-offs:

- Function
- Cost
- Performance
- Implementation
- Marketplace Size
- Competitiveness
- Profitability

These areas of decision and trade-off are interactive, in that a change in one will usually affect another.

An example of the product planning trade-offs can be shown for all these factors.

- *Function*—Function is the easiest factor to handle. The first user decision and equipment selection usually is "Does it do what I want?" Functions planned for a terminal product must be competitive to existing terminals already marketed. In a "plug for plug" replacement market, the unit must duplicate its competitor, and in a general market, the unit must exceed its competitor. This results in the terminal features escalation trends in the industry. A side note on function is that, if a good size market is buying equipment with "bells and whistles" it does not need but has no choice, reducing functions produces a special purpose terminal, generally at a reduced cost, and generally with a reduced market. Note the interaction with Marketplace Size, Cost and Competitiveness.
- *Cost*—The hardest factor to pin down is the cost tradeoffs. The second user decision on equipment selection usually is "Can I afford this?" If the equipment price is out of line with the competition in a marketplace segment, the equipment will quickly disappear from the market without some over-riding function or performance enhancement over the competition. Cost goals during product planning are made reflecting the product nature, split into two basic types: Price Cutters and Function Raisers. Price Cutters must always produce lower cost products, generally with identical functional features. Function Raisers must always produce more functional features (including performance), generally with a higher cost. Occasionally both can be combined and usually appear in the plug to plug replacement market. As cost goals are determined, the product is pushed into a special purpose or general purpose direction or preference. Interactions on cost are Function, Competitiveness and Marketplace.
- *Performance*—This is often viewed as a part of function, but is separate. A 300 Baud terminal and a 110 Baud terminal may have identical functions, but offer distinct performance differences. The tradeoff with special purpose and general purpose performance requirements are strongly coupled to price. The user wants all the performance he can get, if it does not cost him more money. Likewise, the user does not want to pay for any performance his application does not require. Both ends of the performance spectrum lead to a special purpose terminal, mainly because it attracts a limited marketplace that requires the additional performance, or desires the cost benefits. The interactions are Cost, Competitiveness and Marketplace.
- *Implementation*—Implementation is the most difficult portion of the trade-offs to judge. The user sees the packaging and styling and interacts with the operational characteristics. The external features are generally secondary to the equipment user. Internally, the product is strongly shaped by implementation. Functional and

performance growth are effected. Cost and profitability are determined by how the equipment can be manufactured and maintained. The producers emphasis on manufacturing or engineering can shape a product's long-term market and make it general or special purpose to achieve a market share and production volume required by the producer. A producer with low volume and R&D emphasis will tend toward specialized implementations and many product upgrades. A producer desiring high volume and low manufacturing costs will tend toward a generalized implementation to widen the marketplace. Implementation interacts with all the product trade-offs.

- *Marketplace Size*—The product direction to a wide or narrow market with a small or large volume is a producer's trade-off. The general purpose terminal usually is aimed for a large volume with a wide market. The special purpose terminals is usually aimed at a narrow market with a substantial volume. Some special purpose terminals are aimed over a wide market with low volumes in many narrow segments of the market. The decision on customer identification and subsequent marketplace size trade-offs should occur early in the product development cycle to allow the follow-up trade-offs on Function, Cost, Performance and Implementation. The marketplace determination is one of the most difficult ones, and the equipment user interacts in a secondary way, unless equipment is being manufactured to order for the user. The user interacts principally through surveys, sales representatives, and most important, by buying to his preferences in the equipment market.
- *Competitiveness*—This goes 'hand in hand' with marketplace size and forces the decisions on Function, Cost and Performance. The decision on how to compete and with whom to compete is part of all the previously discussed areas. This item also impacts all the above areas because timing of a product release and its subsequent distribution enter into the development cycle. The competitive factor pushes many trade-offs with a business decision to pursue markets, and also, how and when to do it. This factor in particular makes the simplified Figure 1 general versus specific market into the complicated Figure 2.
- *Profitability*—Last but not least important is the profitability trade-off. Profitability is almost always assumed, but is a trade-off along with competitiveness. Profitability is essential for a producer, but the degree and timing of profitability is a trade-off factor. The producer may not become profitable without limit, because the cost will not be competitive or the product will not be purchasable. The profitability in the early stages of a product may be a trade-off against long-term profitability. This factor affects all the other areas before manufacture and throughout the product life. As an unwritten goal it shapes many of the decisions producing special purpose or general purpose terminals.

The product trade-offs that occur in the development cycle affect the production of special versus general purpose equipment. The next step is the actual producers decisions which shape the product and its applications.

DECISION FACTORS IN PRODUCT PLANNING

The trade-offs, detailed above, lead into the actual product planning decisions. The decisions are the end result of the product trade-offs and are the (hopefully) formal documentation of the product direction. In order to concentrate on the basic decisions for product development and planning, a simple technique of 'problem busting' will be used. Problem busting is the subdivision of a major decision—in this case, product development—and generating simpler problems that may be attacked. In a sense, there will be a recombination of the areas discussed in the trade-off section, and responsibility will be assigned to the previously discussed business units.

The first major problem busting will uncover three basic problem areas for a product:

Existence Decisions
Salability Decisions
Administration Decisions

Each of these areas will be discussed and subdivided further to allow proper product analyzation.

The first area of existence decisions concerns fitting a planned product into the real world. The first subdivision is the existence of customer need. Does a customer base exist that needs the product? Does the customer base have the ability to buy the product? The existence of a ready to buy market produces products different from the products requiring an education before customer acceptance. The decision on existence of customer need is most influenced by Marketing and Business Development. The second subdivision is the existence or product viability. Can the product be implemented within the existing or developing technology? Can the product be manufactured within the existing capabilities? Will the product components be available in the future? The decision on the existence of product viability is most influenced by Manufacturing, Engineering and Business Development. The questions shown here break the problems down another level but will not be detailed here. The existence decisions should be made first in the product planning of equipment.

The second area of salability decisions concerns the determination of the product characteristics including the characteristics which make the equipment general purpose or special purpose. The first subdivision is performance and function salability. Can the unit be sold with the planned functions? Can it be sold with the planned performance? Does the unit still attract the customer base anticipated in the section on existence? These are most influenced by Engineering, Marketing and Business Development. This decision formalizes trade-offs on performance and function. The second subdivision is pricing and timing salability. Will the product sell to the customer base anticipated? Is the product on the market in time to sell or too early to be accepted? Can the product distribution handle the product?

These are most influenced by Manufacturing, Engineering and Marketing. This decision begins to lock the product into its role as special or general purpose. The third subdivision is salability against competition. The marketplace and the existing competition are analyzed against the planned product capabilities. Can the unit out-price the competition? Can the unit out-perform the competition? Can the unit 'steal' new business from the competition. Can the unit displace installed products of the competition? Will the unit displace the company's own installed products? The major influences on this are Marketing and Business Development. At this point the product characteristics are firm. The next major set of decisions cover the actual go ahead to produce a product.

The third area of administration decisions produces the final product with any long range modifications to the planned product. The first subdivision is administration of the risk and cost to produce. Can any component not be available in the future? Can any design problem not be solved within fixed constraints of the product? Can key individuals leave the project? Can manufacturing make the quantity forecast economical? Can any Assembly, Test and Quality Assurance areas invalidate basic design areas? This decision is influenced by Manufacturing, Engineering and Marketing. The second subdivision is administration of profitability. Can manufacturing cost and sales price produce a profit with known overhead? Can cost improvements be made? Can manufacturing improvements be made? Can component costs drop with volume and time? Can labor costs be handled? This decision is influenced by Engineering, Marketing and Manufacturing. The third subdivision is the administration of corporate requirements. Can this unit produce subassemblies in common with other equipment? Can this unit use subassemblies from other equipment? Can this unit solve an outstanding problem for another portion of the corporation? Can this unit produce side usage in other areas of corporate business with minor changes? This last area is influenced by all business areas including Administration. At this point the last of the product changes is made and the decision to go ahead with a product occurs. Function and detail specification and marketing literature follow in time, but now the product has become general or special purpose as a result of the previous trade-offs and decisions.

The intention of discussing decision criteria has stayed away from actual mention of terminals and remained as a general analysis. An example of the product planning in a terminal design will be shown in the following section.

EXAMPLE OF A SPECIAL AND GENERAL TERMINAL INSTALLATION DECISION

NCR Data Pathing, Inc. produces factory data collection equipment and systems as front ends for MIS oriented large computer systems. A special purpose data collection terminal, the 103, offered an employee badge reader, a punched card scanner, and keyboard input as well as 16 character message display and a backlighted message panel for output. This unit received wide usage in a narrow market.

In many installation sites, MIS capability was brought out to the factory floor with an IBM 3270 CRT display with keyboard, allowing a general inquiry system to the host computer system. These units often physically resided next to each other. The IBM 3270 is a very general purpose terminal and was used in conjunction with a special purpose terminal in a fairly clumsy manner. As a large number of these combinations showed up, a special purpose terminal with a degree of generality was planned to replace the combination.

DPI introduced the MIT-133 as an IBM 3270 replacement specifically for the factory data collection environment. The MIT-133 had the IBM 3270 CRT and keyboard, but also added a special keyboard for factory environment with large keys and simplified sequential positioning. Also the badge reader and card scanner were added. The keyboard was placed at an angle to make operation easier from a standing position which is typical in factory inquiry, and a quadruple size character font was added to improve readability of the typical short factory messages. This special size character set replaced the 16 character message display, and the backlighted message panel. Special software in the DPI front-end formats the CRT screen with the same data editing capabilities available on the DPI 103.

The unit is a special purpose terminal in a special purpose application displacing a general purpose terminal in a special purpose application. The unit is a function raiser not a price cutter, and the MIT 133 is actually higher priced than the IBM 3270. This unit has extended functions that get the factory data collection job done more efficiently, and as a result, save considerable cost from the main job of MIS, saving manufacturing money.

The decision process covered the customer need and product viability, demonstrated by the actual co-existence of the DPI 103 and the IBM 3270. Performance matched the existing units and was improved by creating a single data entry terminal unit. Pricing and timing recognized additional capability for additional cost when there was a performance benefit. Competitive capabilities were satisfied by incorporating all IBM 3270 features as well as adding new capabilities. Administrative decisions cannot be detailed.

The decision shown here is only a Section B versus Section D, but the decision criteria are valid across all product planning areas.

Making a special purpose terminal work in a general purpose systems environment

by DONALD J. BIRMINGHAM
NCR Data Pathing Inc.
Sunnyvale, California

THE FACTORY DATA SYSTEM

Factory Data Systems have many application requirements not normally satisfied by standard general purpose terminals. In the past twenty years there has been an evolutionary growth of job oriented terminals to satisfy the unique requirements of the factory. To maintain the pace of the current expanding system requirements, the special purpose terminals must communicate on a transaction basis with a general purpose data processing system.

A schematic of a comprehensive factory data system is shown in Figure 1. The factory terminal system has many requirements which include both general purpose and special purpose application parameters in the following areas:

- Time and Attendance
- Labor Distribution
- Job Tracking
- Material Control
  - —Raw Material
  - —Work in Progress
  - —Finished Goods
  - —Shipping and Receiving
- Inquiry
- Tool Tracking
- QA Reporting

Most of the above terminal applications must communicate directly with a large scale general purpose data processing system. This paper outlines the system implementation that Data Pathing Inc. uses to connect an interactive factory data collection system on line to a large scale IBM data processing system. DPI offers special purpose job oriented terminals, general purpose terminals, and terminals which alternately operate in a special purpose job oriented mode and a general purpose mode.

THE SYSTEM FLOW

Figure 2 presents the desired flow of transactions from the job oriented factory terminals through a DPI system control processor to a "host" general purpose data processing system. Not all transaction types have the same real time processing requirements with the host data processing system. Some of the different system requirements include:

- Immediate and Mandatory Interaction
- Queuing for Load Leveling
- Queuing for Time Dependent Processing
- Processing Off-Line for Faster Response
- Processing Off-Line for Back Up Purposes

In most systems the main plant data base is located on the host processor. A prime example of this in the large IBM environment is an IMS data base oriented system.

TYPICAL FACTORY JOB ORIENTED TERMINAL

A typical job oriented special purpose factory data collection terminal is detailed in Figure 3. This particular terminal is designed for "community" applications. A community of workers runs random or time dependent application transactions on the terminal. Examples of the transactions are as follows:

Time Dependent	—Time & Attendance (In & Out)
	—Last Job Checkout (Shift Change)
Random	—Material Move (Function Complete)
	—Material Receipt (Material Available)
	—Labor Transaction (Job Complete)

The DPI SDT 107 is a multi-function terminal which can run the transaction applications gamut from time and attendance through material move to limited inquiry. To do these transactions the terminal incorporates the following features.

- Transaction Descriptions (Applications Menu)
- Transaction Select Keys
- Operation Instruction Mask
- Function Indications
- Keyboard (Numeric and Alpha)
- Alphanumeric In Line Field Display
- Function Keys

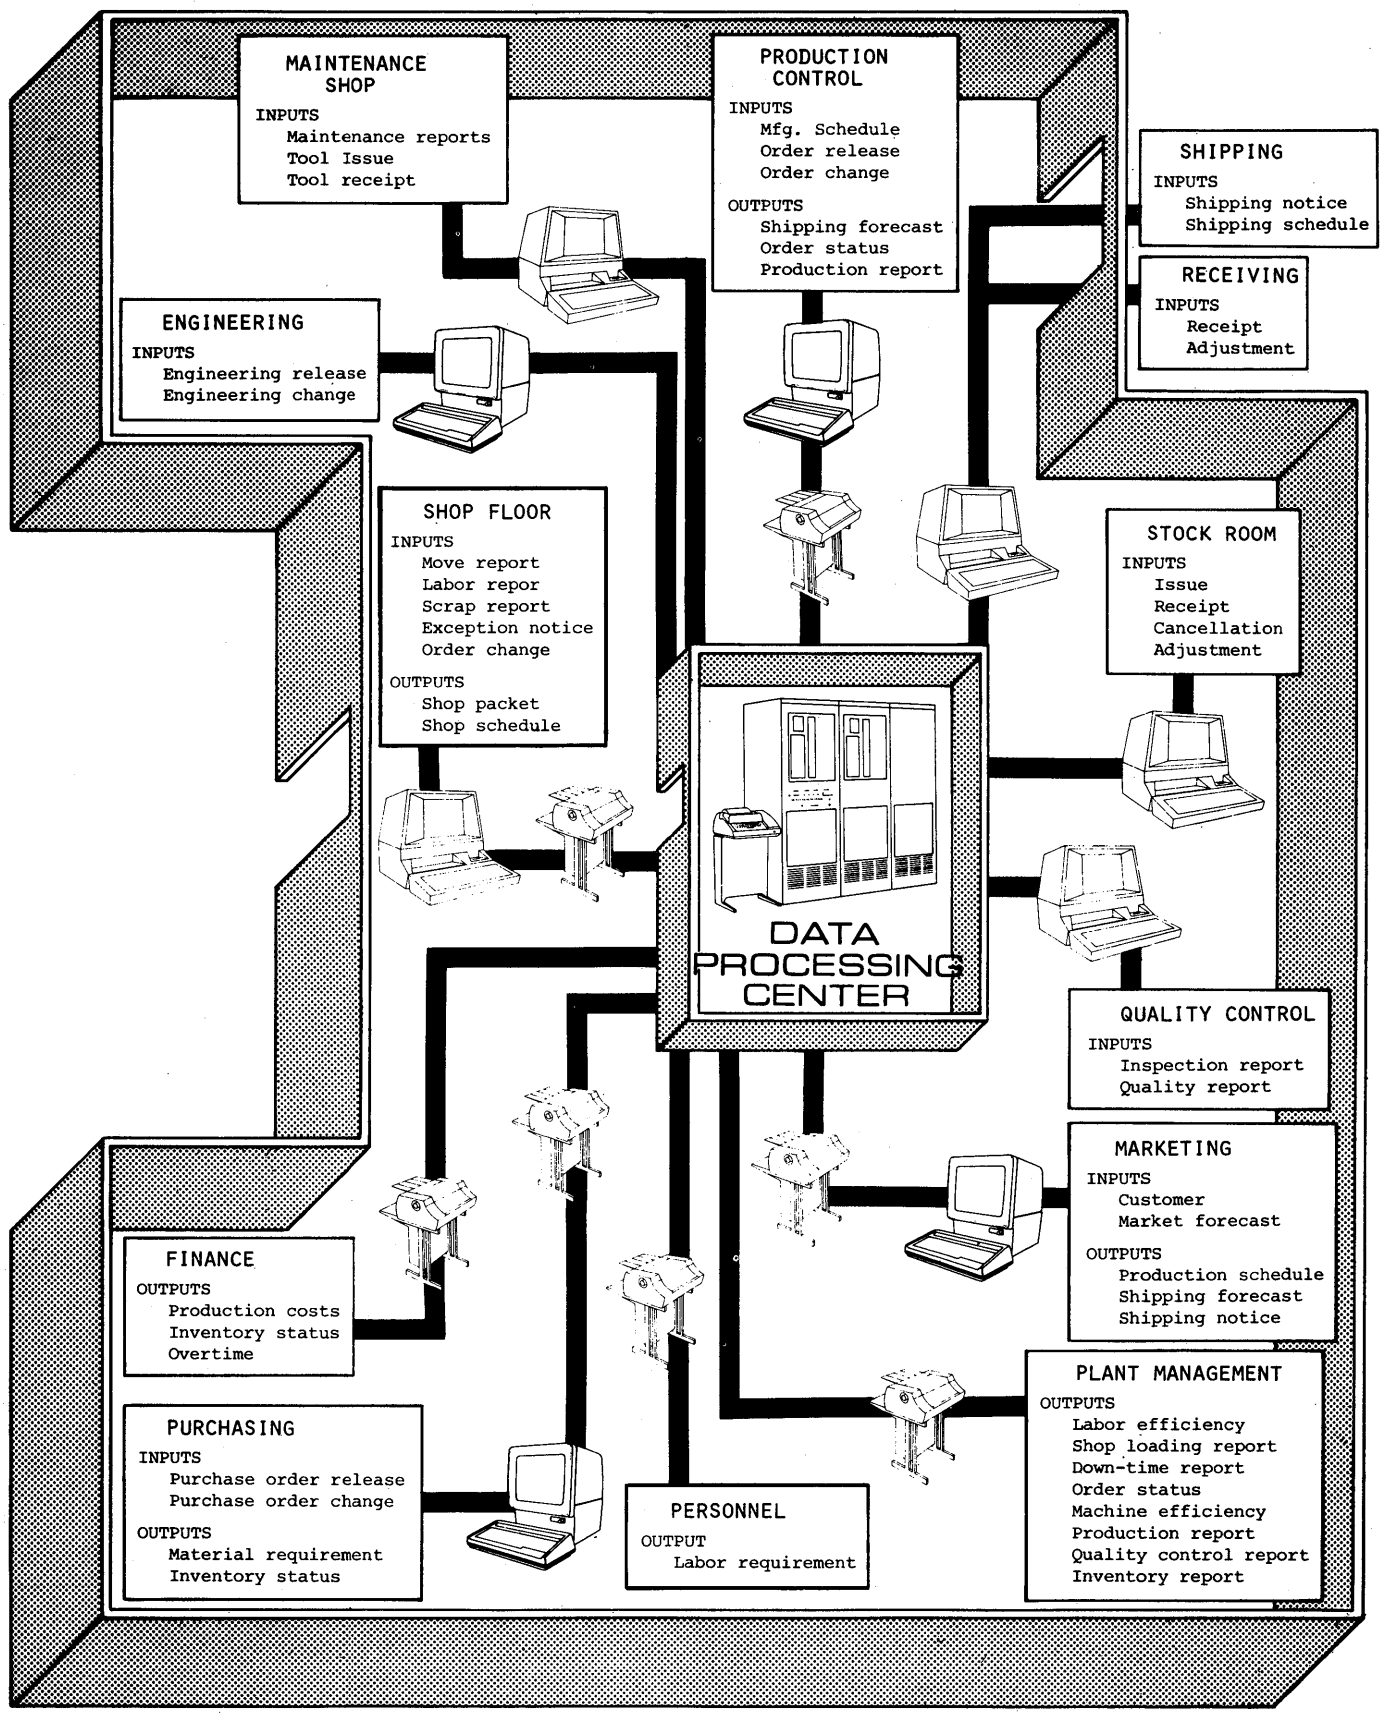

Figure 1—A comprehensive factory data system

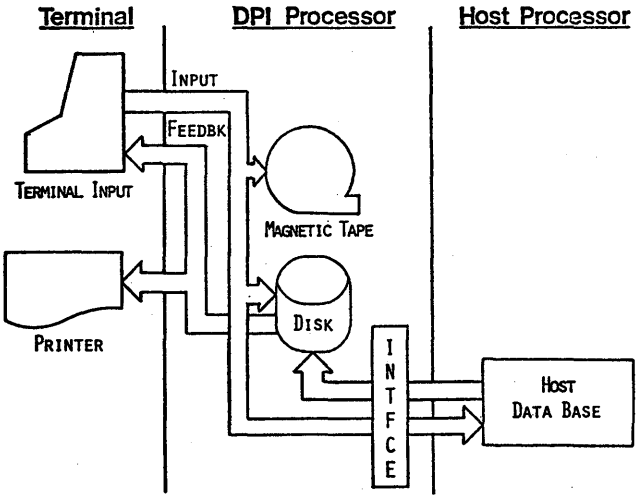

Figure 2—Data disposition

- Badge Reader
- 80 Column Punched Card Reader
- 22 Column Punched Card Reader

THE MULTI FUNCTION FACTORY TERMINAL

The growth of different application terminal requirements has led to the side by side placement of both job oriented and general purpose terminals each installed for specific applications. As new applications are added it becomes a problem as to which terminal the transactions are assigned as most applications have both general purpose and special purpose attributes. To solve this dilemma DPI developed the MIT 133 Factory terminal. This terminal can alternately operate as either a special purpose job oriented terminal or as a general purpose keyboard CRT terminal. In the general purpose mode it operates as an equivalent IBM 3277 terminal. As shown in Figure 4, it has both the main attributes of the general purpose and the job oriented special purpose terminal.

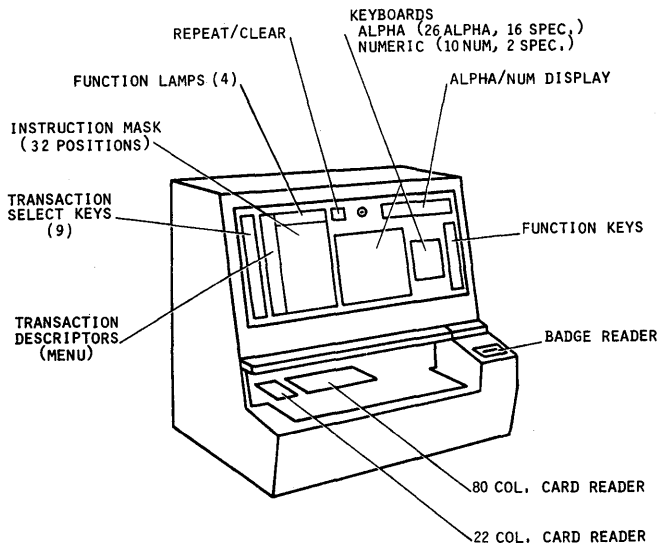

Figure 3—DPI 107 multi-function terminal

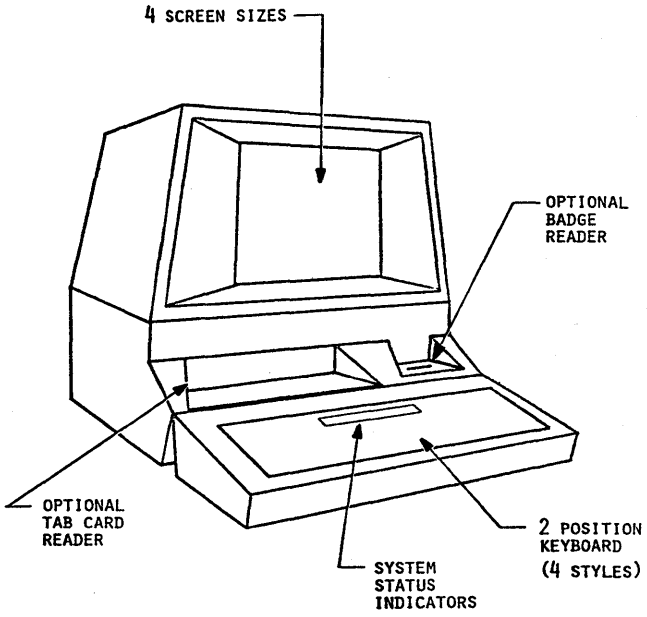

Figure 4—MIT 133 display station

General Purpose		*Special Purpose*
15 inch CRT Screen	w	four different screen sizes
Alphanumeric keyboard	w	special job oriented layouts
Basic system indicators	w	Expanded System Indicators
		Optional Badge Reader
		Optional Tab Card Reader

Figure 5 presents a point by point feature comparison between the DPI MIT 133 and the IBM 3277. Most of the added features were specifically added to allow for alternate or mixed operation in the general purpose or special purpose job oriented mode.

INTERFACE CONTROL SYSTEM

The DPI 3270 Interface Control System (ICS) is an optional system module to interface a DPI system with any host processor system that will support the IBM 3270 terminal system. The module is independent of the specific access method used in the host computer system. The applications can be programmed for interaction with IMS, CICS, TCAM, TOS or any other access method which supports the IBM 3270 general purpose CRT terminal system.

Within this capability the DPI system has a full range of unique interface arrangements to enhance the power and flexibility of the terminal applications.

ICS is an emulation of the IBM 3270 information display

system. Two types of system configurations are supported within ICS:

Figure 6: Direct IBM channel attachment referred to a local attachment (Emulation of IBM 3272)
Figure 7: Communications line attachment hereafter referred to as remote attachment (Emulation of IBM 3271)

The figures show the "Virtual System" which the host IBM processor system "thinks" it is controlling and the "Real System" which is being implemented by DPI.

SPECIFIC TERMINAL OPERATION UNDER ICS

Under ICS DPI terminal can operate in either the "transparent" or "data collection" mode.

- Transparent Mode is a one for one operation of a DPI

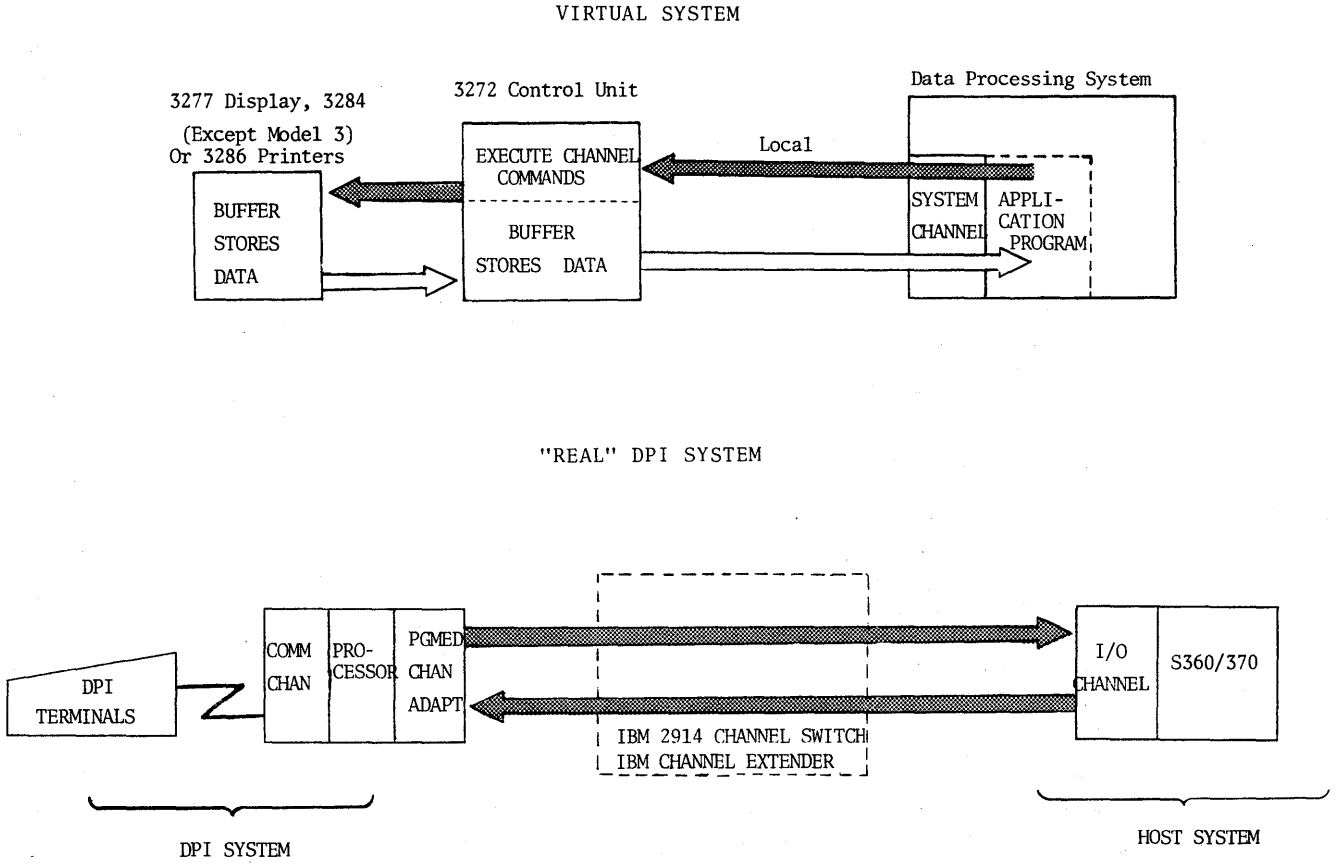

Figure 6—3272 local attachment

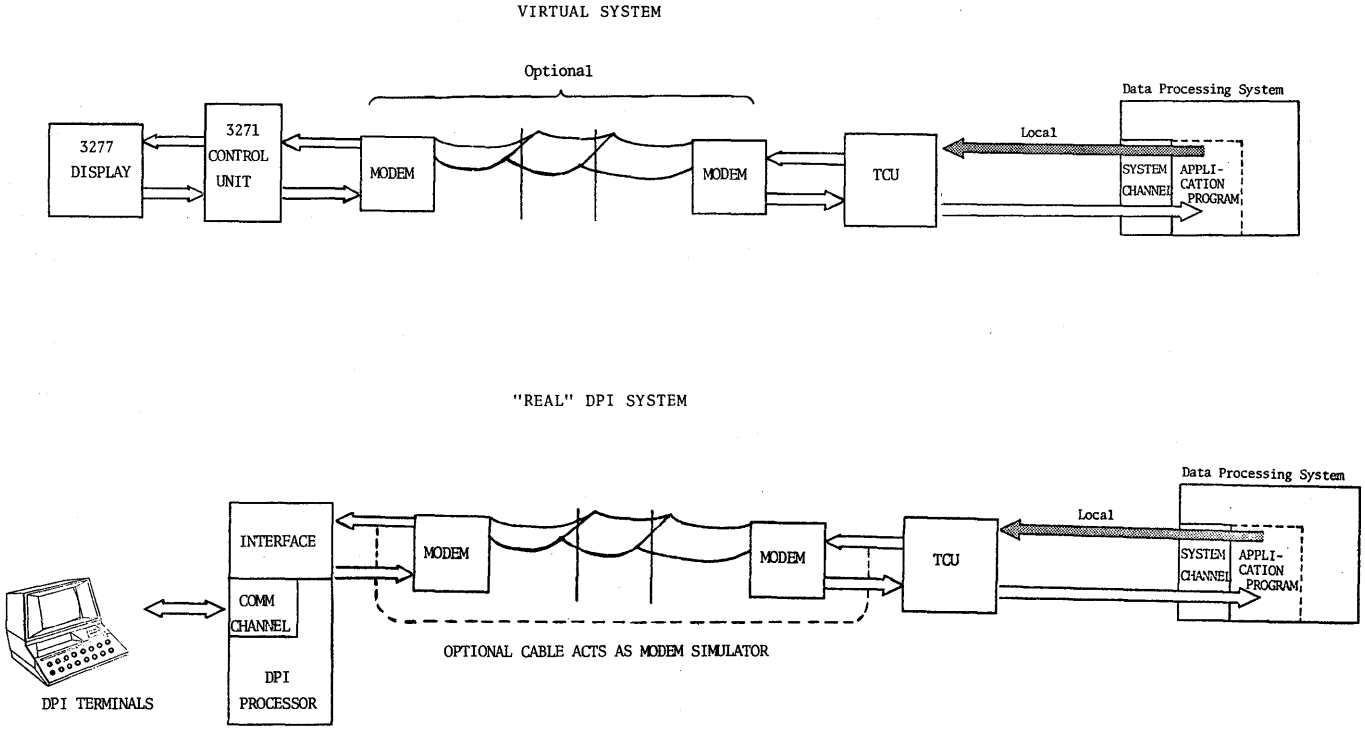

Figure 7—3271 remote attachment

terminal as an equivalent IBM 3277 terminal. The screen format control resides in the host processor and all transaction processing from an applications standpoint is executed in the host processor.

- Data Collection Mode can be either a one for one or group operation of DPI terminals for IBM 3277 terminals. The screen format control resides in the DPI processor. Final transaction processing can be executed in either the DPI processor or the IBM host processor.

A terminal such as the DPI SDT 107 is normally applied only under the data collection mode of operation. As an example it is not uncommon for each of two hundred DPI 107 terminals to appear to an IBM system as the physical equivalent of two IBM 3277 terminals (one for input and one for output). Limited job function terminals such as a dedicated time and attendance terminals are also included under the same emulation mode. The logical terminal addressing is accomplished in the host processors applications.

The DPI MIT 133 terminal can be applied either in the "transparent" or "data collection" mode of operation. It is not unusual for the MIT 133 terminal to be applied in the mixed mode where specific transactions are transparent and others are run in the data collection mode. In this type of application a specific terminal may appear to the host processor as two different logical terminals (one transparent and the other a data collection mode terminal). In such a case the transparent mode of the multi-mode terminal mode would appear to the host as a one for one physical terminal. The data collection mode of the same terminal can appear as either a separate one-for-one physical terminal or grouped as an individual logical terminal with other data collection mode terminals under a single physical virtual terminal.

A data collection mode application can be processed against both a reference (or fast reaction) data base in the DPI processor, and the main data base in the host processor. A "work in process" (WIP) file is the typical factory environment example of the type of data base located in the DPI processor.

SUMMARY

- The concept of having a special purpose terminal system appear to a host processor as a general purpose terminal subsystem has provided a most flexible system method of interfacing factory job oriented terminals to general purpose data processing systems.
- The concept coupled with special purpose terminals such as the DPI MIT 133 designed to operate in both the general purpose and special purpose job oriented mode provides for multi-operation of software control executed from either the best system or the DPI processor.
- The IBM 3270 is an ideal emulation target for providing multi-function on-line operation of job oriented terminals.
- Potential users need not worry about obsoleting existing working 3270 CRT software in the host processor when adding or evolving to a more sophisticated interactive on-line factory terminal system.
- The implementation of virtual logical terminals frees the software writer on the host from redefining all communications devices as new applications and terminals are added or modified.

A panel session—Future developments of special purpose terminals

SESSION CHAIRMAN—REIN TURN

TRW Defense and Space Systems Group
Redondo Beach, California

Panel Members

Carolyn Dunning—PCC Business Systems
Santa Ana, California
M. B. Herscher—Threshold Technology Inc.
Delran, New Jersey
Robert H. Anderson—The Rand Corporation
Santa Monica, California

INTRODUCTION

Many types of special purpose terminals are being developed for various applications to increase the performance and cost-effectiveness of man-computer interfaces. As discussed by the speaker and panelists in this session, future advances in computer technology will provide new design options, such as providing built-in intelligence through the use of microprocessors and memory chips. Thus, in future terminals it will be possible to do much more processing and store much more information than at present, and it will be possible to incorporate more effective security features and use more natural man-computer communication modes.

Donald Kovar in his paper "The Future of Special Purpose Terminals" (in this volume) examines current trends in computer terminal development and extrapolates these into 1978-1988 time period, with special emphasis on the transition from large scale integration (LSI) to very large scale integration (VLSI). He offers projections concerning the demands for special purpose terminals and on the ability of the industry to respond to these demands. His explorations are examined in more detail by the panelists who have chosen to concentrate on specific technology areas as well as on the extent in which future advances in technology are likely to affect terminal systems presently in use.

THE TERMINAL OF THE FUTURE IS A MINICOMPUTER

Panelist Robert H. Anderson of The Rand Corporation, Santa Monica, California asserts that the single most important attribute of the interactive computer terminal of the future is that it contain a general-purpose computer with the approximate characteristics of a present-day minicomputer. Representative of the set of services to be provided by the terminal of the future is a compatible package of user services developed at Rand on a PDP 11/70 minicomputer under the UNIX operating system.[1] The major systems within this software package (in addition to the standard UNIX services) are: a CRT-based two-dimensional text editor (NED);[2] an electronic message system (MS);[3] a reminder facility (REMIND) capable of sending a message or initiating a program at an arbitrary date/time; the RITA system[4-6] for creating user agents defined by sets of condition-action rules; an extension of the operating system called "virtual terminal UNIX" capable of providing the user windows onto multiple simultaneous processes; and an interface to an electronic data network (in this case, ARPANET). The described systems provide a coherent, symbiotic set of services that should co-exist. They should be provided on computing power local to the user for several reasons: their availability is not subject to external schedules and control; access to these services does not require lengthy login and authentication protocols to time-shared systems or data networks; data privacy can be maintained without reliance on central computer system security or transmission lines; programs within the user's terminal can act as "agents" capable of interacting automatically with external systems on behalf of the user, thus providing tailored interfaces and freeing the user from mundane, routine interactions. He concludes that the most valuable service a user terminal can provide is general-purpose computing, both for stand-alone use and as an aid in accessing remote information systems.

THE FUTURE OF SPEECH INPUT TERMINALS

Another panelist, M. B. Herscher of Threshold Technology Inc., Delran, New Jersey, points out that voice data entry, long recognized as an ultimate step towards simplifying communications between a human and a machine, is now a reality. Over 200 voice terminals currently are in operation in a variety of industrial and commercial applications in eight countries around the world. New speech input terminals using microcomputers have been introduced

which can replace and/or complement intelligent CRT/keyboard stations by enabling the user to enter data by voice. In many applications where hands and/or eyes are occupied in normal work environments, voice input terminals permit source data to be captured in an extremely efficient manner. Since these terminals normally provide input verification and editing capabilities, virtually error-free data can be captured. Speech input terminals also are being used for programming NC machines, aids to the handicapped, various material handling applications, and in a variety of training applications.

Currently, almost all of these speech input terminals recognize isolated words or phrases from a limited vocabulary subset and require that the user preprogram (train) the system for his or her pronunciation of the vocabulary. These recognition systems usually require bandwidths of up to seven KHz although some of these terminals can operate over phone lines. A complementary application of current speech input terminals is to recognize (verify identity) of individual talkers from their speech characteristics. The first secure access system for a computer room using speaker authentication has been in operation for several years.

The potential applications of voice data entry are determined by the economic advantages of voice input as compared to other alternative data entry devices and/or techniques. As the cost of voice data entry terminals decreases, more justifiable applications will arise, particularly when the true costs of data capture are considered. In some cases, voice input offers advantages which far outweigh the direct labor savings and permit certain operations to be achieved which could not easily be accomplished using alternative data input techniques.

Almost any system using intelligent CRT/keyboard terminals for data input could use speech input terminals. Virtually any factor or office system which is now directed by instructions from either a keyboard or a computer could be controlled by verbal commands. With current speech technology, the human voice simply replaces the mechanical keyboard or computer control, often with distinct operational and economic advantages.

Mr. Herscher expects the progress in the future for speech input terminals to take several directions. Larger size vocabularies will become practical for isolated word recognition systems. Some systems will be developed which will not require the user to pre-train the system vocabulary, although higher recognition accuracies always will be achievable for the adaptive system. Reliable operation over switched phone lines will open up new applications of speech terminals. Continuous speech recognition terminals will be available within the next one to five years—initially, connected digit recognition, followed by larger vocabularies. Combined recognition/speaker verification terminals will be available for accessing computer data bases and for electronic funds transfer, eventually over the phone lines.

He concludes with the observation that additional progress will be needed to achieve practical continuous speech recognition. Difficulty will mount in a geometric progression as more sophisticated speech systems are attempted. Once the cost barriers are overcome, the benefits will mount quickly, so the results promise to be worth the effort and investment. Over a ten year period, the first terminals for recognizing relatively natural speech input will begin to appear.

KEYBOARD DATA ENTRY ISN'T DEAD YET

The third panelist at this session, Carolyn Dunning of PCC Business Systems, Santa Ana, California addresses the impacts of technology advances on current data entry terminals and their use. How long does it take for an incumbent industry or profession to yield to the onslaught of new advances? She observes that keyboard data entry is supposed to have been 'dying' for over 20 years, ever since the introduction of optical character recognition (OCR). Each time a new device is developed the cry "keyboard data entry will become obsolete in five years" is heard again. Yet through all of this, there are more data entry keyboards of some type in use today, and more are projected for the future.

Special purpose terminals such as point of sale (POS) and new means for data entry such as voice recognition, may indeed have an impact on traditional data entry. But it is unlikely that it will be very great. Special purpose terminals are too specialized, and so is voice data entry (which is also too slow for high volume processing).

Distributed processing and distributed data entry may have a big impact on the traditional centralized data entry concept. However, most distributed data entry still uses a keyboard of some type. While it may look more like a typewriter, it will still use a keyboard. The emphasis may not be on quantity, or production, but on timeliness and accuracy which will be increased by having the person most familiar with the data entering it.

According to forecasts prepared by International Data Corporation (IDC), machine oriented systems such as OCR will experience approximately a 5 percent growth between 1976 and 1981. Keyboard type data entry will see an increase of nearly 100 percent, and this takes into account an estimated 16 percent decrease of centralized data entry systems, such as key punch and key-to-disk.

The predicted growth will come from increased installations of distributed systems, both single station and clustered as well as increased use of conversational and editing terminals. All these employ keyboard devices for data entry.

Another indication that keyboard data entry is still very much alive, even in a centralized environment, is the shortage of data entry operators. The newspapers are full of ads for these people. In addition, many companies are offering a reward for anyone who sends a qualified applicant for data entry. Other companies are taking more trainees or training people themselves. When operators can be found, they cost more. In the decade from 1966 to 1976, the average salaries for key entry operators in all grades increased by more than 50 percent.

While certain types of data can be entered in a 'dumb' sense, exactly as seen, the majority will still take some device capable of thinking and making decisions. The best device for this is still the human brain. Working in conjunc-

tion with the eyes, and fingers, it is the most accurate, rapid and practical method of entering data available, not just now, but for many years to come.

The future of special purpose terminals

by D. G. KOVAR
TRW Communications Systems and Services
Torrance, California

INTRODUCTION

In his book, *Future Shock,* Alvin Toffler dramatized the fact that we live in a rapidly changing world, in which most of us must constantly struggle to merely stay current. With this thought in mind, attempts at predicting the future must always be approached with some trepidation and perhaps a dash of humility. Nevertheless, it is the intent of this article to postulate the future of Special Purpose Terminals over the period of the next 10 years (1978-1988). This will be done by assessing the present state of this field, examining current trends, and extrapolating these findings to produce a range of future expectations. Although the year 1984 falls within the period of study, it is the opinion of the author that "Big Brother" will *not* be watching you on a Special Purpose Terminal during this time.

For the purposes of this paper, we shall define the term Special Purpose Terminal to mean computer input/output devices which are *used by people* and which have physical and/or functional characteristics that are specialized for a particular application or environment. For example, using this definition, we would conclude that a laser scanning, supermarket point of sale unit integrated with the check stand[1] is a Special Purpose Terminal, but on the contrary, a Teletype is not. There are, of course, many examples in which the line between special and general purpose is less clear than the above. Consequently, the definition given is useful as a guideline, but not as a rigid rule. Using this definition guideline, we find the following application areas to be currently active in the field of Special Purpose Terminals:[2]

Point-of-Sale
- Retail Department and Specialty Stores
- Drug and Discount Stores
- Supermarket
- Service Station

Banking
- Teller Assist
- Automated Tellers
- EFT

Industrial/Medical
- Factory Data Collection
- Hospital
- Security Access Control
- Rapid Transit
- Parking Lot

Travel and Entertainment
- Airline Ticketing and Reservation
- Rental Car
- Entertainment Ticketing
- Automated Traveler's Check Dispensers

Miscellaneous
- Library
- Law Enforcement

As time goes on, this already impressive list will be strengthened and some potentially very large new categories will be added.[3] These are as follows:

- Office Automation
- Electronic Mail
- Conferencing
- Distributed Work Environment
- Consumer Applications

The requirement for existence of any of these terminal devices (both current and future) is primarily a question of economics. Advances in technology have made it possible to produce increasingly sophisticated terminals at improving costs and reliability. Yet, in order for equipment to be commercially produced, there must be an adequate demand for the functions provided. Specifically, there must be a large enough separation between the economic value (real or perceived) and the cost of production in order to motivate investment by *both* the supplier and the buyer. This can be visualized as shown in Figure 1.

The relationships of Figure 1 must hold. Otherwise, the product will not be produced even if it is desired, or it will not be sold even if it is produced, or it will be produced and sold for a time period until either buyer or supplier with-

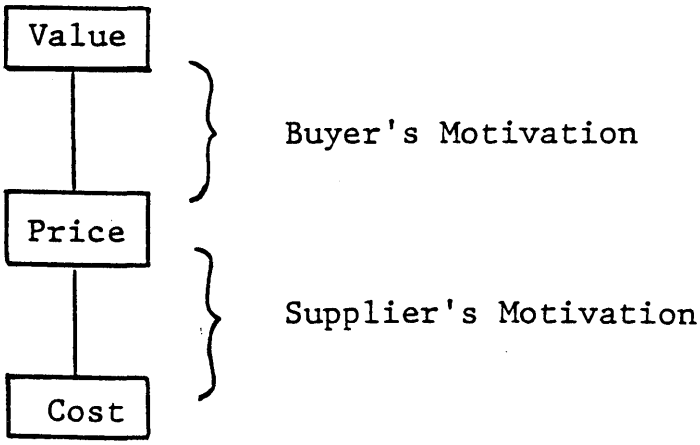

Figure 1—Product viability

drawal occurs. Consequently, it is insufficient to examine the future by studying only the technology. One must examine both sides of the equation and attempt to project product instances where satisfactory value/cost relationships will be likely. This is the methodology used in this paper.

TECHNOLOGY

Dramatic advances in technology have made the modern Special Purpose Terminal a very powerful subsystem. Many of the terminals of today already use one or more microprocessors[4] to control the logical operation and have several 10's of K Bytes of programmable storage. Having this compute power in the terminal allows for such functions as operator prompting, input data validation, transaction-oriented arithmetic, interactive communication with a higher-level computer, and complete stand-alone operation if necessitated by communication failure. This compute power has been made available primarily by advances in the state of the LSI art.[5] It is expected that such advances will continue in this area leading to the realm of VLSI.[6] This will in turn make it practical to house substantially more compute power in the terminal than is possible today. However, before commenting on the significance of this, let us first take a slightly broader look at the technological needs of the Special Purpose Terminal.

The Special Purpose Terminal is primarily a person-computer input/output device. The basic methods used to perform the input/output functions are shown in Figure 2. As can be seen, the variety of input/output means is very large and each of these means involves its own peculiar technology. It should be further noted that only a few of these means directly benefit from advances in LSI technology. Consequently, so far during the 70's, we have experienced considerable disparity between the *rate of change* of technology that is used for the internal logic vis-a-vis that which is used for the input/output functions.[7,8]

The result has been a Special Purpose Terminal price versus time curve that has been almost flat and, in some cases, has even risen slightly. At the same time however, logical capability (or performance, if you will) has risen in direct proportion to LSI progress, thereby producing significant gains in the performance/price ratio. So, one could characterize the experience to date as being essentially flat on price with rising performance rather than fixed in performance at declining prices. In order to be economically viable, such a situation must be accompanied by a rising demand for performance coupled with a tolerance for constant price. So far, this has been the case.

Whether or not we can extrapolate from this constant price, rising performance, profile is a key question in projecting the future. The rising performance part seems a safe bet, so let's examine that first. Depending upon the geometric regularity, current production level MOS LSI could be described as having reached the 10-20 thousand elements/chip level of density. Advances in mask making technology such as electron beam methods promise to raise that density to the one million-plus level during the period of study.[9] In anticipation of these improvements, the term VLSI is coming into popular use. This suggests that we can expect 32-bit computers, one million-bit memories, and combinations of these on individual chips.[10] Perhaps this will introduce the cliche of "the mainframe on a chip."

How will we spend that compute power? What good is that much horsepower in an individual terminal? The current economic picture for the Special Purpose Terminal would suggest that the new levels of compute power be spent on attacking the input/output problem—both for the operator *and* and the programmer. Increased compute power can improve the economics of some of the input/output devices by absorbing more and more of the special electronic processing that is externally contained in current equipment—i.e., laser scanner, OCR wand, etc. Increased compute power can be used to make new input/output methods possible—i.e., fingerprint, signature, voice, etc. The programmability of the Special Purpose Terminal is a very important feature in providing the adaptability and flexibility needed to meet changing requirements. The value of this feature should be expected to increase as time goes on. Consequently, "wasting" some of these new levels of compute power and memory space on higher level, more person-like (less machine-like) programming languages and tools can be anticipated.[11] So, we should look forward to Special Purpose Terminals with some increased function and with substantially improved person-machine interfaces.

In addition to the improvements expected in the basic logic function which are spurred on by advances in LSI, we can also see some considerable advances in the local storage function. Local storage is used primarily to collect data generated by the terminal for subsequent transmission and to store programs used by the terminal. Normally such storage must be non-volatile, and this requirement is currently satisfied by using small disc or tape units. The magnetic bubble memory[12,13] is an attractive alternative technology. Just now being commercially introduced, the bubble memory is expected to surpass these electromechanical devices

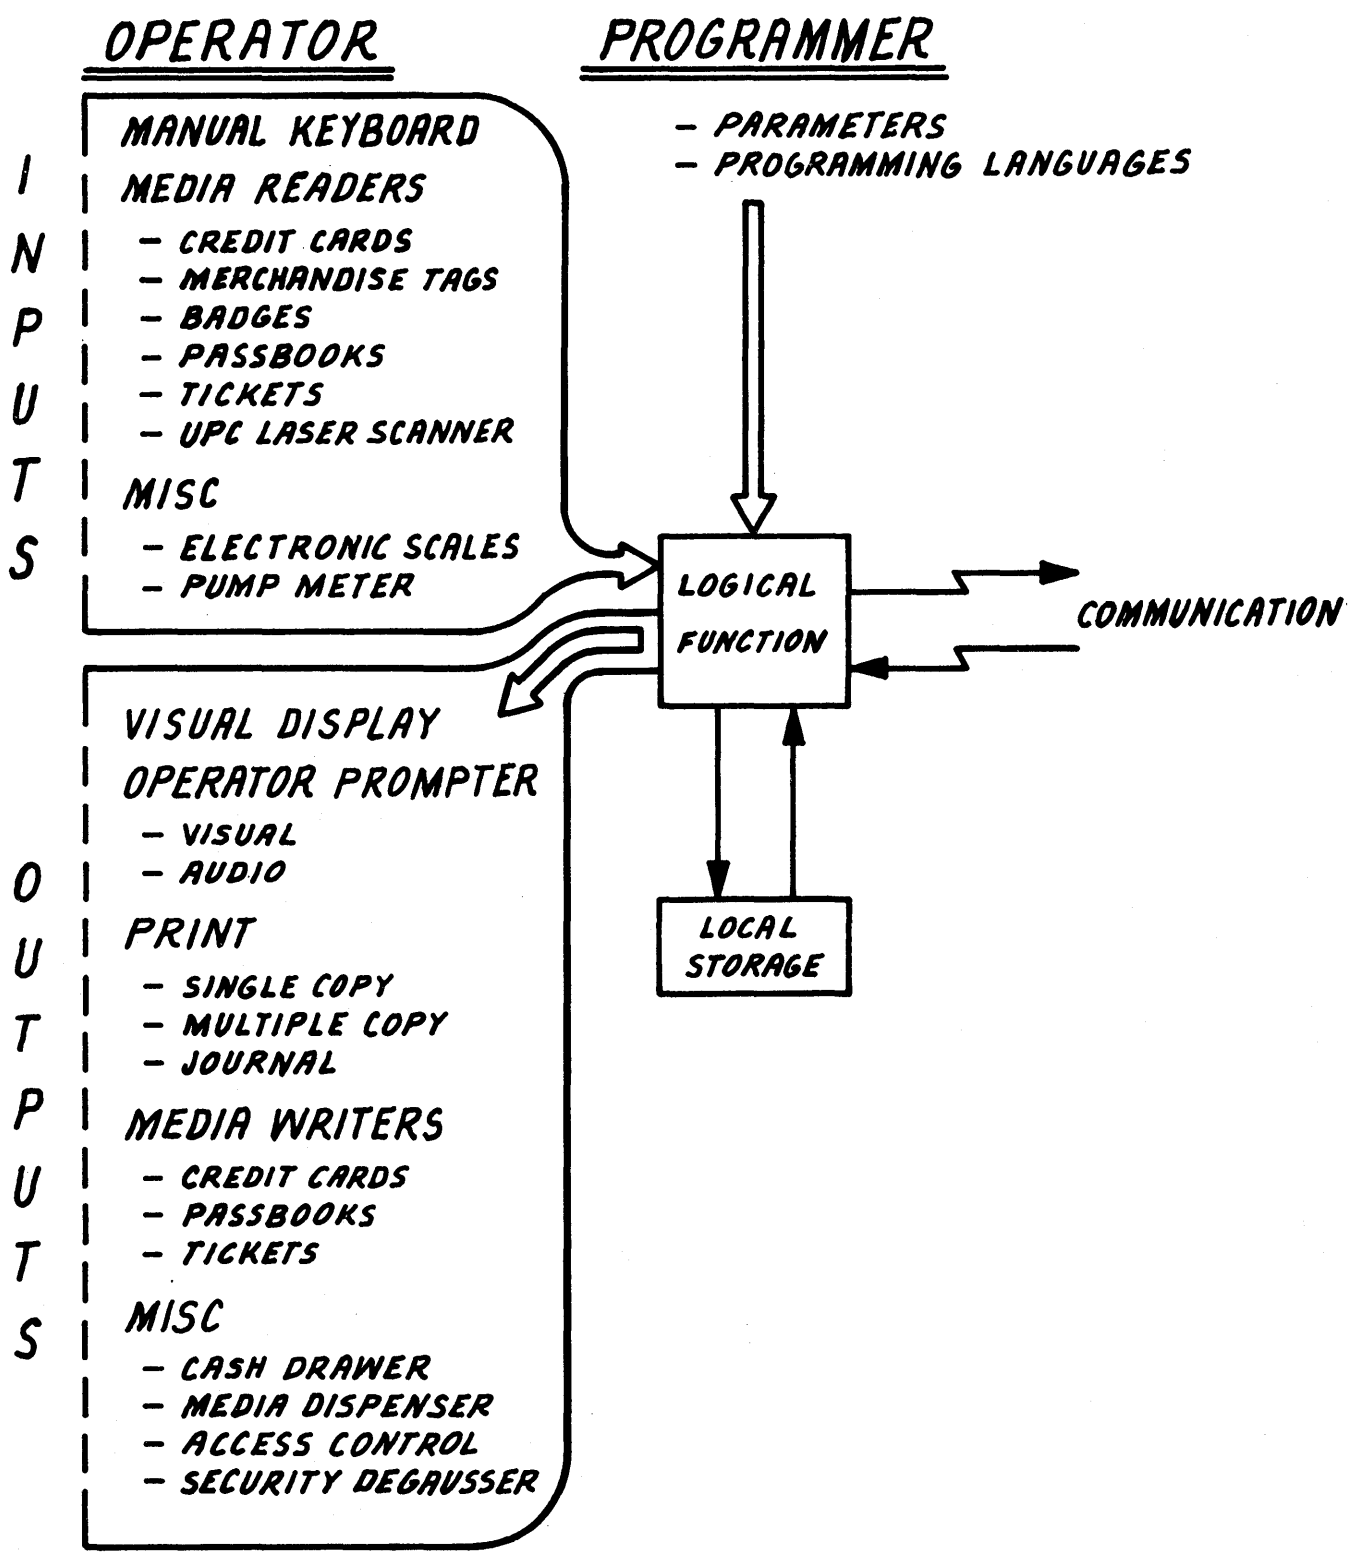

Figure 2—Special purpose terminal interfaces

in performance/price ratio's by 1980. High expectations for continuing bubble memory density improvement beyond 1980 are realistic because such improvements are dependent upon the same improvements in mask making technology as is the case for LSI. Therefore, bubble memory is expected to be used as direct replacement for current local storage systems. In addition, the constantly improving bubble memory economics (ala LSI → VLSI) will make it possible to deploy non-volatile local storage in terminal environments for which such storage is not currently cost-effective.

As previously mentioned, while dramatic advances in some portions of the Special Purpose Terminal technology can be expected, there are some items that resist. Among the technologies implied by Figure 2 displays, printers, packaging and power supplies stand out as the most unyielding. While many new technologies have been introduced for small terminal displays such as liquid crystal, plasma, and LED, they are still not economic for displays of several hundred characters.[14] In fact, compared to CRT, the disparity can approach an order of magnitude.

Because of this difference, and because of the pressure (for improved person-machine interfaces) which will emphasize larger displays (including graphics), the CRT will continue as a major display technology. This projection is made by assuming that a "breakthrough" based upon some currently unknown technology does not take place. Although several printer technologies are being pursued,[15] i.e., impact dot-matrix, thermal, electro-static, ink-jet,[16] etc., they all have moving mechanical parts and suffer from relatively high initial cost and continuing reliability problems. The printer has sometimes been described as the "Achilles' Heel" of the Special Purpose Terminal. However, some cost improvement will be realized by minimizing or completely avoiding the printing requirement through the use of solid state technology as an alternative method for information processing. For example, local storage by bubble memory can eliminate the journal and information distribution by electronic means can offset the need for printing on multi-part forms. The printer will not go away, however, as there will be a continuing need for some hard copy for an indefinite future period. In the packaging and power supply technologies we can expect some improvement via superior materials, components, and design architecture but we should not count on these advances producing any more than a hedge against inflation. As a result of the above observations, the constant price phenomenon is expected to continue for some time except for those gains that can be realized by substituting solid state for printed information handling.

The picture being painted is one of constantly improving performance and functionality under a fairly constant or, at best, modestly declining price umbrella. We can expect those 1988 Special Purpose Terminals to be programmable in very high level languages, to provide solid state, non-volatile local storage, to offer highly economic input media readers, and to introduce some elementary versions of alternate human input such as voice, fingerprint, etc. But where will this technology be used? What actual products can be expected? Let us turn to that now.

DEMAND

Today we find Special Purpose Terminals well entrenched in the major retail department stores and financial institutions.[17,18] The demand for these terminals has come from the values derived from the improved automated assist functions for clerks and tellers and from the improved velocity and accuracy of information associated with consumer transactions in the institutions. Such values can be expressed in terms of improved productivity, asset management, and customer service. In a society confronted with a growing rate of change, these values can be expected to continuously increase. Therefore, we project a continuing demand for Special Purpose Terminals by the retail and financial institutions. Here, we will see heavy emphasis on improving the programmability to keep up with the rate of change, and in moving more and more to automated input means as the economics improve. Some customer fingerprint optical processing for identification may come into use but demand for widespread use of voice input/output is doubtful in the active lobby-like atmosphere of these environments.

The question of demand for Special Purpose Terminals for use in consumer transaction electronic funds transfer (EFT) is fascinating in its complexity.[19] Here is a case in which the necessary technology already exists. But who is the terminal buyer? Who benefits? Who runs the multi-bank, multi-retailer interconnect network? Can terminals be legally shared? What about banking legislation in general? What about consumer protection legislation? Satisfactory answers to these questions will be needed before significant investments are made in EFT.[20]

In spite of these problems, there are some strong motivators for EFT. The banking institutions face the same rising costs of real estate, and energy as are pervasive in society in general. In addition, the growing volume of paper in the system is a constant threat to processing saturation. On a more positive note, EFT should be able to deliver a more expeditious and broader range of financial services to consumers.

So, how will this tug-of-war be decided? It is projected here that consumer transaction EFT will come about but it will be a slow process. Many experiments by individual banking institutions have been conducted and more will follow.[22] The anticipated progress toward true distributed financial institution EFT is projected to still be struggling for definition by 1980 and just beginning to take shape by 1985. Again, note that this is *not* a terminal technology problem. Consequently, the EFT Special Purpose Terminal product will still be quite young in 1988[23] and by then the EFT function will be fully integrated into the retail POS terminal and is not expected to exist as a separate entity.

Many of the forces (high rate of change, rising personnel costs, energy, etc.) that contribute to the demand found in retail and financial institutions are present in other transaction environments as well. Therefore, a similar continuing demand is expected in factory data collection, hospital patient administration, hotel and airline reservation, and other similar situations.

Perhaps the most exciting trends regarding demand are found as we explore the migration of special purpose terminals from the world of transaction control, to the environment of office automation,[24] to the surroundings of our own homes. Here, the rising costs of energy are continuing to raise the value associated with moving electrons instead of moving physical media or people.[25] Interestingly enough, consumer infatuation with calculators, home computers, and TV games could thrust the Special Purpose Terminal into the home more quickly than will be the case for the office. In fact, this phenomenon will tend to blur the distinction between what is office and what is home. One can foresee a complete, home-based, Special Purpose Terminal system with one or more stations for entertainment, for education, for work, and for shopping and banking transactions. Furthermore, such a system could control the home environment and optimize energy consumption in its spare time.

It is reasonable to expect that such equipment will enter the home first on the entertainment motive and then incorporate the other functions incrementally as the necessary supporting systems (i.e., EFT, education, etc.) come into being. It is projected that by 1985, the bulk of the terminal equipment will be available but the community-level supporting systems will be very primitive. By 1988 the distributed, home-based terminal environment will have positioned itself for growth on into the 1990's.

CONCLUSION

We have painted a picture of rising demand and of continuing technological advance which would seem to imply dramatic growth. However, this is offset in those instances where substantial utility-like supporting systems are needed which must cross institutional lines. It doesn't do any good to possess a very sophisticated person-machine interface terminal if there is no distribution system. Therefore, growth is expected; it will be exciting, but except for those pockets of explosive growth that can move ahead on an isolated system basis, the progress *will be slower* than we might otherwise expect. Nevertheless, the Special Purpose Terminal world of 1988 will offer a substantial marketplace for the producer, powerful information systems for the business user, and some real, quality-of-life benefits for the consumer. One of the great entertainment values of the 1980's is going to consist of following the progress of the Special Purpose Terminal. Be sure not to miss it.

Office Systems Integration
Newport Beach, California

Office automation

Daily, new uses appear for computers in the general office environment. While the area is still dominated by word processing, other applications are becoming widespread. Special systems for administrative tasks, records management, document distribution, and communication integrate new activities into the standard word processing and data processing activities.

With these new applications, however, come endless problems—discovering and refining the applications, choosing equipment from the constant new offerings, devising appropriate accounting methods, restructuring organizations, and determining the impact on the corporation—all are complex issues.

The first session will review the history and current state of office automation. The evolutionary changes of the field from the technical and marketing point of view will be reviewed. The history of the industry will be developed and will be compared to the data processing industry. Finally, the surprising diversity of the office automation industry will be outlined with a review of the range and applications and the present areas of concentration.

The architecture of systems for office automation is diverse and rapidly changing. The second session will present three views of these architectural changes; firmware to software, stand-alone to distributed, and maxi to micro. While we observed these changes initially in hardware, they greatly impact the applications. The long range user effects will be the focus of the session.

The third session will address organizational trends in office automation, and will cover methodologies for designing automated office support. They include: integration into computer-based, multi-function terminals for total automated support, cost/benefit analysis for managerial work, increased user participation in the design and revision of automated office systems, and increased attention to organizational and human factors in system design and implementation.

Even with these methodologies, however, the implementation of automated office systems has been difficult. Cost-benefit data is confusing, and overall productivity gains are difficult to determine. This fourth session will present a different, controversial position.

Office automation systems imposed on existing organizational information flows will increase inter-group conflict, confuse assignments, cloud responsibility and provide no overall improvement in performance. If office automation only provides faster switching of messages and easier access to files it will increase

the problems inherent in current information flows and be rejected by the users. What is needed is formal reconstituting of information flows by the major activities of data collection, data base analysis, information packaging and knowledge acceptance. The delineation of basic processes will make possible scheduling and planning models, resource allocation, and assignment of overall objectives and responsibility. Unless these improvements are made in information processes office automation will not realize its full potential.

Finally, some users have begun to reconstitute their information flows and address the issues raised in the previous session. This final, fifth, session focuses on several applications of computer-based message and document distribution systems. Emphasis is on implementation approaches and system value within the organizational context, and on the introduction of such systems to prospective users. Case presentations will be made in which three organizations are represented—one multi-national non-profit, one corporate, and one federal government agency. Each has actually implemented a system and will discuss its usage and related impacts.

Artificial intelligence

The bulk of current Artificial Intelligence research is focused on methods for achieving goals within partially understood environments. In such environments the bodies of knowledge which exist are quite varied; some are systematic and well validated, others are judgemental. Characteristically, there are no known optimal ways of applying the knowledge in the environment to achieve the desired goals. The challenge of Al is to develop methods for handling problems in such environments and to aid the development of a better understanding of these environments, which may in turn lead to more powerful ways of achieving goals within it.

The development of Artificial Intelligence has been marked by two rather distinct periods. In the first, the basic structure of the field emerged, centered on the notion of general purpose mechanisms and general-purpose problem solvers, theorem provers, and semantic nets. Once the limitations of such general purpose mechanisms were generally recognized, the second period of development began. It was, and is, marked by the attempt to incorporate and effectively utilize special purpose knowledge appropriate for some task. Issues such as acquiring such special purpose knowledge from experts, representing it in a useful form, and effectively using it to control a problem solving activity became paramount.

These NCC sessions will focus on this latter period through two invited papers. The first, presented by Professor Edward Feigenbaum, chronicles the development of the specialized knowledge period through the activities of the Stanford Heuristic Programming Project which has long been a leader in the development of expert-level performance programs. The second invited paper is the lecture presented by Professor Douglas Lenat upon his selection for the 1977 Computers and Thought Lecture for outstanding contributions by a young researcher to Artificial Intelligence. Lenat's talk and research describe a system for discovering new mathematical concepts and conjectures involving those concepts. This fascinating work indicates the potential feasibility of providing operational models of the process of mathematical discovery.

These two invited papers, which comprise the first Al session, will surely initiate a rash of questions. Therefore, they will immediately be followed by a

session entirely devoted to answering questions from the audience on these and other Al issues. Joining Feigenbaum and Lenat on the panel of Al experts will be Professors Raj Reddy and Saul Amarel, and Dr. Peter Hart. The final session will present several state-of-the-art applications which have achieved expert-level performance.

The art of artificial intelligence—Themes and case studies of knowledge engineering

by EDWARD A. FEIGENBAUM
Stanford University
Stanford, California

INTRODUCTION—AN EXAMPLE

This paper will examine emerging themes of knowledge engineering, illustrate them with case studies drawn from the work of the Stanford Heuristic Programming Project, and discuss general issues of knowledge engineering art and practice.

Let me begin with an example new to our workbench: a system called PUFF, the early fruit of a collaboration between our project and a group at the Pacific Medical Center (PMC) in San Francisco.*

A physician refers a patient to PMC's pulmonary function testing lab for diagnosis of possible pulmonary function disorder. For one of the tests, the patient inhales and exhales a few times in a tube connected to an instrument/computer combination. The instrument acquires data on flow rates and volumes, the so-called flow-volume loop of the patient's lungs and airways. The computer measures certain parameters of the curve and presents them to the diagnostician (physician or PUFF) for interpretation. The diagnosis is made along these lines: normal or diseased; restricted lung disease or obstructive airways disease or a combination of both; the severity; the likely disease type(s) (e.g., emphysema, bronchitis, etc.); and other factors important for diagnosis.

PUFF is given not only the measured data but also certain items of information from the patient record, e.g., sex, age, number of pack-years of cigarette smoking. The task of the PUFF system is to infer a diagnosis and print it out in English in the normal medical summary form of the interpretation expected by the referring physician.

Everything PUFF knows about pulmonary function diagnosis is contained in (currently) 55 rules of the IF. . . THEN. . . form. No textbook of medicine currently records these rules. They constitute the partly-public, partly-private knowledge of an expert pulmonary physiologist at PMC, and were extracted and polished by project engineers working intensively with the expert over a period of time. Here is an example of a PUFF rule (the unexplained acronyms refer to various data measurements):

RULE 31

IF:
1) The severity of obstructive airways disease of the patient is greater than or equal to mild, and
2) The degree of diffusion defect of the patient is greater than or equal to mild, and
3) The tlc (body box) observed/predicted of the patient is greater than or equal to 110 and
4) The observed-predicted difference in rv/tlc of the patient is greater than or equal to 10

THEN:
1) There is strongly suggestive evidence (.9) that the subtype of obstructive airways disease is emphysema, and
2) It is definite (1.0) that "OAD, Diffusion Defect, elevated TLC, and elevated RV together indicate emphysema." is one of the findings.

One hundred cases, carefully chosen to span the variety of disease states with sufficient exemplary information for each, were used to extract the 55 rules. As the knowledge emerged, it was represented in rule form, added to the system and tested by running additional cases. The expert was sometimes surprised, sometimes frustrated, by the occasional gaps and inconsistencies in the knowledge, and the incorrect diagnoses that were logical consequences of the existing rule set. The interplay between knowledge engineer and expert gradually expanded the set of rules to remove most of these problems.

As cumulation of techniques in the art demands and allows, a new tool was not invented when an old one would do. The knowledge engineers pulled out of their toolkit a version of the MYCIN system (to be discussed later), with the rules about infectious diseases removed, and used it as the inference engine for the PUFF diagnoses. Thus PUFF, like MYCIN, is a relatively simple backward-chaining infer-

* Dr. J. Osborn, Dr. R. Fallat, John Kunz, Diane McClung.

ence system. It seeks a valid line-of-reasoning based on its rules and rooted in the instrument and patient data. With a little more work at fitting some existing tools together, PUFF will be able to explain this line-of-reasoning, just as MYCIN does.

As it is, PUFF only prints out the final interpretation, of which the following is an example:

PATIENT DATA:
The degree of dyspnea: MODERATELY-SEVERE
The severity of coughing: MILD
Sputum production MODERATELY-SEVERE
The number of pack-years of smoking: 48
referral diagnosis: BRONCHITIS
IVC/IVC-predicted: 80
RV/RV-predicted: 191
FVC/FVC-predicted: 87
TLC(body box)observed/predicted: 127
Predicted FEV1/FVC: 83
TLC(DLCO)observed/predicted: 83
FEV1/FVC ratio: 50
RV/TLC Observed-Predicted: 21
MMF/MMF-predicted: 19
the DLCO/DLCO-predicted: 48
The slope (F50_obs-F25_obs)/FVC_obs: 19

DEGREE OF OBSTRUCTIVE AIRWAYS DISEASE:

OAD degree by SLOPE: (MODERATELY-SEVERE 700)
OAD degree by MMF: (SEVERE 900)
OAD degree by FEV1: (MODERATELY-SEVERE 700)
FINAL OAD DEGREE: (MODERATELY-SEVERE 910) (SEVERE 900)
No conflict. Final degree: (MODERATELY-SEVERE 910)

INTERPRETATION:

Obstruction is indicated by curvature of the flow-volume loop.
Forced Vital Capacity is normal and peak flow rates are reduced, suggesting airway obstruction.
Flow rate from 25-75 of expired volume is reduced, indicating severe airway obstruction.
OAD, Diffusion Defect, elevated TLC, and elevated RV together indicate emphysema.
OAD, Diffusion Defect, and elevated RV indicate emphysema.
Change in expired flow rates following bronchodilation shows that there is reversibility of airway obstruction.
The presence of a productive cough is an indication that the OAD is of the bronchitic type.
Elevated lung volumes indicate overinflation.
Air trapping is indicated by the elevated difference between observed and predicted RV/TLC ratios.
Improvement in airway resistance indicates some reversibility of airway
Airway obstruction is consistent with the patient's smoking history.
The airway obstruction accounts for the patient's dyspnea.
Although bronchodilators were not useful in this one case, prolonged use may prove to be beneficial to the patient.
The reduced diffusion capacity indicates airway obstruction of the mixed bronchitic and emphysematous types.
Low diffusing capacity indicates loss of alveolar capillary surface.
Obstructive Airways Disease of mixed types

150 cases not studied during the knowledge acquisition process were used for a test and validation of the rule set. PUFF inferred a diagnosis for each. PUFF-produced and expert-produced interpretations were coded for statistical analysis to discover the degree of agreement. Over various types of disease states, and for two conditions of match between human and computer diagnoses ("same degree of severity" and "within one degree of severity"), agreement ranged between approximately 90 percent and 100 percent.

The PUFF story is just beginning and will be told perhaps at a later NCC. The surprising punchline to my synopsis is that the current state of the PUFF system as described above was achieved in less than 50 hours of interaction with the expert and less than 10 man-weeks of effort by the knowledge engineers. We have learned much in the past decade of the art of engineering knowledge-based intelligent agents!

In the remainder of this essay, I would like to discuss the route that one research group, the Stanford Heuristic Programming Project, has taken, illustrating progress with case studies, and discussing themes of the work.

ARTIFICIAL INTELLIGENCE & KNOWLEDGE ENGINEERING

The dichotomy that was used to classify the collected papers in the volume *Computers and Thought* still characterizes well the motivations and research efforts of the AI community. First, there are some who work toward the construction of intelligent artifacts, or seek to uncover principles, methods, and techniques useful in such construction. Second, there are those who view artificial intelligence as (to use Newell's phrase) "theoretical psychology," seeking explicit and valid information processing models of human thought.

For purposes of this essay, I wish to focus on the motivations of the first group, these days by far the larger of the two. I label these motivations "the intelligent agent viewpoint" and here is my understanding of that viewpoint:

"The potential uses of computers by people to accom-

plish tasks can be 'one-dimensionalized' into a spectrum representing the nature of instruction that must be given the computer to do its job. Call it the WHAT-to-HOW spectrum. At one extreme of the spectrum, the user supplies his intelligence to instruct the machine with precision exactly HOW to do his job, step-by-step. Progress in Computer Science can be seen as steps away from the extreme 'HOW' point on the spectrum: the familiar panoply of assembly languages, subroutine libraries, compilers, extensible languages, etc. At the other extreme of the spectrum is the user with his real problem (WHAT he wishes the computer, as his instrument, to do for him). He aspires to communicate WHAT he wants done in a language that is comfortable to him (perhaps English); via communication modes that are convenient for him (including perhaps, speech or pictures); with some generality, some vagueness, imprecision, even error; without having to lay out in detail all necessary subgoals for adequate performance—with reasonable assurance that he is addressing an intelligent agent that is using knowledge of his world to understand his intent, to fill in his vagueness, to make specific his abstractions, to correct his errors, to discover appropriate subgoals, and ultimately to translate WHAT he really wants done into processing steps that define HOW it shall be done by a real computer. The research activity aimed at creating computer programs that act as "intelligent agents" near the WHAT end of the WHAT-To-HOW spectrum can be viewed as the long-range goal of AI research." (Feigenbaum, 1974)

Our young science is still more art than science. Art: "the principles or methods governing any craft or branch of learning." Art: "skilled workmanship, execution, or agency." These the dictionary teaches us. Knuth tells us that the endeavor of computer programming is an art, in just these ways. The art of constructing intelligent agents is both part of and an extension of the programming art. It is the art of building complex computer programs that represent and reason with knowledge of the world. Our art therefore lives in symbiosis with the other worldly arts, whose practitioners—experts of their art—hold the knowledge we need to construct intelligent agents. In most "crafts or branches of learning" what we call "expertise" is the essence of the art. And for the domains of knowledge that we touch with our art, it is the "rules of expertise" or the rules of "good judgment" of the expert practitioners of that domain that we seek to transfer to our programs.

Lessons of the past

Two insights from previous work are pertinent to this essay.

The first concerns the quest for generality and power of the inference engine used in the performance of intelligent acts (what Minsky and Papert [see Goldstein and Papert, 1977] have labeled "the power strategy"). We must hypothesize from our experience to date that the problem solving power exhibited in an intelligent agent's performance is primarily a consequence of the specialist's knowledge employed by the agent, and only very secondarily related to the generality and power of the inference method employed. Our agents must be knowledge-rich, even if they are methods-poor. In 1970, reporting the first major summary-of-results of the DENDRAL program (to be discussed later), we addressed this issue as follows:

> ". . . general problem-solvers are too weak to be used as the basis for building high-performance systems. The behavior of the best general problem-solvers we know, human problem-solvers, is observed to be weak and shallow, except in the areas in which the human problem-solver is a specialist. And it is observed that the transfer of expertise between specialty areas is slight. A chess master is unlikely to be an expert algebraist or an expert mass spectrum analyst, etc. In this view, the expert is the specialist, with a specialist's knowledge of his area and a specialist's methods and heuristics." (Feigenbaum, Buchanan and Lederberg, 1971, p. 187)

Subsequent evidence from our laboratory and all others has only confirmed this belief.

AI researchers have dramatically shifted their view on generality and power in the past decade. In 1967, the canonical question about the DENDRAL program was: "It sounds like good chemistry, but what does it have to do with AI?" In 1977, Goldstein and Papert write of a paradigm shift in AI:

> "Today there has been a shift in paradigm. The fundamental problem of understanding intelligence is not the identification of a few powerful techniques, but rather the question of how to represent large amounts of knowledge in a fashion that permits their effective use and interaction." (Goldstein and Papert, 1977).

The second insight from past work concerns the nature of the knowledge that an expert brings to the performance of a task. Experience has shown us that this knowledge is largely heuristic knowledge, experiential, uncertain—mostly "good guesses" and "good practice," in lieu of facts and rigor. Experience has also taught us that much of this knowledge is private to the expert, not because he is unwilling to share publicly how he performs, but because he is unable. He knows more than he is aware of knowing. [Why else is the Ph.D. or the Internship a guild-like apprenticeship to a presumed "master of the craft?" What the masters really know is not written in the textbooks of the masters.] But we have learned also that this private knowledge can be uncovered by the careful, painstaking analysis of a second party, or sometimes by the expert himself, operating in the context of a large number of highly specific performance problems. Finally, we have learned that expertise is multifaceted, that the expert brings to bear many and varied sources of knowledge in performance. The approach to capturing his expertise must proceed on many fronts simultaneously.

The knowledge engineer

The knowledge engineer is that second party just discussed. She works intensively with an expert to acquire domain-specific knowledge and organize it for use by a program. Simultaneously she is matching the tools of the AI workbench to the task at hand—program organizations, methods of symbolic inference, techniques for the structuring of symbolic information, and the like. If the tool fits, or nearly fits, she uses it. If not, necessity mothers AI invention, and a new tool gets created. She builds the early versions of the intelligent agent, guided always by her intent that the program eventually achieve expert levels of performance in the task. She refines or reconceptualizes the system as the increasing amount of acquired knowledge causes the AI tool to "break" or slow down intolerably. She also refines the human interface to the intelligent agent with several aims: to make the system appear "comfortable" to the human user in his linguistic transactions with it; to make the system's inference processes understandable to the user; and to make the assistance controllable by the user when, in the context of a real problem, he has an insight that previously was not elicited and therefore not incorporated.

In the next section, I wish to explore (in summary form) some case studies of the knowledge engineer's art.

CASES FROM THE KNOWLEDGE ENGINEER'S WORKSHOP

I will draw material for this section from the work of my group at Stanford. Much exciting work in knowledge engineering is going on elsewhere. Since my intent is not to survey literature but to illustrate themes, at the risk of appearing parochial I have used as case studies the work I know best.

My collaborators (Professors Lederberg and Buchanan) and I began a series of projects, initially the development of the DENDRAL program, in 1965. We had dual motives: first, to study scientific problem solving and discovery, particularly the processes scientists do use or should use in inferring hypotheses and theories from empirical evidence; and second, to conduct this study in such a way that our experimental programs would one day be of use to working scientists, providing intelligent assistance on important and difficult problems. By 1970, we and our co-workers had gained enough experience that we felt comfortable in laying out a program of research encompassing work on theory formation, knowledge utilization, knowledge acquisition, explanation, and knowledge engineering techniques. Although there were some surprises along the way, the general lines of the research are proceeding as envisioned.

THEMES

As a road map to these case studies, it is useful to keep in mind certain major themes:

Generation-and-test: Omnipresent in our experiments is the "classical" generation-and-test framework that has been the hallmark of AI programs for two decades. This is not a consequence of a doctrinaire attitude on our part about heuristic search, but rather of the usefulness and sufficiency of the concept.

Situation⇒Action Rules: We have chosen to represent the knowledge of experts in this form. Making no doctrinaire claims for the universal applicability of this representation, we nonetheless point to the demonstrated utility of the rule-based representation. From this representation flow rather directly many of the characteristics of our programs: for example, ease of modification of the knowledge, ease of explanation. The essence of our approach is that a rule must capture a "chunk" of domain knowledge that is meaningful, in and of itself, to the domain specialist. Thus our rules bear only a historical relationship to the production rules used by Newell and Simon (1972) which we view as "machine-language programming" of a recognize⇒act machine.

The Domain-Specific Knowledge: It plays a critical role in organizing and constraining search. The theme is that in the knowledge is the power. The interesting action arises from the knowledge base, not the inference engine. We use knowledge in rule form (discussed above), in the form of inferentially-rich models based on theory, and in the form of tableaus of symbolic data and relationships (i.e., frame-like structures). System processes are made to conform to natural and convenient representations of the domain-specific knowledge.

Flexibility to modify the knowledge base: If the so-called "grain size" of the knowledge representation is chosen properly (i.e., small enough to be comprehensible but large enough to be meaningful to the domain specialist), then the rule-based approach allows great flexibility for adding, removing, or changing knowledge in the system.

Line-of-reasoning: A central organizing principle in the design of knowledge-based intelligent agents is the maintenance of a line-of-reasoning that is comprehensible to the domain specialist. This principle is, of course, not a logical necessity, but seems to us to be an engineering principle of major importance.

Multiple Sources of Knowledge: The formation and maintenance (support) of the line-of-reasoning usually require the integration of many disparate sources of knowledge. The representational and inferential problems in achieving a smooth and effective integration are formidable engineering problems.

Explanation: The ability to explain the line-of-reasoning in a language convenient to the user is necessary for application and for system development (e.g., for debugging and for extending the knowledge base). Once again, this is an engineering principle, but very important. What con-

stitutes "an explanation" is not a simple concept, and considerable thought needs to be given, in each case, to the structuring of explanations.

CASE STUDIES

In this section I will try to illustrate these themes with various case studies.

DENDRAL: Inferring chemical structures

Historical note

Begun in 1965, this collaborative project with the Stanford Mass Spectrometry Laboratory has become one of the longest-lived continuous efforts in the history of AI (a fact that in no small way has contributed to its success). The basic framework of generation-and-test and rule-based representation has proved rugged and extendable. For us the DENDRAL system has been a fountain of ideas, many of which have found their way, highly metamorphosed, into our other projects. For example, our long-standing commitment to rule-based representations arose out of our (successful) attempt to head off the imminent ossification of DENDRAL caused by the rapid accumulation of new knowledge in the system around 1967.

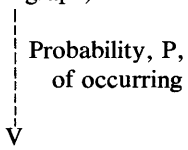
Task

To enumerate plausible structures (atom-bond graphs) for organic molecules, given two kinds of information: analytic instrument data from a mass spectrometer and a nuclear magnetic resonance spectrometer; and user-supplied constraints on the answers, derived from any other source of knowledge (instrumental or contextual) available to the user.

Representations

Chemical structures are represented as node-link graphs of atoms (nodes) and bonds (links). Constraints on search are represented as subgraphs (atomic configurations) to be denied or preferred. The empirical theory of mass spectrometry is represented by a set of rules of the general form:

Situation: Particular atomic configuration (subgraph)



Action: Fragmentation of the particular configuration (Breaking links)

Rules of this form are natural and expressive to mass spectrometrists.

Sketch of method

DENDRAL's inference procedure is a heuristic search that takes place in three stages, without feedback: plan-generate-test.

"Generate" (a program called CONGEN) is a generation process for plausible structures. Its foundation is a combinatorial algorithm (with mathematically proven properties of completeness and non-redundant generation) that can produce all the topologically legal candidate structures. Constraints supplied by the user or by the "Plan" process prune and steer the generation to produce the plausible set (i.e., those satisfying the constraints) and not the enormous legal set.

"Test" refines the evaluation of plausibility, discarding less worthy candidates and rank-ordering the remainder for examination by the user. "Test" first produces a "predicted" set of instrument data for each plausible candidate, using the rules described. It then evaluates the worth of each candidate by comparing its predicted data with the actual input data. The evaluation is based on heuristic criteria of goodness-of-fit. Thus, "test" selects the "best" explanations of the data.

"Plan" produces direct (i.e., not chained) inference about likely substructure in the molecule from patterns in the data that are indicative of the presence of the substructure. (Patterns in the data trigger the left-hand-sides of substructure rules). Though composed of many atoms whose interconnections are given, the substructure can be manipulated as atom-like by "generate." Aggregating many units entering into a combinatorial process into fewer higher-level units reduces the size of the combinatorial search space. "Plan" sets up the search space so as to be relevant to the input data. "Generate is the inference tactician; "Plan" is the inference strategist. There is a separate "Plan" package for each type of instrument data, but each package passes substructures (subgraphs) to "Generate." Thus, there is a uniform interface between "Plan" and "Generate." User-supplied constraints enter this interface, directly or from user-assist packages, in the form of substructures.

Sources of knowledge

The various sources of knowledge used by the DENDRAL system are:

Valences (legal connections of atoms); stable and unstable configurations of atoms; rules for mass spectrometry fragmentations; rules for NMR shifts; experts' rules for planning and evaluation; user-supplied constraints (contextual).

Results

DENDRAL's structure elucidation abilities are, paradoxically, both very general and very narrow. In general, DENDRAL handles all molecules, cyclic and tree-like. In pure structure elucidation under constraints (without instrument data), CONGEN is unrivaled by human performance. In structure elucidation with instrument data, DENDRAL's performance rivals expert human performance only for a small number of molecular families for which the program has been given specialist's knowledge, namely the families of interest to our chemist collaborators. I will spare this computer science audience the list of names of these families. Within these areas of knowledge-intensive specialization, DENDRAL's performance is usually not only much faster but also more accurate than expert human performance.

The statement just made summarizes thousands of runs of DENDRAL on problems of interest to our experts, their colleagues, and their students. The results obtained, along with the knowledge that had to be given to DENDRAL to obtain them, are published in major journals of chemistry. To date, 25 papers have been published there, under a series title "Applications of Artificial Intelligence for Chemical Inference: ⟨specific subject⟩" (see for example, the Buchanan, Smith, et al., 1976, reference).

The DENDRAL system is in everyday use by Stanford chemists, their collaborators at other universities and collaborating or otherwise interested chemists in industry. Users outside Stanford access the system over commercial computer/communications network. The problems they are solving are often difficult and novel. The British government is currently supporting work at Edinburgh aimed at transferring DENDRAL to industrial user communities in the UK.

Discussion

Representation and extensibility. The representation chosen for the molecules, constraints, and rules of instrument data interpretation is sufficiently close to that used by chemists in thinking about structure elucidation that the knowledge base has been extended smoothly and easily, mostly by chemists themselves in recent years. Only one major reprogramming effort took place in the last 9 years—when a new generator was created to deal with cyclic structures.

Representation and the Integration of multiple sources of knowledge. The generally difficult problem of integrating various sources of knowledge has been made easy in DENDRAL by careful engineering of the representations of objects, constraints, and rules. We insisted on a common language of compatibility of the representations with each other and with the inference processes: the language of molecular structure expressed as graphs. This leads to a straightforward procedure for adding a new source of knowledge, say, for example, the knowledge associated with a new type of instrument data. The procedure is this: write rules that describe the effect of the physical processes of the instrument on molecules using the situation⇒action form with molecular graphs on both sides; any special inference process using these rules must pass its results to the generator only (!) in the common graph language.

It is today widely believed in AI that the use of many diverse sources of knowledge in problem solving and data interpretation has a strong effect on quality of performance. How strong is, of course, domain-dependent, but the impact of bringing just one additional source of knowledge to bear on a problem can be startling. In one difficult (but not unusually difficult) mass spectrum analysis problem,* the program using its mass spectrometry knowledge alone would have generated an impossibly large set of plausible candidates (over 1.25 million!). Our engineering response to this was to add another source of data and knowledge, proton NMR. The addition on a simple interpretive theory of this NMR data, from which the program could infer a few additional constraints, reduced the set of plausible candidates to one, the right structure! This was not an isolated result but showed up dozens of times in subsequent analyses.

DENDRAL and data. DENDRAL's robust models (topological, chemical, instrumental) permit a strategy of finding solutions by generating hypothetical "correct answers" and choosing among these with critical tests. This strategy is opposite to that of piecing together the implications of each data point to form a hypothesis. We call DENDRAL's strategy largely model-driven, and the other data-driven. The consequence of having enough knowledge to do model-driven analysis is a large reduction in the amount of data that must be examined since data is being used mostly for verification of possible answers. In a typical DENDRAL mass spectrum analysis, usually no more than about 25 data points out of a typical total of 250 points are processed. This important point about data reduction and focus-of-attention has been discussed before by Gregory (1968) and by the vision and speech research groups, but is not widely understood.

Conclusion. DENDRAL was an early herald of AI's shift to the knowledge-based paradigm. It demonstrated the point of the primacy of domain-specific knowledge in achieving expert levels of performance. Its development brought to the surface important problems of knowledge representation, acquisition, and use. It showed that, by and large, the AI tools of the first decade were sufficient to cope with the demands of a complex scientific problem-solving task, or were readily extended to handle unforeseen difficulties. It demonstrated that AI's conceptual and programming tools were capable of producing programs of applications interest, albeit in narrow specialties. Such a demonstration of competence and sufficiency was important for the credibility of the AI field at a critical juncture in its history.

META-DENDRAL: inferring rules of mass spectrometry

Historical note

The META-DENDRAL program is a case study in automatic acquisition of domain knowledge. It arose out of our

* The analysis of an acyclic amine with formula C20H45N.

DENDRAL work for two reasons: first, a decision that with DENDRAL we had a sufficiently firm foundation on which to pursue our long-standing interest in processes of scientific theory formation; second, by a recognition that the acquisition of domain knowledge was the bottleneck problem in the building of applications-oriented intelligent agents.

Task

META-DENDRAL's job is to infer rules of fragmentation of molecules in a mass spectrometer for possible later use by the DENDRAL performance program. The inference is to be made from actual spectra recorded from known molecular structures. The output of the system is the set of fragmentation rules discovered, summary of the evidence supporting each rule, and a summary of contra-indicating evidence. User-supplied constraints can also be input to force the form of rules along desired lines.

Representations

The rules are, of course, of the same form as used by DENDRAL that was described earlier.

Sketch of method

META-DENDRAL, like DENDRAL, uses the generation-and-test framework. The process is organized in three stages: Reinterpret the data and summarize evidence (INTSUM); generate plausible candidates for rules (RULEGEN); test and refine the set of plausible rules (RULEMOD).

INTSUM: gives every data point in every spectrum an interpretation as a possible (highly specific) fragmentation. It then summarizes statistically the "weight of evidence" for fragmentations and for atomic configurations that cause these fragmentations. Thus, the job of INTSUM is to translate data to DENDRAL subgraphs and bond-breaks, and to summarize the evidence accordingly.

RULEGEN: conducts a heuristic search of the space of all rules that are legal under the DENDRAL rule syntax and the user-supplied constraints. It searches for plausible rules, i.e., those for which positive evidence exists. A search path is pruned when there is no evidence for rules of the class just generated. The search tree begins with the (single) most general rule (loosely put, "anything" fragments from "anything") and proceeds level-by-level toward more detailed specifications of the "anything." The heuristic stopping criterion measures whether a rule being generated has become too specific, in particular whether it is applicable to too few molecules of the input set. Similarly there is a criterion for deciding whether an emerging rule is too general. Thus, the output of RULEGEN is a set of candidate rules for which there is positive evidence.

RULEMOD: tests the candidate rule set using more complex criteria, including the presence of negative evidence. It removes redundancies in the candidate rule set; merges rules that are supported by the same evidence; tries further specialization of candidates to remove negative evidence; and tries further generalization that preserves positive evidence.

Results

META-DENDRAL produces rule sets that rival in quality those produced by our collaborating experts. In some tests, META-DENDRAL re-created rule sets that we had previously acquired from our experts during the DENDRAL project. In a more stringent test involving members of a family of complex ringed molecules for which the mass spectral theory had not been completely worked out by chemists, META-DENDRAL discovered rule sets for each subfamily. The rules were judged by experts to be excellent and a paper describing them was recently published in a major chemical journal (Buchanan, Smith, et al, 1976).

In a test of the generality of the approach, a version of the META-DENDRAL program is currently being applied to the discovery of rules for the analysis of nuclear magnetic resonance data.

MYCIN and TEIRESIAS: Medical diagnosis

Historical note

MYCIN originated in the Ph.D. thesis of E. Shortliffe (now Shortliffe, M.D. as well), in collaboration with the Infectious Disease group at the Stanford Medical School (Shortliffe, 1976). TEIRESIAS, the Ph.D. thesis work of R. Davis, arose from issues and problems indicated by the MYCIN project but generalized by Davis beyond the bounds of medical diagnosis applications (Davis, 1976). Other MYCIN-related theses are in progress.

Tasks

The MYCIN performance task is diagnosis of blood infections and meningitis infections and the recommendation of drug treatment. MYCIN conducts a consultation (in English) with a physician-user about a patient case, constructing lines-of-reasoning leading to the diagnosis and treatment plan.

The TEIRESIAS knowledge acquisition task can be described as follows:

In the context of a particular consultation, confront the expert with a diagnosis with which he does not agree. Lead him systematically back through the line-of-reasoning that produced the diagnosis to the point at which he indicates the analysis went awry. Interact with the expert to modify offending rules or to acquire new rules. Rerun the consultation to test the solution and gain the expert's concurrence.

Representations:

MYCIN's rules are of the form:

IF ⟨conjunctive clauses⟩ THEN ⟨implication⟩

Here is an example of a MYCIN rule for blood infections.

RULE 85

IF:
1) The site of the culture is blood, and
2) The gram stain of the organism is gramneg, and
3) The morphology of the organism is rod, and
4) The patient is a compromised host

THEN:
There is suggestive evidence (.6) that the identity of the organism is pseudomonas-aeruginosa

TEIRESIAS allows the representation of MYCIN-like rules governing the use of other rules, i.e., rule-based strategies. An example follows.

METARULE 2

IF:
1) the patient is a compromised host, and
2) there are rules which mention in their premise pseudomonas
3) there are rules which mention in their premise klebsiellas

THEN:
There is suggestive evidence (.4) that the former should be done before the latter.

Sketch of method

MYCIN employs a generation-and-test procedure of a familiar sort. The generation of steps in the line-of-reasoning is accomplished by backward chaining of the rules. An IF-side clause is either immediately true or false (as determined by patient or test data entered by the physician in the consultation); or is to be decided by subgoaling. Thus, "test" is interleaved with "generation" and serves to prune out incorrect lines-of-reasoning.

Each rule supplied by an expert has associated with it a "degree of certainty" representing the expert's confidence in the validity of the rule (a number from 1 to 10). MYCIN uses a particular ad-hoc but simple model of inexact reasoning to cumulate the degrees of certainty of the rules used in an inference chain (Shortliffe and Buchanan, 1975).

It follows that there may be a number of "somewhat true" lines-of-reasoning—some indicating one diagnosis, some indicating another. All (above a threshold) are used by the system as sources of knowledge indicating plausible lines-of-reasoning.

TEIRESIAS' rule acquisition process is based on a record of MYCIN's search. Rule acquisition is guided by a set of rule models that dictate the form and indicate the likely content of new rules. Rule models are not given in advance, but are inferred from the knowledge base of existing rules.

Language of interaction

The language used looks like it might be English but is actually the dialect "Doctor-ese" used by members of the tribe of healing arts practitioners. Reasonably simple language processing methods suffice. When ambiguities of interpretation are encountered, they are fed back to the user for decisions about meaning.

Example diagnosis and treatment plan

The following is an example of a diagnosis reported by MYCIN to one of its users following a consultation. An example consultation will not be shown, but one can be found in Shortliffe's book (Shortliffe, 1976).

My therapy recommendations will be designed to treat for organisms that are either very likely or, although less likely, would have a significant effect on therapy selection if they were present. It is important to cover for the following probable infection(s) and associated organism(s):

INFECTION-1 is CYSTITIS
⟨Item 1⟩ PSEUDOMONAS-CEPACIA [ORGANISM-5]
⟨Item 2⟩ CITROBACTER-DIVERSUS [ORGANISM-4]
⟨Item 3⟩ E.COLI [ORGANISM-3]

INFECTION-2 is UPPER-RESPIRATORY-INFECTION
⟨Item 4⟩ LISTERIA [ORGANISM-2]

INFECTION-3 is BACTEREMIA
⟨Item 5⟩ ENTEROCOCCUS [ORGANISM-1]

[REC-1] My preferred therapy recommendation is as follows:

In order to cover for Items ⟨1 2 3 4 5⟩:
Give the following in combination:
1) KANAMYCIN
Dose: 750 mg (7.5 mg/kg) q12h IM (or IV) for 28 days
Comments: Modify dose in renal failure
2) PENICILLIN
Dose: 2,500,000 units (25000 units/kg) q4h IV for 28 days

Results

No clinical evaluation of MYCIN is currently being done. In a preliminary evaluation, done outside of the clinical setting, a panel of expert judges was asked to rate MYCIN's performance along a number of dimensions (e.g., infecting organism identification, organism significance). In 90 percent of the cases submitted to the judges, a majority of the judges said that the program's decisions were the-same-as or as-good-as the decisions they would have made.

Explanation

MYCIN can expose its line of reasoning by offering explanations of various kinds. "Why" and "How" questions can be asked by the user during the consultation. "Why" is the user's way of inquiring, "Why do you want to know that?" "How" is his way of asking, "How did you conclude that. . . ?" In a post-consultation, he can similarly inquire about how the diagnostic conclusions were reached, and inquire about the reasons why certain other conclusions were ruled out. Examples of the MYCIN-TEIRESIAS explanation capabilities follow:

MYCIN: Is the patient's illness with ORGANISM-1 a hospital-acquired infection?
USER: WHY
TEIRESIAS: (i.e., WHY is it important to determine whether or not the infection with ORGANISM-1 was acquired while the patient was hospitalized?)

[1.0] This will aid in determining the category of ORGANISM-1.

It has already been established that

[1.1] the gram stain of ORGANISM-1 is gramneg, and
[1.2] the morphology of ORGANISM-1 is rod, and
[1.3] the aerobicity of ORGANISM-1 is facultative

Therefore, if

[1.4] the infection with ORGANISM-1 was not acquired while the patient was hospitalized

then

there is strongly suggestive evidence (.8) that the category of ORGANISM-1 is enterobacteriaceae

Also: there is weakly suggestive evidence (.1) that the identity of ORGANISM-1 is pseudomonas-aeruginosa [RULE 37]

USER: HOW 1.3

TEIRESIAS: [i.e. HOW was it established that the aerobicity of ORGANISM-1 is facultative?]

The following were used:

[3.1] RULE 27 indicated there is strongly suggestive evidence (.8) that the aerobicity of ORGANISM-1 is facultative

[3.2] RULE 27 indicated there is weakly suggestive evidence (.2) that the aerobicity of ORGANISM-1 is anaerobic

Since this gave a cumulative CF of (.8) for facultative, and (.2) for anaerobic, it has been established that the aerobicity of ORGANISM-1 is facultative.

USER: WHY DIDN'T YOU CONSIDER STREPTOCOCCUS AS A POSSIBILITY FOR ORGANISM-1?

TEIRESIAS: The following rule could have been used to determine that the identity of ORGANISM-1 was streptococcus: RULE 33

But clause 2 ("the morphology of the organism is coccus") was already known to be false for ORGANISM-1, so the rule was never tried.

Discussion

A few short comments aimed at knowledge engineering are in order.

English is the language most natural and comfortable for our experts and users, and was therefore the language chosen for interactive consultation, explanation, and external representation of the rules (the internal format is INTERLISP). This situation is not peculiar to doctors; in most areas of application of intelligent agents I believe that English (i.e., natural language) will be the language of choice. Programming an English language processor and front-end to such systems is not a scary enterprise because:

(a) the domain is specialized, so that possible interpretations are constrained.

(b) specialist-talk is replete with standard jargon and stereotyped ways of expressing knowledge and queries—just right for text templates, simple grammars and other simple processing schemes.

(c) the ambiguity of interpretation resulting from simple schemes can be dealt with easily by feeding back interpretations for confirmation. If this is done with a pleasant "I didn't quite understand you. . ." tone, it is not irritating to the user.

English may be exactly the wrong language for representation and interaction in some domains. It would be awkward, to say the least, to represent DENDRAL's chemical structures and knowledge of mass spectrometry in English, or to interact about these with a user.

Simple explanation schemes have been a part of the AI scene for a number of years and are not hard to implement. Really good models of what explanation is as a transaction between user and agent, with programs to implement these models, will be the subject (I predict) of much future research in AI.

Without the explanation capability, I assert, user acceptance of MYCIN would have been nil, and there would have been a greatly diminished effectiveness and contribution of our experts.

MYCIN was the first of our programs that forced us to deal with what we had always understood: that experts' knowledge is uncertain and that our inference engines had to be made to reason with this uncertainty. It is less important that the inexact reasoning scheme be formal, rigorous, and uniform than it is for the scheme to be natural to and easily understandable by the experts and users.

All of these points can be summarized by saying that MYCIN and its TEIRESIAS adjunct are experiments in the design of a see-through system, whose representations and processes are almost transparently clear to the domain specialist. "Almost" here is equivalent to "with a few minutes of introductory description." The various pieces of MYCIN—the backward chaining, the English transactions, the explanations, etc.—are each simple in concept and realization. But there are great virtues to simplicity in system design; and viewed as a total intelligent agent system, MYCIN/TEIRESIAS is one of the best engineered.

SU/X: signal understanding

Historical note

SU/X is a system design that was tested in an application whose details are classified. Because of this, the ensuing discussion will appear considerably less concrete and tangible than the preceding case studies. This system design was done by H. P. Nii and me, and was strongly influenced by the CMU Hearsay II system design (Lesser and Erman, 1977).

Task

SU/X's task is the formation and continual updating, over long periods of time, of hypotheses about the identity, location, and velocity of objects in a physical space. The output desired is a display of the "current best hypotheses" with full explanation of the support for each. There are two types of input data: the primary signal (to be understood); and auxiliary symbolic data (to supply context for the understanding). The primary signals are spectra, represented as descriptions of the spectral lines. The various spectra cover the physical space with some spatial overlap.

Representations

The rules given by the expert about objects, their behavior, and the interpretation of signal data from them are all represented in the situation⇒action form. The "situations" constitute invoking conditions and the "actions" are processes that modify the current hypotheses, post unresolved issues, recompute evaluations, etc. The expert's knowledge of how to do analysis in the task is also represented in rule form. These strategy rules replace the normal executive program.

The situation-hypothesis is represented as a node-link graph, tree-like in that it has distinct "levels," each representing a degree of abstraction (or aggregation) that is natural to the expert in his understanding of the domain. A node represents an hypothesis; a link to that node represents support for that hypothesis (as in HEARSAY II, "support from above" or "support from below"). "Lower" levels are concerned with the specifics of the signal data. "Higher" levels represent symbolic abstractions.

Sketch of method

The situation-hypothesis is formed incrementally. As the situation unfolds over time, the triggering of rules modifies or discards existing hypotheses, adds new ones, or changes support values. The situation-hypothesis is a common workspace ("blackboard," in HEARSAY jargon) for all the rules.

In general, the incremental steps toward a more complete and refined situation-hypothesis can be viewed as a sequence of local generate-and-test activities. Some of the rules are plausible move generators, generating either nodes or links. Other rules are evaluators, testing and modifying node descriptions.

In typical operation, new data is submitted for processing (say, N time-units of new data). This initiates a flurry of rule-triggerings and consequently rule-actions (called "events"). Some events are direct consequences of data; other events arise in a cascade-like fashion from the triggering of rules. Auxiliary symbolic data also cause events, usually affecting the higher levels of the hypothesis. As a consequence, support-from-above for the lower level processes is made available; and expectations of possible lower level events can be formed. Eventually all the relevant rules have their say and the system becomes quiescent, thereby triggering the input of new data to reenergize the inference activity.

The system uses the simplifying strategy of maintaining only one "best" situation-hypothesis at any moment, modifying it incrementally as required by the changing data. This

approach is made feasible by several characteristics of the domain. First, there is the strong continuity over time of objects and their behaviors (specifically, they do not change radically over time, or behave radically differently over short periods). Second, a single problem (identity, location and velocity of a particular set of objects) persists over numerous data gathering periods. (Compare this to speech understanding in which each sentence is spoken just once, and each presents a new and different problem.) Finally, the system's hypothesis is typically "almost right," in part because it gets numerous opportunities to refine the solution (i.e., the numerous data gathering periods), and in part because the availability of many knowledge sources tends to over-determine the solution. As a result of all of these, the current best hypothesis changes only slowly with time, and hence keeping only the current best is a feasible approach.

Of interest are the time-based events. These rule-like expressions, created by certain rules, trigger upon the passage of specified amounts of time. They implement various "wait-and-see" strategies of analysis that are useful in the domain.

Results

In the test application, using signal data generated by a simulation program because real data was not available, the program achieved expert levels of performance over a span of test problems. Some problems were difficult because there was very little primary signal to support inference. Others were difficult because too much signal induced a plethora of alternatives with much ambiguity.

A modified SU/X design is currently being used as the basis for an application to the interpretation of x-ray crystallographic data, the CRYSALIS program mentioned later.

Discussion

The role of the auxiliary symbolic sources of data is of critical importance. They supply a symbolic model of the existing situation that is used to generate expectations of events to be observed in the data stream. This allows flow of inferences from higher levels of abstraction to lower. Such a process, so familiar to AI researchers, apparently is almost unrecognized among signal processing engineers. In the application task, the expectation-driven analysis is essential in controlling the combinatorial processing explosion at the lower levels, exactly the explosion that forces the traditional signal processing engineers to seek out the largest possible number-cruncher for their work.

The design of appropriate explanations for the user takes an interesting twist in SU/X. The situation-hypothesis unfolds piecemeal over time, but the "appropriate" explanation for the user is one that focuses on individual objects over time. Thus the appropriate explanation must be synthesized from a history of all the events that led up to the current hypothesis. Contrast this with the MYCIN-TEIRESIAS reporting of rule invocations in the construction of a reasoning chain.

Since its knowledge base and its auxiliary symbolic data give it a model-of-the-situation that strongly constrains interpretation of the primary data stream, SU/X is relatively unperturbed by errorful or missing data. These data conditions merely cause fluctuations in the credibility of individual hypotheses and/or the creation of the "wait-and-see" events. SU/X can be (but has not yet been) used to control sensors. Since its rules specify what types and values of evidence are necessary to establish support, and since it is constantly processing a complete hypothesis structure, it can request "critical readings" from the sensors. In general, this allows an efficient use of limited sensor bandwidth and data acquisition processing capability.

Other case studies

Space does not allow more than just a brief sketch of other interesting projects that have been completed or are in progress.

AM: mathematical discovery

AM is a knowledge-based system that conjectures interesting concepts in elementary mathematics. It is a discoverer of interesting theorems to prove, not a theorem proving program. It was conceived and executed by D. Lenat for his Ph.D. thesis, and is reported by him in these proceedings.

AM's knowledge is basically of two types: rules that suggest possibly interesting new concepts from previously conjectured concepts; and rules that evaluate the mathematical "interestingness" of a conjecture. These rules attempt to capture the expertise of the professional mathematician at the task of mathematical discovery. Though Lenat is not a professional mathematician, he was able successfully to serve as his own expert in the building of this program.

AM conducts a heuristic search through the space of concepts creatable from its rules. Its basic framework is generation-and-test. The generation is plausible move generation, as indicated by the rules for formation of new concepts. The test is the evaluation of "interestingness." Of particular note is the method of test-by-example that lends the flavor of scientific hypothesis testing to the enterprise of mathematical discovery.

Initialized with concepts of elementary set theory, it conjectured concepts in elementary number theory, such as "add," "multiply" (by four distinct paths!), "primes," the unique factorization theorem, and a concept similar to primes but previously not much studied called "maximally divisible numbers."

MOLGEN: planning experiments in molecular genetics

MOLGEN, a collaboration with the Stanford Genetics Department, is work in progress. MOLGEN's task is to

provide intelligent advice to a molecular geneticist on the planning of experiments involving the manipulation of DNA. The geneticist has various kinds of laboratory techniques available for changing DNA material (cuts, joins, insertions, deletions, and so on); techniques for determining the biological consequences of the changes; various instruments for measuring effects; various chemical methods for inducing, facilitating, or inhibiting changes; and many other tools.

Some MOLGEN programs under development will offer planning assistance in organizing and sequencing such tools to accomplish an experimental goal. Other MOLGEN programs will check user-provided experiment plans for feasibility; and its knowledge base will be a repository for the rapidly expanding knowledge of this specialty, available by interrogation.

In MOLGEN the problem of integration of many diverse sources of knowledge is central since the essence of the experiment planning process is the successful merging of biological, genetic, chemical, topological, and instrument knowledge. In MOLGEN the problem of representing processes is also brought into focus since the expert's knowledge of experimental strategies—proto-plans—must also be represented and put to use.

One MOLGEN program (Stefik, 1978) solves a type of analysis problem that is often difficult for laboratory scientists to solve. DNA structures can be fragmented by chemicals called restriction enzymes. These enzymes cut DNA at specific recognition sites. The fragmentation may be complete or partial. One or more enzymes may be used. The fragmented segments of the DNA are collected and sorted out by segment length using a technique called gel electrophoresis. The analytical problem is similar to that faced by DENDRAL: given an observed fragmentation pattern, hypothesize the best structural explanation of the data. More precisely the problem is to map the enzyme recognition sites of a DNA structure from complete or partial "digests".

The program uses the model-driven approach that is similar to DENDRAL's and is discussed earlier. The method is generate-and-test. A generator is initiated that is capable of generating all the site-segment maps in an exhaustive, irredundant fashion. Various pruning rules are used to remove whole classes of conceivable candidates in light of the data. Some of the pruning rules are empirical and judgmental. Others are formal and mathematically based.

The program solves simpler problems of this type of analysis better than laboratory scientists. The harder problems, however, yield only to the broader biological knowledge known by the scientists and not yet available to the program's reasoning processes. In a recent test case, a problem whose solution space contained approximately 150,000,000 site-fragment "maps" was solved in 27 seconds of PDP-10 time using the INTERLISP programming system.

Interestingly, the computer scientist's formal understanding of the nature of the problem, his formal representation of the knowledge used for pruning out inappropriate candidates, and the computational power available to him enabled him to suggest a few new experiment designs to his geneticist collaborators that were not previously in their repertoire.

CRYSALIS: inferring protein structure from electron density maps

CRYSALIS, too, is work in progress. Its task is to hypothesize the structure of a protein from a map of electron density that is derived from x-ray crystallographic data. The map is three-dimensional, and the contour information is crude and highly ambiguous. Interpretation is guided and supported by auxiliary information, of which the amino acid sequence of the protein's backbone is the most important. Density map interpretation is a protein chemist's art. As always, capturing this art in heuristic rules and putting it to use with an inference engine is the project's goal.

The inference engine for CRYSALIS is a modification of the SU/X system design described above. The hypothesis formation process must deal with many levels of possibly useful aggregation and abstraction. For example, the map itself can be viewed as consisting of "peaks," or "peaks and valleys," or "skeleton." The protein model has "atoms," "amide planes," "amino acid sidechains," and even massive substructures such as "helices." Protein molecules are so complex that a systematic generation-and-test strategy like DENDRAL's is not feasible. Incremental piecing together of the hypothesis using region-growing methods is necessary.

The CRYSALIS design (alias SU/P) is described in a recent paper by Nii and Feigenbaum (1977).

SUMMARY OF CASE STUDIES

Some of the themes presented earlier need no recapitulation, but I wish to revisit three here: generation-and-test; situation⇒action rules; and explanations.

Generation and test

Aircraft come in a wide variety of sizes, shapes, and functional designs and they are applied in very many ways. But almost all that fly do so because of the unifying physical principle of lift by airflow; the others are described by exception. If there is such a unifying principle for intelligent programs and human intelligence it is generation-and-test. No wonder that this has been so thoroughly studied in AI research!

In the case studies, generation is manifested in a variety of forms and processing schemes. There are legal move generators defined formally by a generating algorithm (DENDRAL's graph generating algorithm); or by a logical rule of inference (MYCIN's backward chaining). When legal move generation is not possible or not efficient, there are plausible move generators (as in SU/X and AM). Sometimes generation is interleaved with testing (as in MYCIN, SU/X, and AM). In one case, all generation precedes testing (DENDRAL). One case (META-DENDRAL) is mixed, with some testing taking place during generation, some after.

Test also shows great variety. There are simple tests (MYCIN: "Is the organism aerobic?"; SU/X: "Has a spectral line appeared at position P?") Some tests are complex heuristic evaluations (AM: "Is the new concept 'interesting'?"; MOLGEN: "Will the reaction actually take place?") Sometimes a complex test can involve feedback to modify the object being tested (as in META-DENDRAL).

The evidence from our case studies supports the assertion by Newell and Simon that generation-and-test is a law of our science (Newell and Simon, 1976).

Situation⇒action rules

Situation⇒Action rules are used to represent experts' knowledge in all of the case studies. Always the situation part indicates the specific conditions under which the rule is relevant. The action part can be simple (MYCIN: conclude presence of particular organism; DENDRAL: conclude break of particular bond). Or it can be quite complex (MOLGEN: an experiential procedure). The overriding consideration in making design choices is that the rule form chosen be able to represent clearly and directly what the expert wishes to express about the domain. As illustrated, this may necessitate a wide variation in rule syntax and semantics.

From a study of all the projects, a regularity emerges. A salient feature of the Situation⇒Action rule technique for representing experts' knowledge is the modularity of the knowledge base, with the concomitant flexibility to add or change the knowledge easily as the experts' understanding of the domain changes. Here too one must be pragmatic, not doctrinaire. A technique such as this cannot represent modularity of knowledge if that modularity does not exist in the domain. The virtue of this technique is that it serves as a framework for discovering what modularity exists in the domain. Discovery may feed back to cause reformulation of the knowledge toward greater modularity.

Finally, our case studies have shown that strategy knowledge can be captured in rule form. In TEIRESIAS, the metarules capture knowledge of how to deploy domain knowledge; in SU/X, the strategy rules represent the experts' knowledge of "how to analyze" in the domain.

Explanation

Most of the programs, and all of the more recent ones, make available an explanation capability for the user, be he end-user or system developer. Our focus on end-users in applications domains has forced attention to human engineering issues, in particular making the need for the explanation capability imperative.

The Intelligent Agent viewpoint seems to us to demand that the agent be able to explain its activity; else the question arises of who is in control of the agent's activity. The issue is not academic or philosophical. It is an engineering issue that has arisen in medical and military applications of intelligent agents, and will govern future acceptance of AI work in applications areas. And on the philosophical level one might even argue that there is a moral imperative to provide accurate explanations to end-users whose intuitions about our systems are almost nil.

Finally, the explanation capability is needed as part of the concerted attack on the knowledge acquisition problem. Explanation of the reasoning process is central to the interactive transfer of expertise to the knowledge base, and it is our most powerful tool for the debugging of the knowledge base.

ACKNOWLEDGMENT

The work reported herein has received long-term support from the Defense Advanced Research Projects Agency (DAHC 15-73-C-0435). The National Institutes of Health (5R24-RR00612, RR-00785) has supported DENDRAL, META-DENDRAL, and the SUMEX-AIM computer facility on which we compute. The National Science Foundation (MCS 76-11649, DCR 74-23461) has supported research on CRYSALIS and MOLGEN. The Bureau of Health Sciences Research and Evaluation (HS-10544) has supported research on MYCIN. I am grateful to these agencies for their continuing support of our work.

I wish to express my deep admiration and thanks to the faculty, staff and students of the Heuristic Programming Project, and to our collaborators in the various worldly arts, for the creativity and dedication that has made our work exciting and fruitful.

The ubiquity of discovery*

by DOUGLAS B. LENAT
Carnegie-Mellon University
Pittsburgh, Pennsylvania

INTRODUCTION

Much of the behavior which we regard as "intelligent" involves some sort of *discovery* process.** This is obvious for some of the most creative and intellectually difficult human activities (identifying an unknown chemical compound, composing a new sonnet, deriving a new cosmological model, ligating plasmids, conjecturing a new theorem, probing the internal structure of a proton, solving the N.Y. Times crossword puzzle, . . .). By the end of this talk we'll see that it's no less true for our everyday activities (understanding spoken English, making a joke, driving from CMU to MIT, cutting cheese, playing board games, finding our way about Boston, solving the Pittsburgh Press crossword puzzle, . . .).

Model-building in science

We in the field of Artificial Intelligence (AI) want to understand how it's possible to do such things, to understand the mechanisms of intelligence. I'll propose a theory of how humans are able to carry out such tasks, and then embody that theory in several concrete, testable models.

Scientific models are useful because they (i) *unify* large masses of empirical data (e.g., the periodic table); and they (ii) *predict* new effects, which subsequently can be tested for by conducting experiments (e.g., Young's two-slit interference test for the wave theory of light).

In very "hard" sciences, objective data are available about isolated and relatively simple phenomena. This enables the construction of small yet quite rigorous *predictive* models, using the language of mathematics (e.g., Maxwell's equations). But in the so-called "soft" fields, the phenomena cannot be measured precisely (the role of the family, the "life after life" reports, etc.), or are not so reproducible (the evolution of life, the origins of WWI, etc.), or (as in the case of human intelligence) cannot be easily isolated for study (e.g., the genetic component of IQ). The resulting models are usually only *descriptive*, and may often be presented in everyday prose (e.g., psychological theories of personality).***

The physicist's model (his set of equations) is better than mere prose because it is able to draw on the power of established mathematics† to make *quantitative* predictions.

But planets and atoms behave in much more regular a fashion than do people. Can we build a hard, predictive sort of model for the phenomena of discovery and creativity? Or are we limited to sterile prose discussions about the mysteries of incubation and illumination (e.g., as in References 3 and 4)? Can we draw only metaphorical pictures (e.g., as in the 'hooked atoms' image that Einstein conjured up when pressed to introspect on how he attained his insights;[5] or as in the "snake swallowing its own tail" dream that inspired Kekule to consider that the structure of the benzine molecule might be a *ring*)? The answer, until just twenty years ago, was unfortunately "We can't do any better." When the answer changed, a whole new science, Artificial Intelligence, was born.

Choosing an approach in science

Each science is differentiated from the others not merely by the set of *phenomena* it claims as its object of study, but also by the *approach* it takes (the science's *view* of those phenomena; its *paradigm*,[6] if you will).

So even though we've decided to study the phenomena of human intelligence (creativity, problem solving, concept formation, etc.), we must still choose a *view* of Man.

If we view Man as an actor whose internal thought processes can't be investigated, then we are called "behavioral psychologists," and we study human behavior. If we view Man as a brain, as a piece of hardware built out of neurons, then we're called "biologists" and we study neurophysio-

* This work was supported in part by the National Science Foundation (MCS77-04440), and in part by the Defense Advanced Research Projects Agency (F44620-73-C-0074).

** Much of the rest of "intelligence" involves algorithmic solving of well-structured problems. That topic will not be emphasized in this paper. We take the position that "algorithms known and used by experts" is just a proper subset of "knowledge experts use to reduce search."

*** Attempts to formalize "soft" phenomena do go on continually, but the interpretation of the resultant rigorous mathematics is often a topic of heated debate (a current example is Catastrophe Theory.[1]

† The power to solve analysis problems in closed form (e.g., to solve a differential equation simply by repeatedly manipulating it according to known transformations), or the power to make approximations when necessary, or the power to somehow "run" the model (to "grind out" solutions to his equations).

SOME HEURISTICS ARE ALMOST ALWAYS RELEVANT

(a) >If X is often true, try to find out exactly where it does and doesn't hold.
(b) >If you must do some new, complicated task, try to arrange things so that the tools, subtasks, etc. are very familiar.
>Look at the extreme cases of the known relationships.
>Ignore minor details until a basic plan is formed.

.
.
.

SOME HEURISTICS ARE RELEVANT WHEN DOING MATH OR SCIENCE

>Even if a theory predicts something strongly, if a very easy test is available, do it (you may be surprised).
>The more important a step is (in a proof, an experiment, etc.), the more stringent verification to which it should be subjected.
>Design experiments so that a negative result will still be interesting.
>When preparing an article's bibliography, cite all possible referees.

. . .

SOME HEURISTICS ARE RELEVANT WHEN DOING BIOLOGY

(a) >It's interesting to study whether a mechanism from one species also operates in another species.
(b) >When choosing which type of experimental animal to use, favor a species about which much is already known.

. . .

SOME HEURISTICS ARE RELEVANT WHEN DOING MOLECULAR GENETICS

(a) >It's interesting to study whether gene control signals from one species are operative in another species.
(b) >E. Coli is a favorite because much is known about its genetics; many of its plasmids have been characterized and are available.
>If you want to introduce DNA between strains of bacteria, then typical vectors to use are plasmids and lysogenic viruses.
>To check whether a gene transferred to a new host has been modified, reintroduce it into its donor.

. . .

SOME HEURISTICS ARE RELEVANT WHEN DOING MATHEMATICS

>If $f: A \times A \times \ldots \times A \to B$, and $A \subset B$, then see if in fact $f: A \times A \times \ldots \times A \to A$;
Else try to find a subset S of A for which $f: S \times S \times \ldots \times S \to S$.
>If a set S has only a few elements, then it's no longer of interest;
But it is worth trying to understand the reason why S is so small.

Figure 1—Hierarchy of heuristic rules

logical responses (e.g., by implanting electrodes). If we view Man as a machine, as an automaton, then we're called "cyberneticists," and we investigate mathematical properties of feedback networks of simple components. If we view Man as a collection of atomic particles, then we're called foolish,** for this is too fine a "granularity" with which to investigate intelligence.

Another view arose about twenty years ago, from three independent sources: (*i*) engineering (Donald Broadbent: Man can be viewed as an information processor with a limited memory system), (*ii*) psycholinguistics (Noam Chomsky: Grammar characterizes human competence; hence, Man can be viewed as a system governed by abstract rules), and (*iii*) computer science and cognitive psychology (Allen Newell and Herbert Simon: Man can be viewed as a processor of symbols). If we adopt that view of Man, then we're working in the field of "Artificial Intelligence."

No one view of Man is "right" or "wrong;" each is adopted because from it we can build a model, which in turn

** Unlike the Brownian motion of atoms in a perfect gas, the fundamental information processes of intelligence are *not random*.

has some practical consequences and uses. When I'm ill, I want to go to a doctor who practices medicine based on Man as a biological organism, not Man as an economic agent. At the present limited state of our understanding, any one view is bound to be simplistic and incomplete.* It is the *whole man* who lives and reacts, even though we can only *view* him, first this way, then that.

The foundation for artificial intelligence

Suppose we view Man as information processor.[7,6] How can we construct models of intelligence that are predictive rather than just descriptive? We might build *operational* models, which can *exhibit* whatever behavior our theory called for. To do this, we need to use a general purpose symbol manipulator: (*i*) a way to specify what processing gets done when, (*ii*) a memory in which to store symbol structures,** and (*iii*) an "engine" that can actually cause such processing to occur. The science of Artificial Intelligence ("AI") sprang into being soon after the invention of one such computational engine: the digital computer. In fact, AI is sometimes called "Machine Intelligence."

The paradigm of AI research

We in AI have evolved the following paradigm:

(i) Choose some human cognitive activity (like playing chess, proving theorems, understanding spoken English).
(ii) Develop hypotheses and eventually a theory about what kinds of information processing could be taking place to produce such ability.
(iii) Incorporate that theory into a computer program, which serves as the model. Make that computer program carry out the original activity, and observe how well it does.†
(iv) Experiment with the program, attempting to find out where the apparent "intelligence" is really coming from.

Over the last twenty years, we've hypothesized and tested scores of models, for several different sophisticated tasks. There have been many successes (such as the Hearsay speech understanding programs), and many failures. Failure often stemmed from *underestimating* how complicated some activity is, which human beings are able to do fairly easily (for instance, driving a car, or understanding someone who's speaking into a microphone.) We once thought that translation by machine could be accomplished by a program which simply looked up each word in a Russian/English dictionary. Legend has it that "*The spirit is willing but the flesh is weak*" was translated into Russian as "*The vodka is fine but the meat is rotten.*"

We've learned a lot from both the successes and the failures. Some of these experiments will be described later; for now, I just want to present a single, very central result.

It turns out that we can model a surprising variety of cognitive activities (recognizing, problem solving, inventing) as a *search* in which the performer is guided by a large collection of informal rules of thumb, which we shall call "heuristics" or "heuristic rules." But what's really exciting is that not only can this single theory (intelligence as heuristic rule guided search) explain the behavior of the brainstorming math researcher and the wandering Boston visitor, but when we go off and build up such models in detail, we find that they can all contain many of the same—or at least similar—heuristics. If we look at many heuristics (see Figure 1), we find that each one seems to have its own sphere of influence, its own domain of applicability, outside of which it is meaningless or useless. There exist many heuristics at all these levels; many of the specific ones are just specializations of one at higher levels (e.g., "*study gene control signals across species boundaries*" is a special case of "*study the scope of biological mechanisms,*" which in turn is a special case of "*study the scope of any phenomenon.*")

HEURISTIC RULE GUIDED SEARCH

The theory

There is a theory of intelligence lurking here:

1. Human cognitive tasks can be cast as *searches,* as explorations wandering toward some goal.
2. We are guided in these searches by a large collection of informal rules of thumb (which we've been calling *heuristics*).
3. We access relevant heuristics in each situation, and follow their advice.

That's it.* It sounds plausible; in fact, it sounds trivial. Yet the models which incorporate this theory are capable of performing many tasks which one would suppose require intelligence (organic chemistry problem solving and research, chess playing, composing musical variations, diagnosing blood infections, discovering new math concepts and conjectures, etc.). (See Figure 2)

* On the other hand, we never capriciously adopt a view with impunity.

** Symbol processing is not the same as mere data processing. See Reference 8. It was some years after its discovery that the electronic digital computer was perceived as a general symbol manipulator.

† AI deviates from cognitive psychology at this stage. Psychologists would run experiments on people, to see if they really do fit the theory. We in AI are more concerned with whether the programs containing the hypothesized mechanisms are capable of *any* sort of "intelligent" behavior—even if it differs somewhat from human performance at that task.

* Notice the conspicuous absence of the word "representation" anywhere in the theory. To design and construct a *model* for this theory would entail grappling with representational issues, much as any running instance of an abstract algorithm must exist on some particular machine. But the validity and power of the theory are independent of representation, just as the validity and complexity of an algorithm are independent of which machine it's implemented on.

Program	Task
AM	Elementary theory formation and discovery in mathematics
DENDRAL	Enumeration of atom-bond graphs of organic molecules
EURISKO	Discovery of new mathematics and new heuristics
Meta-DENDRAL	Abstraction of new fragmentation rules for Dendral
M-METHOD	Improvization of variations on melodies
MOLGEN	Planning of molecular genetics experiments
MYCIN	Clinical diagnosis of blood infections
PECOS	Expert at coding programs in Lisp
PROSPECTOR	Evaluating the mineral potential of sites
PUFF	Medical expert for pulmonary disorders
RITA	Learns how to run programs at remote Arpanet sites
SU/X	Combine many sources' signals into a global model
TEIRESIAS	Expert at extracting new Mycin rules from physicians
UT-ITP	Natural deduction proofs of theorems

Figure 2—Heuristic rule based search program

Intelligence and information

The theory contains two important implicit assumptions, which are worth displaying explicitly:

- Man is viewed as a processor of symbolic information.
- Man exhibits "intelligence" by his performance at various cognitive tasks.

They say that information processing has something to do with intelligence. Let's try to justify that.

Twenty-seven years ago, Alan Turing[9] rejected as meaningless the question "*Can machines think?*" He replaced it with a game, called the Imitation Game (now commonly referred to as the Turing Test). One version of the game would go as follows: A human interrogator is placed in an isolated room. A teletype exists in the room, and by using it he can communicate with a computer and with another human, both located in the next room. The interrogator asks them each some questions, and then must guess which is the human and which is the machine. If we can program a machine in such a way that it fools the interrogator into making the wrong identification at least 50 percent of the time, then we shall say that the machine (as programmed) is "intelligent." Many of you are familiar with this game. Now let me introduce you to a slightly different one:

Thirteen years ago, Keith Gunderson[10] rejected as meaningless the question "*Can rocks think?*" He replaced it with a game, an Imitation Game. A human interrogator is placed in an isolated room. A small hole exists near the bottom of the door, through which the interrogator can shove most of his foot. On the other side of the door are located a human and a rock. Sometimes the human will stomp on the interrogator's foot, and sometimes the rock will fall on it. The interrogator then must guess which one is the human. If we can shape a rock in such a way that it fools the interrogator at least 50 percent of the time, then we shall say that the rock (as shaped) is "intelligent".*

* During the oral presentation of this talk at IJCAI-77, the rock test was demonstrated onstage, with Allen Newell in the role of the unfortunate interrogator.

Why does the dialogue-test sound so much less silly, so much more indicative of intelligence, than the stomping-test? Because unrestricted dialogue is open-ended; it permits genuine interrogation of information and information processing capabilities. The second test doesn't. If you agree that the first test is genuine and the second one bogus, it must be because intelligence has *something* to do with sophisticated processing of massive quantities of information.

Thus it seems that the information processing view of Man is an especially good one from which to study intelligence. Before we see what happens when one tries to build models based on it, let's look at six different kinds of situations requiring intelligence, and see if our theory can handle them all.

Some examples supporting the theory

Everyday problem solving

Suppose we decide to plan a trip from CMU to MIT. How can we find a good route to take? We will probably obtain a detailed road map and begin *searching*. We have some powerful rules of thumb which make our search very short. We look for some main highways that will take us most of the way, and then do some "fixing up" around the termini.

The map-makers aid us by drawing the biggest highways as very thick red lines. Needless to say, ignoring all but the red lines makes the map much simpler. (Thick red lines constrain furiously.) The very general heuristic of *planning* has reduced our search dramatically. One could imagine even a computer being able to solve it. In the next subsection, we'll show that the same kind of analysis can explain episodes of brainstorming (in particular, the inventing some new kitchen gadget).

Everyday invention

Suppose we're confronted with the following problem: we're fond of eating cheese, but it's difficult to use a knife to cut uniform, thin slices. Let's assume that we try

The thinner the knife, the thinner the slices
The softer the cheese, the easier it is cut [except: Brie, . . .]
The slower the slicing, the more uniform the slices
The longer the knife, the more uniform the slices
The rounder the whole cheese, the more irregular slices there will be
etc.

Figure 3—Cheese-cutting relationships

to design an improved tool. We are now facing a search in an enormous space of possibilities. But we have many informal rules of thumb which may help us:

1. Sometimes, there will be a good way (perhaps a recent invention) to do something *more general* than what is strictly asked for.
2. Consider what variables affect the success/failure of the current (inadequate) technique. Look for motivation at the *extreme* cases of the various known relationships involving those variables.
3. Look carefully at what is truly wanted; maybe the problem can be completely bypassed; at least, perhaps it's over-specified.

One of them (#2) says to look for motivation at the *extreme* cases of various known relationships. We know several things about cutting thin slices (see Figure 3). There seems to be some relationship between the thickness of the knife and the thinness of the slices we can cut. So we might consider as an extreme the thinnest knife possible, just a knife *edge*, and perhaps we thereby invent the wire cheese cutter. Or we might look at the extreme case of the relation that says that most cheese can be cut thinner if it's softer, moreso than if it's dry and crumbly. We may ask ourselves if we can get the cheese very soft; completely molten; maybe then pour it into slice-molds, much like making a thin crepe. That's too messy. If we keep the cheese solid, and use a knife, maybe we could just get the cheese *directly under the knife-edge* completely molten; so we've invented the "hot-knife;" General Electric will probably come out with one soon.

This brainstorming seemed like fun. Incorporating heuristic rules into a computer model which could then tirelessly systematically apply them seems like a very promising direction to follow. We'll follow it in a later section. Bear in mind, however, that inventions are rarely made with little or no search. In the cheese-cutting case, there might be hundreds of somewhat relevant heuristics, and many ways of applying each one, and only a few of these combinatorial possibilities are even remotely viable.

On the other hand, both of these other heuristics *can* be used in this situation. The first one is the "inventor's paradox": sometimes the easiest way to solve a problem is to find and solve a more general case, an apparently-harder problem. In the cheese-cutting situation, the heuristic might direct us to look at various devices which "cut": a big scissors? a paper-cutter? a light-saber? the new whirling-nylon-cord grass-cutters? It so happened that recently I came across a cheese slicer which operates remarkably like a paper-cutter. (See Figure 4).

Heuristic number three might have us build a better mousetrap: go into business selling already sliced cheese; or try to devise a "cheese press" that takes the crumbs and squeezes or melts them together into shapes that resemble cheese slices. "Kraft singles" are just such a product: processed cheese shaped into slices and then individually wrapped.

Judging "interestingness"

Let's put our theory to a most severe test, by asking whether it can account for our everyday judgments about

Figure 4—Paper-cutter-like cheese slicer

MOLECULAR GENETICS EXPERIMENT

Transform Thy$^-$ E. Coli into Thy$^+$ E. Coli
by transferring the relevant gene from the bacteriophage Phi-3-T.

EXPANDED PLAN

1. Extract Phi-3-T DNA from bacteriophage Phi-3-T.
   Verify the purity of the DNA by measuring UV absorbtion.
   Check that the molecules are intact, using electron microscope.
   Ensure adequate transforming ability in B. Subtilis.
2. Add restriction enzymes to break the DNA into fragments.
   Completely digest the DNA, by adding enzyme EcoR$_I$.
   Use electrophoresis to estimate the molecular wts. of the fragments.
   Study, hypothesize, and test until confident of what's happening.
   Re-do the digestion, but stopping it after partially complete.
3. Mix the fragments with E. Coli plasmids to construct hybrid plasmids.
   Use EcoR$_I$ to cut out psc101 plasmids from E. Coli.
   After mixing these with the fragments, ligate with T4 ligase.
4. Use these cloned plasmids to transform the E. Coli.
   Grow colonies, selecting for Thy$^+$
5. Verify the Thy$^+$ character of the transformed E. Coli.
   Use a curing technique to remove the hybrid plasmids from E. Coli.
   Confirm the experiment by reintroducing them into cured bacteria and testing that th
   observed frequencies of transform stay constant.

PLAN FOR THE EXPERIMENT

1. Extract Phi-3-T DNA from bacteriophage Phi-3-T.
2. Add restriction enzymes to break the DNA into fragments.
3. Mix the fragments with E. Coli plasmids to construct hybrid plasmids.
4. Use these cloned plasmids to transform the E. Coli.
5. Verify the Thy$^+$ character of the transformed E. Coli.

Figure 5—Molecular genetics experiment

what is and isn't "interesting." This would seem to be the realm of intuition, emotion, taste, and aesthetics—the antithesis of logical empiricism.* If we look, we find that texts on the arts abound with "rules" of composition. They analyze artistic works in terms of symmetry, recency, unconventionality, harmony, utility, etc. A typical rule might say:

> IF two apparently disparate parts of the work are suddenly recognized as being very closely related,
> THEN that increases the interestingness of both parts, and of the whole work as well.

Charles Dickens' popularity is due in no small measure to his mastery of this heuristic of "coincidence:" the reader is always astonished and pleased when two separate characters are discovered to be one and the same person. Escher's art is pervaded by just this sort of co-identification (consider his print where geese and fish "turn into" one another).

* If in fact there is a large non-rational component to such judgments, then it is not surprising if they lie outside the power of any theory founded on a view of Man which ignores that aspect of him. So even a partial success at explaining "taste" in terms of heuristic rules would be significant.

Scientific Problem Solving

Suppose we're designing a molecular genetics experiment, whose ultimate goal is to transfer a gene from one bacteria to another, by using a plasmid (a small, circular DNA molecule). (See Figure 5) We must design a very long chain of steps (perhaps reaching into the thousands), each of the form "raise the temperature to x degrees," "add the following restriction enzyme in order to cut the DNA at a certain place," etc.

It's a common practice to ignore certain kinds of minor steps, and to concentrate on finding a relatively small sequence of important intermediate goals. Afterwards, we can "expand" each subgoal into a detailed list of small steps. (See Figure 5, again) We solved the problem by applying a general heuristic—planning—plus several heuristics specific to molecular genetics.

The heuristic used is just the one we used previously to find a route from CMU to MIT. There, we chose to ignore all minor roads on the map. Here, we chose to ignore the minor experimental steps. This repetition is not accidental; it illustrates the commonality between everyday problem solving and scientific problem solving. Let's see if this sim-

ilarity also occurs between everyday invention and scientific invention.

Scientific invention

Suppose we're confronted with the following problem: we're fond of factoring numbers, but it's difficult to use *division* to cut the numbers up in any uniform, repeatable way. E.g., one time, we may factor 12 into 2×6, another time into 3×4, and another time it crumbles into even more pieces: {1,2,2,3}. We may be content with this situation, or we may try to find out more about factoring, to improve our "cutting tool"—division—or the way in which we wield it.

Such an endeavor would involve searching an enormous space (looking for a new kind of factoring; looking for new facts about factoring). But we have many rules of thumb to help us, including the three rules which were displayed earlier.

One of them (#2) says to look for motivation at the *extreme* cases of various known relationships. In other words, when you've got an interesting function f from A into B, and there are some special subsets of B, extreme kinds of B's, then it's worth defining and studying the inverse images of those special parts of B, i.e., the members of A which map into those special B's. (See Figure 6) The function in this case is "Divisors-of." It maps a number into a set of numbers. (E.g., Divisors-of [12]={1,2,3,4,6,12}.) An extreme case would be when it mapped a number into an extreme kind of set, say an extremely *small* kind of set (e.g., into a singleton, an empty set, a doubleton, etc.).

In other words, this heuristic rule says that it's worth defining and studying the set of numbers with no divisors, with just one divisor, with precisely two divisors, and maybe the set of numbers with precisely three divisors. *Voila'*, we've invented prime numbers. Notice that we used the very same heuristic that led earlier to the invention of the wire cheese cutter and the hot-knife.

Judging "interestingness"

Even allowing that the "heuristic rule guided search" theory could account for the *discovery*—the definition—of prime numbers, could it also explain how a researcher might have noticed that they were valuable and interesting?

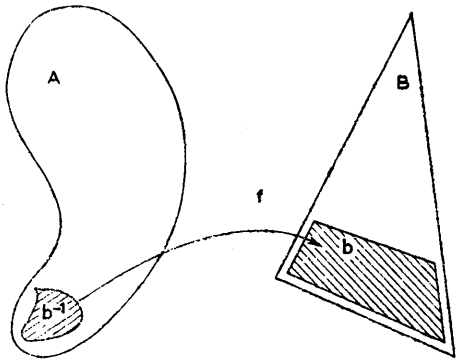
Let's look at how the following four heuristic rules could lead to the conclusion that "Primes" is interesting, soon after it had first been defined.

(#1) IF specializations of concept C have just been created, and the current task is to find examples of each of them,
THEN one method is to look over the known examples of C; they may be examples of some of the new specialized concepts as well.

(#2) IF all examples of a concept C turn out to be examples of another concept D as well, and C was not previously known to be a specialization of D,
THEN conjecture that C is a specialization of D, and raise the "interestingness" value of both concepts.

(#3) IF all examples of a concept turn out to be in the domain of a rarely-applicable function F,
THEN it's worth computing all their F-values (their images under the function F), and studying that collection of F-values as a separate concept.

(#4) IF a concept has very few examples (say, less than 2),
THEN it's worth trying to find out why, but the concept itself is not interesting.



If b is some unusual subset of B,
Then isolate the subset $f^{-1}(b)$ of A.
Figure 6—Go to extremes

The first heuristic tells us that IF we've just created some special kinds of Numbers, and we want to fill in examples of them, THEN one quick way to find such examples is to look at the known examples of Numbers, say the integers from 1 to 1000, and dump each one into whichever new specialized set(s) it belongs. If we do this, we get the following empirical results:

Number with no divisors:	(none found)
Numbers with 1 divisor:	1
Numbers with 2 divisors:	2, 3, 5, 7, 11, 13, 17, 19, . . .
Numbers with 3 divisors:	4, 9, 25, 49, 121, 169, 289, . . .

Heuristic #4 says to rule out any sets which are very tiny; that immediately causes us to lose interest in the first two kinds of numbers, those with zero or one divisor. None of the heuristics have much to say about the next set of numbers (with 2 divisors); what about this final set, numbers which have precisely 3 divisors? Heuristic #2 says, IF all these numbers are also examples of some other special kind of number, THEN they'd be interesting. Well, is there anything special about all of them? Most of them seem to be odd, . . . , *all of them* seem to be perfect squares. That's very unexpected and surprising. All these numbers have integer square roots; that's a very rare thing. Heuristic #3 says that in such a case it's worth actually computing what their square roots are. So let's take their square roots. Lo

and behold! They're precisely the set of numbers with two divisors; i.e., primes. Heuristic #2 explains why we might have noticed this, and indicates that it would cause us to drastically increase the interestingness values of both Numbers-with-3-divisors and Primes. This heuristic was the same one we talked about before, in connection with Dickens and Escher: the rule of startling coincidence.

So we *were* able to fit this kind of judgmental evaluation of "interestingness" into the same theory.

MODELS

The examples I've shown you so far have been merely suggestive. The heuristics which I claimed "explained" various behaviors might really be just comments on those behaviors, ways of rationalizing in hindsight what was actually done. I claim that the heuristic rules can be an *operational* part of the theory, that predictive models can be built which use them for guidance in solving problems and making discoveries. To that end, I'm going to briefly describe a few landmark computer programs that have been written, models based on the theory of intelligence as heuristic rule guided search. These programs form but a thin sliver of the work that has gone on under the label of "Artificial Intelligence."

LT and GPS—general problem solving

Probably one of the earliest AI programs written was the Logic Theorist ("LT", to its friends).[7] It was repeatedly given symbolic logic theorems from *Principia Mathematica,* and its task was to find a formal proof of each theorem. LT had some given axioms and rules of inference. To search for a proof, in a completely exhaustive, systematic manner, could literally be an impossible undertaking! But LT had a few heuristics which constrained its search:

> *". . . selective principles that enable solutions to be found after examining only a relatively tiny subset of the set of possibilities. One such principle—illustrated by the methods in the Logic Theorist—is to generate only elements of the set that are already guaranteed to possess at least some of the properties that define a solution. Another principle—illustrated by the matching process in LT—is to make use of information obtained sequentially in the course of generating possible solutions in order to guide the continuing search. A third principle—illustrated by the use of similarity tests in LT—is to abstract from the detail of the problem expressions and to work in terms of the simpler abstractions."*
>
> —[Newell and Simon 1972], p. 137.[11]

One of LT's heuristics was *constrained generation:* if you want an entity satisfying ten specific properties P1 . . . P10, try to arrange things in such a way that you only have to consider entities already guaranteed to satisfy P1 . . . P7; then just test each one to see if it meets the final three criteria. Another principle was to *learn from your failures:* instead of just blindly backtracking, use the nature of your failure to help guide you in the future, so you won't make exactly the same mistake again.

After they learned the power of heuristics from LT, the same group of researchers then worked on a program called GPS, for General Problem Solver. Its aim was to embed the few general heuristics above in a domain-independent form. It was hoped that *any* problem could be represented in the GPS formalism, and hence solved by GPS. It was the first program to isolate explicitly these general methods:

1. Means ends analysis: Decide what the most important difference is between the current state and the desired goal, locate an operator which is known to be relevant to reducing that kind of difference, and then try to actually apply that operator. With any luck, you'll be one step closer to the goal.
2. Setting up subgoals, equivalent to the idea of *problem reduction,* and to divide and conquer strategies.
3. Planning in an abstraction space.

Two decades of experimenting with GPS have shown that, yes, a large array of problems can be cast in terms that GPS can deal with (states, operators, difference tables), but no, GPS's few general heuristics just aren't powerful enough to solve problems as difficult as can be tackled by humans.

DENDRAL—scientific problem solving

The next giant step along the line of development we're following was taken by Ed Feigenbaum[24] and Joshua Lederberg[22] at Stanford, and independently by Joel Moses[23] here at MIT. They recognized what was lacking: expertise. After all, humans have to train in specialized fields for quite a while before they are able to solve any hard problems in them. This phenomenon might not just be a reflection of human brain frailties, it might indicate a necessary requirement for intelligent problem solving in a complex knowledge-rich domain.

In 1965 they conceived a new kind of computer program, and in the process a whole new approach for AI: they were willing to commit their programs to working on a very specific kind of problem—in Moses' case, symbolic integration; in Lederberg, Feigenbaum, and Buchanan's[25] case, the enumeration of atom-bond graphs of organic molecules (based on analysis of mass spectrograph data and nuclear mass resonance data). For instance, you type in "$C_{10}H_{22}$," and their program types back a list of all 71 structural isomers of decane. They built their program, DENDRAL, around a body of heuristics—not just a few, but a few *dozen* heuristic rules. Some of them were as general as the rules that GPS had, but most of them were specific rules of thumb which they extracted from chemists (e.g., rules for recognizing imbedded subgraphs which are impossible; knowledge of aggregates of radicals which co-occur often; heuristic estimation of the worth of pursuing a particular subproblem;

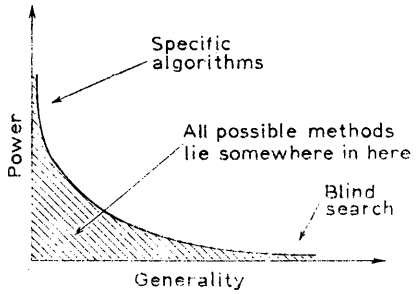


Figure 7—Generality vs. power

rules for recognizing current subproblems which have been worked on before).

The success of this research (measured partly by the large number of articles which have been published in chemical journals) confirmed Feigenbaum's hypothesis about the tradeoff between generality and power. (See Figure 7) Heuristics are distributed along the pictured curve (and below it); the more general they are, the weaker they must be. Experiments with Dendral have demonstrated the importance of using both general heuristics and task-specific heuristics for guidance.

AM—scientific invention

We now jump to some quite recent research by the speaker, which involved collecting *hundreds* of heuristics, to do elementary mathematics research, open-ended discovery. This is scientific *invention,* as compared to Dendral, which performs scientific *problem solving.**

Math discovery as heuristic rule-guided search

The task which this program, called *AM*, performs is the discovery of new mathematics concepts and relationships between them. The simple paradigm it follows for this task is the one specified by our theory:

1. Open-ended math research is viewed as a search, an exploration in a space of partially-developed concepts.**
2. AM is guided in this exploration by a collection of a few hundred heuristic rules. They are rules of varied generality which guide it to define and study the most plausible thing next.
3. In each situation, AM quickly accesses relevant heuristic rules, and then follows (obeys) them.

For example, AM discovered "Multiplication" in four separate ways. This coincidence raised its interestingness value to quite a high level. One of AM's heuristic rules said *"If f is an interesting operation, Then look at its inverse."* This rule was relevant (with f=Multiplication) and was actually followed in this context. It directed AM to define and study the relation "divisors-of." Another heuristic rule which later was obeyed (see Figure 8) said to examine the inverse image of extrema under interesting functions. We've seen this rule before, but Figure 8 indicates more accurately how it appeared in the AM computer program. Just as we saw before, AM was driven by this rule to define prime numbers.

The same heuristic also directed AM to study not only various kinds of numbers having very *few* divisors, but also classes of numbers with very *many* divisors; such "maximally-divisible" numbers were also found to be interesting (by AM, by the author, and by professional mathematicians). In fact, a couple minor new results in number theory were developed regarding them. Still another time, AM was guided by the same heuristic to define and study the pairs of sets whose intersection is empty; i.e., this rule also led to the definition of the relation "Disjointness." This multiple usage of the heuristics is strong evidence that they are truly general.†

Representation of mathematical knowledge

What exactly does it mean for AM to "have the notion of" a concept? It means that AM *represents* that concept somehow in the computer, that there is a data structure of some kind which is meant to correspond to, and contain information about, that concept. While the entire issue of how to represent knowledge has been de-emphasized in this talk, it is helpful to glance at how some typical concepts looked. (See Figure 9)

The representation of a concept is as a collection of *facets,* or slots, (e.g., Definitions, Conjectures, Worth‡) each of which can have some associated value, or entry.

Flow of Control

AM is initially given a collection of 115 core concepts, (see Figure 10) each with only a few facets (slots) filled in. AM repeatedly chooses some facet of some concept, and tries to fill in some entries for that particular slot. Thus a "job" for AM is simply to engage in a mini-research project, to commit a simple act of discovery. Its overall task—to discover interesting concepts and conjectures—is accom-

* This is not the "inductive vs. deductive" issue: both Dendral and author's program (AM) perform quite inductive tasks. The difference is that Dendral is given specific problems to solve (specific mass spectra to identify), whereas AM's activities are open-ended research, with no particular goal specified.

** The goal of this search is ill-defined: to maximize the interestingness value of the concepts which are available for AM to develop further.

† If a supposedly general rule were only involved in one major discovery, there would always be the question of whether the rule is merely a subtle encoding of that discovery.

‡ Unlike the other numbers appearing as part of the pictured 'Primes' concept, the number "800" is merely an estimate, an ad hoc value for the overall worth of this concept. It would be preferable to replace this by a mass of symbolic reasons, by a plausible justification for why this concept was and wasn't useful, interesting, etc. But in lieu of the ability to reason about, create, manipulate, and otherwise use such knowledge, we opt for a simple scalar, a numeric rating which in effect crudely *summarizes* these reasons.

In English and Math notation:

IF f: A → B is an interesting function,
and there's some interesting or extremal subset X of B,
THEN it's worth defining and naming and studying $f^{-1}(X)$.

Roughly as it appeared in the AM program:

```
(IF
  (CURRENT-TASK DEALT-WITH "F")
  AND (F IS-A FUNCTION)
  AND ((WORTH-OF F) IS-GREATER-THAN 600)
  AND (THERE-ARE-KNOWN-ENTRIES-FOR (BOUNDARY-OF (RANGE-OF F)))
THEN
  (FOR-EACH X IN (BOUNDARY-OF (RANGE-OF F))
    (CREATE-A-NEW-CONCEPT
      (WHOSE NAME IS "F-INVERSE-OF-X")
      (WHOSE WORTH · IS (WORTH-OF F)×(WORTH-OF X))
      (WHOSE DEFINITION IS (LAMBDA (z) (F (z) IS-A X)))
      (WHOSE GENERALIZATION IS (DOMAIN-OF F))
      (WHOSE ORIGIN IS "Inverse image of extrema")
      (WHOSE INTEREST IS "(TIES-TO F) (TIES-TO F-INVERSE)"))))
```

Figure 8—Go to extremes, again

plished as a composition of hundreds of these repeated attempts at little discoveries.

To decide which small job to work on next, AM maintains an *agenda* of jobs, a global queue ordered by priority. (See Figure 11) A typical job is *"Fill-in examples of Primes."* The agenda may contain hundreds of such jobs. AM repeatedly selects the top-rated job from the agenda and tries to find *relevant* rules (i.e., heuristics which, when obeyed, bring AM closer to satisfying that job). Potential relevance is determined *a priori* by where the rule is stored. Each of AM's 250 heuristic rules is tacked onto the most general (or abstract) concept** C to which it's relevant and meaningful. The relevance of these heuristic rules is presumed to be inherited by all C's specializations. A method which can

** It was very important to place each heuristic on as general a concept as possible, to give it a large scope of applicability, to bring it close to the generality versus power curve.

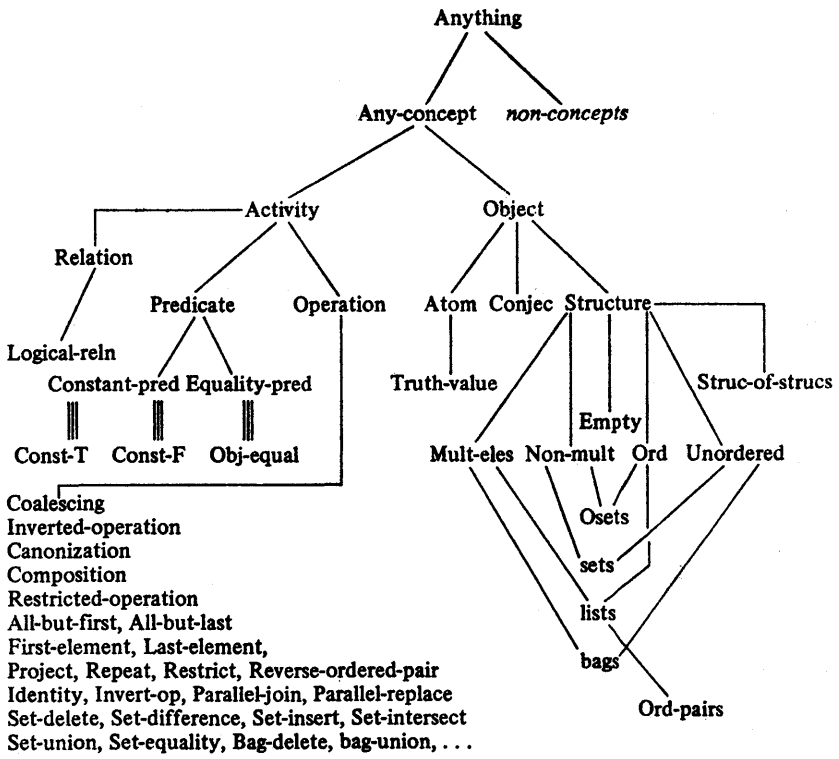
IN-DOMAIN-OF: Union, Intersection, Set-difference, Subset,
    Member, Cartesian-prod, Set-equality
IN-RANGE-OF: Union, Intersect, Set-difference, Satisfying

NAME(s): Prime Numbers, Primes, Numbers-with-2-Divisors
DEFINITIONS:
  ORIGIN: Divisors-of(x) is-a Doubleton
  PRED.-CALCULUS: Prime(x) ≡ (∀z)(z|x → z = 1 XOR z = x)
  ITERATIVE: (for x > 1): For i from 2 to x−1, ¬(i|x)
EXAMPLES: 2, 3, 5, 7, 11, 13, 17
  BOUNDARY: 2, 3
  BOUNDARY-FAILURES: 0, 1
  FAILURES: 12
GENERALIZATIONS: Numbers, Numbers with an even no. of
    divisors, Numbers with a prime no. of divisors
SPECIALIZATIONS: Prime pairs, Prime uniquely-addables
CONJECS: Unique factorization, Goldbach's conjecture
ANALOGIES: Maximally-divisible numbers are converse
    extremes of Divisors-of
INTEREST: Conjec's tying Primes to Times, to Divisors-of, and
    to other closely related operations
WORTH: 800

Figure 9—Two typical math concepts



The diagram above represents the "topmost" concepts which AM had initially, shown connected via Specialization links (\) and Examples links (‖).

Figure 10—Initial concepts

(*Fill in Generalizations facet of "Equality concept"*)
Priority = 700
Reasons = ((No known generalizations of Equality)
(Equality is rarely satisfied)
(Focus of attention: recently worked on Equality))

(*Check Conjecs facet of "Equality" concept*)
Priority = 500
Reasons = ((Worth of Equality has recently risen)
(Conjecs involving Equality have just been found)
(Focus of attention: recently worked on Equality))

(*Fill in Examples facet of "Primes concept"*)
Priority = 400
Reasons = ((No known exs of primes yet))

(*Check Examples facet of "Set-union" concept*)
Priority = 350
Reasons = (Many examples of Set-union recently added)
(Worth of Set-union has recently risen))

(*Check Domain/range facet of "Square-root" concept*)
Priority = 300
Reasons = ((Square-root was unable to return a value for 8)
(Square-root was unable to return a value for 3)
(Should check the domain/range entries for any operation created as an inverse)

(*Fill in new Algorithms for Compose concept*)
Priority = 200
Reasons = ((Empirical: taking too long))

Figure 11—Agenda of jobs

generalize any operation can certainly generalize any composition; any heuristic that knows how to find examples of any concept can find examples of "Numbers-with-3-divisors." And so on. In other words, the aggregate of the Generalization/Specialization relationships among the *concepts* induces a similar graph structure upon the set of *heuristic rules*. (See Figure 12 and also Figure 1, again) This "inheritability property" permits potentially relevant rules to be located efficiently.

The IF-part of each potentially relevant rule is evaluated to determine whether the rule is truly relevant. If so, it's obeyed. At that time, it can direct three kinds of actions or effects:

(i) Facets of some concepts can get filled in (e.g., examples of primes may actually be found and tacked onto the "Examples" facet of the "Primes" concept).
(ii) New concepts may be created (e.g., the concept "numbers which are uniquely representable as the sum of two primes" may be explicitly deemed worth studying).
(iii) New jobs may be added to the agenda (e.g., the current activity may suggest that the following job is worth considering: Find new generalizations of the concept of prime numbers").

Behavior of this Rule System

AM began its investigations with scanty knowledge of one hundred elementary concepts of finite set theory. Most of the obvious set-theoretic concepts and relationships were quickly found (e.g., de Morgan's laws; singletons), but no sophisticated set theory was ever done (e.g., diagonalization). Rather, AM discovered natural numbers, rated them highly, and went off exploring elementary number theory. (See Figure 13) AM discovered scores of well-known concepts (some of them in novel ways,* some of them in several ways**), and a roughly equal number of "losers" (most of which were quickly recognized as such by AM). All this occurred in two cpu hours (see Figure 14).

The AM project has demonstrated that that open-ended scientific theory formation (the defining and exploring of new concepts and relationships) *could* be mechanized, could

* E.g., AM restricted the operation 'Addition' to prime numbers; i.e., it asked "For which primes p,q,r is it true that $p+q=r$?" In such a case, p or q must be "2'," and the other two primes must be a *prime pair*.

** E.g., *multiplication* was discovered in four separate ways: as repeated addition, as an analogue to the Cartesian product of sets, as the cardinality of the union of the powersets of two sets, and as the total number of symbols one gets by replacing (in parallel) each element of bag X by a complete copy of bag Y.

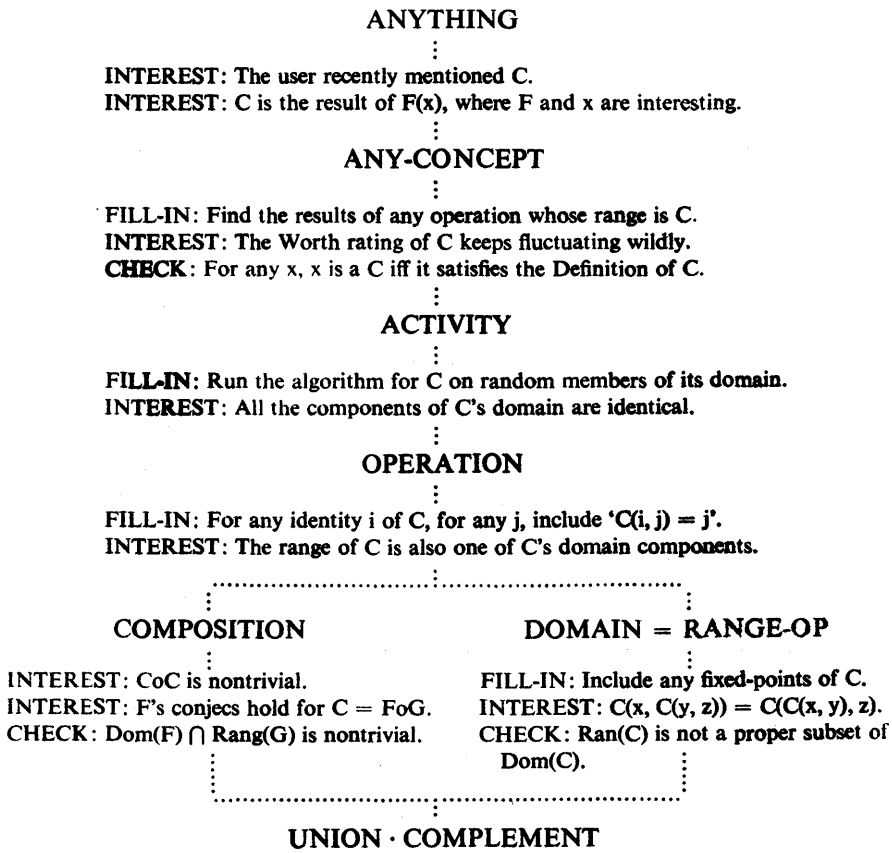


Figure 12—Induced structuring of the heuristics

Sets with less than 2 elements (singletons and empty sets).
Sets with no atomic elements (nests of braces).
Singleton sets.
Bags containing (multiple occurrences of) just one kind of element.
Superset (contains).
Doubleton bags and sets.
Set-membership.
Disjoint bags.
Subset.
Disjoint sets.
Singleton osets.
Same-length (same number of elements).
Same number of left parentheses, plus identical leftmost atoms.
Count (find the number of elements of a given structure).
Numbers (unary representation).
Add.
Minimum.
SUB1 (λ (x) x−1).
Insert x into a given Bag-of-T's (almost ADD1, but not quite).
Subtract (except: if x < y, then the result of x−y will be zero[71]).
Less than or equal to.
Times.
Union of a *bag* of structures.
& (the ampersand represents the creation of several real losers.)
Compose a given operation F with itself (form F.F).
Insert structure S into itself.
Try to delete structure S from itself (a loser).
Double (add 'x' to itself).
Subtract 'x' from itself (as an operation, this is a real zero[72]).
Square (TIMES(x,x)).
Union structure S with itself.
Coalesced-replace2: replace each element s of S by F(s,s).
Coalesced-join2: append together F(s,s), for each member s∈S.
Coa-repeat2: create a new op which takes a struc S, op F, and repeats F(s,t,S) all along
Compose three operations: λ(F,G,H) F.(G.H).
Compose three operations: λ(F,G,H) (F.G).H.
& (lots of losing compositions created, e.g. Self-insert.Set-union.)
ADD^{-1}(x): all ways of representing x as the sum of a bunch of nonzero numbers.
G.H, s.t. H(G(H(x))) is always defined (wherever H is), and G and H are interesting.
Insert.Delete.
Delete.Insert.
Size.ADD^{-1}. (λ (n) The number of ways to partition n)
Cubing
&
Exponentiation.
Halving (in natural numbers only; thus Halving(15)−7).
Even numbers.
Integer square-root.
Perfect squares.
Divisors-of.
Numbers-with-0-divisors.
Numbers-with-1-divisor.
Primes (Numbers-with-2-divisors).
Squares of primes (Numbers-with-3-divisors).
Squares of squares of primes.
Square-roots of primes (a loser).
TIMES^{-1}(x): all ways of representing x as the product of a bunch of numbers (>1).
All ways of representing x as the product of just one number (a trivial notion).
All ways of representing x as the product of primes.
All ways of representing x as the sum of primes.
All ways of representing x as the sum of two primes.
Numbers uniquely representable as the sum of two primes.
Products of squares.
Multiplication by 1.
Multiplication by 0.
Multiplication by 2.
Addition of 0.
Addition of 1.
Addition of 2.
Product of even numbers.
Sum of squares.
Sum of even numbers.
& (losers: various compositions of 3 operations.)
Pairs of perfect squares whose sum is also a perfect square ($x^2+y^2=z^2$).
Prime pairs (p,p+2 are prime).

Figure 13—Concepts discovered

be modelled as heuristic rule guided search, using a few hundred heuristics for guidance. This is a significant verification of the theory of intelligence presented earlier.

AM had some difficulties. As it ran longer and longer, the concepts it defined were further and further from the primitives it began with; while the general set-theoretic heuristics were technically valid for dealing with primes and arithmetic, they were simply too general, too weak to guide effectively. The key deficiency was AM's inability to create and modify new specific heuristics.

Machine: SUMEX, PDP-10, KI-10 uniprocessor
Language: INTERLISP, January 1975 release
Number of small support functions for AM: 200
Number of heuristics: 250
Number of Initial concepts: 115
Number of Final concepts: 300
Average Initial concept: 8 facets
Average Final concept: 11 facets
Average size of a concept: 700 list cells
Average size of a concept: 1 typed page
Total CPU Time: 1 hour
Speedup factor if user advises AM: 3
Total number of jobs executed: 200
Average time allocated per task: 30 secs.
Average time actually used by a task: 18 secs.
Number of winning concepts: 25 (estimated)
Number of acceptable concepts: 100 (est.)
Number of losing concepts: 60 (est.)

Figure 14—Performance statistics

The next step: EURISKO

These findings came to light only because the AM program existed, was run, and was experimented with. Recall that the final step in the AI paradigm is to experiment with the computational model. In this case, what we've learned from AM is guiding our current efforts at writing a program which discovers new task-dependent heuristics as well as new concepts. Our new program, EURISKO, is quite ambitious, because even scientists are very poor at formulating—or even recognizing—new heuristics.

We asked ourselves how new heuristics get discovered; we took the same kind of heuristically-guided approach to the problem that AM would have. By using general rules, we were led to ponder whether heuristics mightn't get discovered and reasoned about in much the same way that math concepts do (i.e., by hindsight, by manipulating existing ones, and so on). We think they might.

So EURISKO's method for discovering and developing

NAME(s): Generalize-rare-predicate
STATEMENT
  English: If a predicate is rarely True, create a generalization of it
  IF-Current-task-deals-with: a predicate P
  AND-IF: P returns "True" less than one tenth of the time
  THEN-Conjecture:
    C1: P is a little less interesting than expected.
    C2: Generalizations of P may be more interesting than P.
  Then-add-a-new-task:
    "Fillin Generalizations of P" because C2
  Then-modify-facet:
    Reduce the Worth of P by 10%, because C1
SPECIALIZATIONS: Generalize-rare-set-predicate
  BOUNDARY: Enlarge-domain-of-predicate
GENERALIZATIONS: Modify-predicate, Generalize-concept
  JUSTIFYING GENERALIZATION: Hill-climbing
IS-A: Heuristic
EXAMPLES:
  GOOD: Generalize "set-equality" into "same-length"
  BAD: Generalize "set-equality" into "same-first-element"
CONJEC's: Special cases of this rule are MUCH more powerful than it is.
ANALOGIES: Weaken-an-overconstrained-problem
WORTH: 600 [on a scale of 0–1000]
VIEW:
  ENLARGE-STRUCTURE: let the structure be {x | P(x)}
ORIGIN: A specialization of "Modify-predicate", via empir. induction
HISTORY
  Summary of examples: 1 good, 1 bad example known; average +0.4
  Summary of conjectures proposed: 3 correct, 1 unclear
  Summary of tasks added to agenda: 2 added, 2 tried, 2 succeeded, +0.8
  Summary of facets modified: 2 Worth lowerings, 1 verified
  CPU Time used: Average 9.4 cpu seconds
  Space used: Average 250 list cells

Figure 15—Heuristic represented as a concept

heuristics is therefore simply to *not distinguish* between concepts and heuristics; i.e., each heuristic is represented internally as a full-fledged concept. (See Figure 15)* Any heuristic which, say, can advise when it's time to generalize any concept, can also automatically tell when it's time to generalize any heuristic. Any method for creating a new concept out of old ones can be used to create new heuristics out of old ones. Evaluating the new heuristics is done just like evaluating any new concepts: by observing them in action, by gathering empirical data about them. Naturally, there are some special heuristics which are meaningful only for reasoning about other heuristics, just as there are some special heuristics that apply only to ligating plasmids.

We've taken the same AM-like approach to solving *most* of the problems that beset AM.

Other heuristic rule guided expert programs

There are several programs like AM in existence, knowledge based expert programs which perform under the guidance of a large collection of heuristic rules.

The MYCIN program[12] contains a couple hundred judgmental rules which were extracted from physicians, and it uses them to make diagnoses of various blood infections.

MOLGEN[13] (still under construction) attacks the molecular genetics experiment-planning problem discussed earlier.

The PROSPECTOR program[14] performs geological analysis of on-site data relayed to the computer by a human expert. It aids him in the evaluation of the mineral potential of exploration sites. Prospector's rules were gleaned from geologists, much as MYCIN's were from physicians.

These programs perform complex *problem solving*. A few programs exist which, like AM, use heuristic rules to guide them in scientific and other *invention* tasks.

META-DENDRAL[15] is a theory formation program which looks over mass spectra and their correct identifications, and then abstracts that data into new fragmentation rules, which are then usable by the Dendral program, as if they had been extracted from a human expert.

The M-Method program[16] for improvising variations on a given melody is based around a body of musicology rules.

Several other such programs are listed in Figure 2.

* Notice its similarity to a typical math concept.

CONCLUSIONS

The main points to remember

- We viewed Man as a processor of symbolic information. Keeping in mind that this is but one narrow view, we found it a useful vantage point from which to study the phenomenon of intelligence.
- Many cognitive tasks can be cast as explorations through more or less enormous* search spaces. "Intelligence" is the ability to zero in effectively on a solution, despite the apparent size of the search space.
- We theorize that humans possess thousands of informal rules of thumb, of varying levels of generality and power, which they use to guide them in these searches. These rules are the prime repository for domain-specific knowledge (i.e., for expertise).
  - —We have seen the relationships among knowledge, search, and intelligence.
    Search is ubiquitous.
    Knowledge reduces search.
    Using knowledge is intelligent.
  - —It is therefore meaningless to debate whether the source of intelligence lies in "search" or in "knowledge:" *both* are prerequisites. They interact synergetically: each would be almost powerless without the other. Search by itself leads to small programs with impossible running times. Knowledge by itself just sits on library shelves and gets dusty.
  - —The theory of intelligence as heuristic rule guided search contains the power of *additivity:* many small pieces of "local knowledge" combine to produce sophisticated "global effects," with a consequent ease of introducing new pieces of knowledge.
  - —This methodology contains the power** afforded by *coarse granularity:* a rule can express any arbitrarily complex heuristic, can embody a meaningful chunk of domain-specific knowledge. In particular, it can have some significance to a human expert. Thus each model of the theory will be self-explaining:[17] it need only keep the user posted of each rule firing. Also, new heuristic rules can be added by a human expert at a level which seems "natural" to him.[18]
- Several example scenarios have been presented, to show that this theory can account for everyday and scientific problem solving, invention, and judging the "interestingness" of newly synthesized inventions. There is a whole lattice of increasingly more specialized heuristics. Some of them, at the very top, are useful in all six types of situations.
- Three kinds of models, based on this theory, were examined (LT/GPS, Dendral, and AM). The efforts are separated in time by periods of about ten years (1957, 1967, 1977) and factors of about ten in the number of heuristics they utilized (3, 30, 300). All three serve to support the theory of intelligence we've been discussing.
- We saw in particular how AM is able to use its heuristics to guide attention (add and modify jobs on its agenda), to synthesize new concepts, to explore them (fill in their facets), and to evaluate their interestingness. This demonstrated that the general heuristic rules are not merely a descriptive commentary, they are an operational part of the theory. AM and its predecessors are not merely lucky accidents.

The goals of AI

Toward a science of science

In the Middle Ages, only a few European artists incorporated linear perspective into their paintings. The techniques were never communicated explicitly; rather, the would-be artist had to serve as an apprentice to a master. Gradually, by example, the student learned the necessary skills. Some time between Giotto and Da Vinci, the artists wrote down, explicitly, the knowledge they were really using, to create perspective. Once they did that, anyone could learn how to create such drawings. In place of mystery was understanding.

There is a similar mystique today, about how doctors can diagnose disease, how mathematicians can discover new theorems, how scientists in general are able to carry out productive research. The doing of science today is not unlike the guilds of the Middle Ages. We scientists rarely try to introspect on our own creativity, to explicate our skills.

One very significant reason for doing Artificial Intelligence research is that it starts the metamorphoses of the nature of scientific fields, from incomprehensible guilds into well-understood technical crafts. It leads to a science of science. AI programs make explicit, in a very usable form, the knowledge necessary to perform some complicated activity, thereby de-mystifying it.

Mental enhancement

A concrete *understanding* of intelligence, as might be achieved by the above "Science of Science", enables attempts to *synthesize* it. What good would a synthetic intellect be?

The ultimate material benefit to be derived from Science is the enhancement of (some aspect of) Man. Medicine views him as an organism, and is able to provide biological enhancement (pharmacological agents and techniques which improve his resistance to disease, his longevity, etc.). Engineering views him as a dynamic actor, and is able to provide physical enhancement (devices and techniques which enable better locomotion than legs, better communication that shouting, etc.). AI views Man as a symbol processor, and provides mental enhancement: programs and techniques

* The less structured the domain, the larger the search space. One extreme of this "tradeoff" is an *algorithm,* which is a highly "compiled" search.

** Promised by general "heuristic search,"[19] and by some rule-based system architectures,[20] but not by "pure" production systems.[21]

which augment his ability to *reason:* automation of routine tasks (bookkeeping, housekeeping*), aids to artists and scientists (partial automation of the "hack" side of composing, proving, diagnosing, exploring, programming), an avenue leading to the understanding (and appreciation of the sophistication) of his own intelligence, and perhaps—in the *far* distant future—even finding his way around the streets of Boston.

A panel session—AI in medicine

SESSION CHAIRMAN—SAUL AMAREL *Rutgers University*

Panel Members

Peter Szolovits—Massachusetts Institute of Technology
Harry Pople—University of Pittsburgh
Casimir A. Kulikowski—Rutgers University
Sholom M. Weiss—Rutgers University
J. C. Kunz—The Institutes of Medical Science, Pacific Medical Center
L. M. Fagan—Stanford University
R. J. Fallat—The Institutes of Medical Science, Pacific Medical Center
D. H. McClung—The Institutes of Medical Science, Pacific Medical Center
J. S. Aikins—Stanford University
H. P. Nii—Stanford University
E. A. Feigenbaum—Stanford University
J. J. Osborn—The Institutes of Medical Science, Pacific Medical Center
Mark Stefik—Stanford University
Peter Friedland—Stanford University
R. O. Duda—SRI International
P. E. Hart—SRI International
R. Reboh—SRI International

PANEL OVERVIEW—Saul Amarel

The papers in this session will focus on applications of Artifical Intelligence in the development of knowledge-based systems in medical decision-making situations, in scientific inquiry, and in mineral exploration.

Much of the work which will be reported in this session is being done within the AIM community. [AIM stands for Artificial Intelligence in Medicine.] The AIM project is a national resource sharing activity supported by the biotechnology resources program (BRP) of DRR, NIH, whose principal objective is to promote applications of AI to medicine and the life sciences. The main focus of AIM activity is at the Stanford University SUMEX-AIM project, which provides computer shared resources to the AIM community via national networks. The Rutgers research resource on computers in biomedicine[1] is one of the (BRP-supported) projects in the AIM community. Included in its functions is the organization of AIM workshops.[2] The objective of the workshops is to strengthen scientific interactions within the national AIM community and to disseminate AI-based methodologies, tools, and specific systems that are relevant to AIM. The next AIM workshop (this is the fourth) will be held at Rutgers on June 25-28, 1978. All the participants in this session are expected to attend the Rutgers workshop and to discuss in depth various aspects of their research on knowledge-based systems. The present session will provide an opportunity to bring summary accounts of this research to a wide national audience of computer professionals; a similar session was held last year at the Fifth International Joint Conference on Artificial Intelligence.[3]

Experience with work in AI applications to date shows the following:

(a) The problem of acquiring specific knowledge in a domain, managing it in an AI system, modifying it, and using it appropriately is fundamental. The approach to most designs is incremental and responsive to the fact that the knowledge base in the domain is not stationary. Initially, a relatively low-performance AI system is created to provide the basis for subsequent stages of knowledge acquisition and improvement, which eventually leads to high performance, and expert systems.

(b) Work on applications requires very close collaboration between AI experts and experts in the problem domain. Furthermore, special technical support facilities (e.g., computer networks) can play a significant role in establishing these collaborations and in sustaining their effectiveness. This is a key point which has important implications for organizational and shared resource aspects of applied AI projects.

(c) The development of an expert system within a reasonable time span requires more powerful technologies than those in use today—especially when the knowledge bases will grow from the present 10**2 to 10**3 "facts" to more realistic situations with 10**4 to 10**5 "facts". So far, system development times (from conception to expert level in a research environment) have been 4 to 8 years. To reduce this time span, or to keep it from growing too much as knowledge bases grow, we need more effective methods of knowledge acquisition and organization and more powerful program design environments. Related to this, we need better techniques for interfacing AI programs with experts and users. At a more basic level, we need better schemes for coordinating multiple knowledge bases and for handling inconsistent and/or uncertain information.

Experience of several years in the development of clinical decision-making "expert" systems at MIT to be discussed by Peter Szolovits illustrates the ways in which these issues are encountered in specific AI application projects. Another important conclusion obtained from the MIT experience is that the choice of medical tasks to be approached via AI methodologies/techniques should be made after a careful assessment of the nature and complexity of the task. Only tasks requiring complex knowledge bases and difficult reasoning processes should be approached via AI methods; in many situations simpler computer-based methods may be more appropriate.

One of the key processes in medical reasoning and in scientific inquiry is the interpretation of empirical data in the light of a given body of theoretical knowledge. Much of the work presented in this session is concerned with these processes. Typically, a problem of interpretation involves reasoning about an individual case. Given evidence (data) about the case and a theory within which the evidence is to be understood/explained, find a hypothesis which explains the case on the basis of the theory. While there has been considerable progress in the development of strategies for solving interpretation problems, there still remain several open problems: under what conditions the interpretation process should be controlled by the specific, "low level" features of the case under consideration or by possible "high level" hypotheses and by expectations derived from these hypotheses; how to best represent and keep track of information about a special case, of general knowledge in terms of which the case is interpreted, and of alternative interpretations of the case as the process evolves with time.

Some of these issues will be discussed in depth by Harry Pople in the context of his research (in collaboration with Dr. Jack Myers) on diagnostic problem solving in internal medicine. These are also important issues in (I) the work of John Kunz, Larry Fagan and their collaborators in the domain of pulmonary disorders, (II) the work of Richard Duda, Peter Hart and their collaborators in the domain of mineral explorations, and (III) the work of Sridharan, which is oriented to the development of an AI system for assisting in the formulation of psychological theories of action interpretation.

Processes of planning are becoming another focus of interest in AI applications to natural systems. The synthesis of plans has been a subject of research since the early days of AI. In this session, the synthesis of treatment plans in a medical context (consultation in glaucoma) will be discussed in the paper by Casimir Kulikowski and Sholom Weiss. AI approaches to the development of plans in the context of scientific experimentation (in molecular genetics) will be discussed in the paper by Mark Stefik. Research on the analysis/interpretation of plans is of a more recent vintage in AI and it has been stimulated by AI work in "real life" situations. Work on this problem will be presented in the context of AI applications to scientific work in the papers by Stefik (molecular genetics) and Sridharan (psychology).

Some of the systems presented in this session have already reached high levels of expertise in limited domains. CASNET/glaucoma at Rutgers and INTERNIST at the University of Pittsburgh and PROSPECTOR at SRI are in this category. There are also several "younger" systems that are still in a process of intense development and growth. In some of them techniques developed/tried in previous knowledge-based systems are being assimilated and adapted (e.g., the structure of MYCIN[4] is being used in the PUFF project) and the DENDRAL[5] experience as well as ideas from several more recent AI efforts are being used in the MOLGEN project. On the other hand, in the BELIEVER task discussed by Sridharan, a new system, called AIMDS, is being developed to provide an appropriate environment for theoretical work on the task.

We are now at a point where substantial achievements have been made in AI applications and there are several new efforts that are starting to build on top of past experience. In general, there has been good progress in this area and the prospects for the future of high performance in AI expert systems are bright.

The following is a summary of the papers to be presented at the NCC session.

THE DEVELOPMENT OF CLINICAL EXPERTISE IN THE COMPUTER—THE EVOLUTION OF CLINICAL DECISION-MAKING PROGRAMS AT MIT—Peter Szolovits

We at the Clinical Decision Making Group at MIT's Laboratory for Computer Science, along with our collaborators at the Tufts-New England Medical Center Hospital, have been engaged for several years in the development of computer programs which embody expert medical knowledge. We have applied techniques developed in the study of Artificial Intelligence (AI) to encode expert clinicians' approaches to handling a number of important medical problems: (1) prescribing appropriate doses of digitalis glycosides to patients with congestive heart failure or arrhythmias (the DIG program), (2) taking the history of the present illness

of a patient with kidney disease (the program is called PIP), and (3) diagnosing and treating patients with acid/base and electrolyte disturbances. We have also studied the application of decision analytic techniques to the testing and treatment of Hodgkin's disease, the differential diagnosis of acute renal failure, the value of coronary surgery to the individual patient, and other problems.

Throughout many of these projects, we have discovered that our initial estimate of the difficulty of the problem has been far from what we finally decided. Naturally, we have often underestimated the magnitude of the effort needed to collect data, generate plausible decision structures, and choose and build computer implementations for the data base and reasoning components of the program. Not so obviously, however, we have also found that some problems succumb to much simpler techniques than what we had originally estimated to be needed.

The key to these observations, we now think, concerns the degree to which limited human-like expertise in a computer program is adequate to cover the great majority of situations which arise in the program's domain. To the extent that a simple statistical model or a small set of decision rules or protocols can be made to work, any program which uses those models will be straightforward. It is only when the task involves complex reasoning to deal with a wide variety of medical possibilities, when a "deep" understanding of a problem is needed, or when the medical situation can consist of a complex combination of many simultaneous difficulties that the programs we write (and the experts' knowledge which with models) must be sophisticated.

The presentation will review a number of attempts to build programs for digitalis therapy, to contrast them in terms of the magnitude of medical knowledge involved in each and the corresponding sophistication demanded of the computer implementation.

THE ROLE OF HYPOTHETICAL REASONING IN DIAGNOSTIC PROBLEM SOLVING—Harry Pople

INTERNIST is a computer-based system designed to deal with complex diagnostic problems in internal medicine. An important aspect of this task domain is the need to synthesize ad hoc diagnostic categories to characterize patients with two or more disease processes at one time. The presentation will review the role of hypothetical reasoning in the INTERNIST approach to this concept-formation component of the diagnostic task.

STRATEGIES OF GLAUCOMA TREATMENT PLANNING—Casimir A. Kulikowski and Sholom M. Weiss

The ultimate goal of most difficult medical consultations is to produce advice that will help formulate a plan of treatment with the greatest likelihood of success for the patient. Recently, several computer consultation programs using Artificial Intelligence techniques have developed different strategies for treatment planning.[1-3] The strategies used in the CASNET/Glaucoma program.[2,4] are designed to select plans for the long-term management of complex glaucoma cases over many follow-up visits.

Although many subjective rules of clinical judgment enter into the formulation of treatment plans, the expected outcomes are usually based on an understanding of the physiological effects of the treatment. In CASNET/Glaucoma, a causal model describes the mechanisms of disease as well as their expected changes following treatment. A two-level data structure is used: general treatment plans subsume ordered sequences of specific treatments. The initial step is to select a general plan of treatment on the basis of the patient's diagnostic categorization. The choice of specific treatment within the plan is determined by many of the individual characteristics of the patient, through the use of scoring functions for the enhancement and inhibition of selections. For example, the status of the fellow eye of a patient becomes a crucial factor when surgery is contemplated: the potential risk may be too great if there is little or no vision in the fellow eye.

For follow-up visits, the effectiveness of any current treatments must be judged and compared with the expected benefits of the alternatives suggested by the selection strategy. The diagnostic status of the patient must also be reassessed, in the case that changes dictate a complete change of treatment plan. In the event that the patient remains within the scope of the original general plan, but the original specific treatment is not sufficient to control the progression of disease, the program selects the next, stronger medication in

the sequence. Potential side-effects or complications are monitored and may result in changing the order in the sequence of specific therapies.

The CASNET/Glaucoma program's recommendations were compared to those of a panel of experts at the 1976 meeting of the American Academy of Ophthalmology and Otolaryngology.[5] The resulting discussion is serving as the basis for testing a variety of new model-based strategies for treatment.

USE OF ARTIFICIAL INTELLIGENCE FOR INTERPRETATION OF PHYSIOLOGICAL MEASUREMENTS: PULMONARY FUNCTION DIAGNOSIS AND I.C.U. VENTILATOR MANAGEMENT—J. C. Kunz, L. M. Fagan, R. J. Fallat, D. H. McClung, J. S. Aikins, H. P. Nii, E. A. Feigenbaum and J. J. Osborn

Interpretation of physiological measurement data is a central process in medical diagnosis. Biomedical engineering has succeeded in providing a wide variety of quantitative measures of physiological state, but the biomedical community has made only limited effort at systematically attempting to automate the interpretation of the medical significance of these quantitative measurements.

We characterize the problem of medical data interpretation by its medical and its sociological aspects. We choose to highlight the following features of the medical problem:

Judgmental: Deductive and inductive reasoning are both used to conclude a diagnosis given a medical situation;
Uncertain: There is only a loose relation between measured result, physiological state, overall clinical state, and effects of therapy;
Redundant: Measurements have redundancy with each other;
Context-dependent: Interpretation depends upon the clinical situation;
Time-dependent: The value and meaning of information changes.

In addition, we highlight the following features of the sociological situation in which medicine is practiced:

Experience: Good clinical practice is characterized by experience, in addition to didactic knowledge;
Interpretation: The consultant, either human or automated, should explain the process followed in making a consulting diagnosis.
Expectation: Patient condition is viewed as improving or deteriorating in relation to an expectation of disease course.

We will describe a general architecure for a medical interpretation system which recognizes these features of the problem. We have chosen Artificial Intelligence (AI) techniques for our approach to medical data interpretation. AI offers an approach to symbolic reasoning which is amenable to automation. The symbolic manipulation allows us to represent the knowledge of the clinical problem in a direct form, i.e., as structured relations among medical states and measurements. We report here on our early progress with use of AI to address two medical problems as we see them.

The PUFF system is now in routine use in our hospital for interpreting pulmonary function test measurements. PUFF interprets the medical significance and implications of input quantitative test data and patient history. Using a production rule formalism, PUFF has a set of about 60 physiological rules of the general form "IF condition THEN draw conclusion." The rule formalism has allowed our pulmonary physiologist to define the medical interpretation problem in his terms, using a level of judgment and a compensation for the uncertainty and redundancy of the data which he feels appropriate. The system is implemented in a version of the MYCIN system on the PDP 10 and in a straightforward way on the PDP-11. The system operates in a batch mode, accepting input from the data collection computer and printing out interpretations. In a 144-case evaluation, the system showed 86-93 percent agreement with the physiologist in diagnosing the presence of major pulmonary disease. For comparison, the physiologist changed his initial diagnosis of the presence and severity of major pulmonary disease upon further consideration in 42 of 107 cases during an early validation process.

The VM system is designed to interpret the clinical significance of quantitative measurements from our ICU patient monitoring system. Every 2-10 minutes, VM will accept the 40 measurements comprising the monitoring data and make a context and time dependent interpretation of the significance of data. The system first compares measured data with expected values in order to identify the possible presence of alarm conditions. The system has rules which define criteria for accepting data as physiologically indicative or possibly spurious. Next the system focuses its attention on the measurements which categorize the clinical state of the patient, and then it attempts to identify possibly advantageous therapies. VM now includes the capability to process rules describing optimal procedures for removing patients from mechanical respirators. The program will print suggestions to clinicians concerning optimal control of respirator settings and choice of specific respirator types. Detection of unexpected mechanical failures and potentially significant

changes in the patient's physiological measurements will be interpreted and reported to the clinician.

MACHINE INFERENCE FOR MOLECULAR GENETICS: METHODS AND APPLICATIONS —Mark Stefik and Peter Friedland

An increasing amount of research in Artificial Intelligence is involved with difficult applications which require representing and using significant amounts of specialized knowledge in a computer. Several researchers[2,4] have suggested that this represents a shift of paradigm in AI—from seeking performance via powerful general methods toward a recognition that many difficult processes are knowledge intensive. This view emphasizes the use of large amounts of specialized knowledge in a fashion that facilitates their effective use and interaction.

The MOLGEN project at Stanford is an example of this trend in research. MOLGEN the joint effort of computer scientists and geneticists at Stanford, is broadly concerned with the application of symbolic reasoning to molecular genetics. Molecular genetics is a vigorous and rapidly developing discipline with many logical and medium-sized problems for potential computer application. The main thrust of the MOLGEN effort has been in the development of programs to assist in the design of laboratory experiments. Experiment design requires information about problem solving goals, available laboratory techniques, and strategies for combining these techniques to achieve the desired goals. Work in computer-assisted design has been concentrated in a limited class of analysis experiments and a limited class of synthesis experiments.

Development of performance programs in the MOLGEN project has required work on several fronts. Experiment planning involves representation of many kinds of laboratory methods and objects. To avoid creating separate packages for each kind of knowledge, we have developed a schema-based representation package[5] with some fairly general capabilities. This part of our work, which occupied much of our first year of research, was considerably influenced by recent work in representation languages.[1] At the same time, the process of planning experiments and resolving conflicts has drawn on recent work in problem solving.[6] Prior to beginning our work in this area, we did a substantial review of problem solving methods.[7]

Projects like MOLGEN foster the art of applying the principles and tools of AI research to bear on specific problems. This usually involves adapting and combining these tools; it always involves comparing and selecting among alternative approaches. One of the motivations for these efforts is their utility as case studies in methodology. We believe that artificial intelligence will mature as a discipline only by confrontation of its basic methods with the challenges of various applications. From the case studies are slowly emerging the bits of a theory, which consists of an increasingly well characterized collection of paradigms for solving problems and representing knowledge. One example of the results of a case study from our own work is in Reference 8.

COMPUTER-BASED CONSULTANT FOR MINERAL EXPLORATION—R. O. Duda, P. E. Hart, and R. Reboh

For the past two years, we have been developing an interactive system of computer programs called PROSPECTOR that is intended to act as a consultant to field geologists on problems of mineral exploration. The performance of the system is based on an internal set of models of various types of mineral deposits, and on a taxonomy of rocks, minerals, and other geological concepts. The models and taxonomy, termed the knowledge base, are provided to the system over a period of time by a panel of expert geological consultants. The field geologist using the system furnishes a set of observations, often incomplete and uncertain, about the particular prospect under investigation. The principal tasks of PROSPECTOR are to compare the observations of the user against the models, to find the most promising matches, to identify for the user the most important missing observational data, and finally to form an estimate of the likelihood that a deposit in fact occurs on the prospect. Viewed abstractly, PROSPECTOR attempts to aggregate the knowledge of expert geologists in order to apply that knowledge to particular mineral exploration problems.

The models of mineral deposits are represented in a special data structure termed an inference network. A node in the network represents an arbitrary geological situation like "The prospect lies within 200 miles of a subduction zone" or "The ratio of pyrite to bornite on the prospect is less

than 1." Each node has an associated probability. A subset of nodes are distinguished as model nodes; that is, a node in this subset represents the situation that a mineral deposit satisfying a model occurs on the prospect.

Nodes in the network are connected by directed arcs. An arc corresponds to either a logical connective or to a probabilistic inference relating the nodes it joins. An important form of reasoning in PROSPECTOR is to propagate probabilities along arcs from one node to the next. The computations for propagation are based on subjective probabilities furnished by the experts, and are described in Reference 1.

The inference network formulation is particularly well-suited to our purpose because it allows models to be built up incrementally over time by defining new situations and relations. Each relation, together with the nodes it joins, is called a rule, and for this reason PROSPECTOR is termed a rule-based inference system.

The situations described by the nodes in the inference network are frequently compounded out of simpler situations; in the previous illustration the occurrence of pyrite and bornite are evidently the primitive geological situations of interest. It is often important to reason about these primitive constituents of a more complex situation. For example, the user may have already supplied the system with the observation that no sulfide minerals occur on the prospect. Since both pyrite and bornite are sulfides, PROSPECTOR should be able to infer that it is meaningless to inquire about their ratio. To support reasoning such as this, we represent each situation in the inference network in a more detailed structure called a semantic network.[2,3] The semantic network for the previous example would explicitly articulate a situation in which both pyrite and bornite are present and are in the prescribed ratio. Furthermore, additional arcs denoting the subset relation would link pyrite and bornite to the mineral taxonomy in general and to the sulfide minerals in particular.

PROSPECTOR operates as a mixed-initiative system. At any time the user may take the initiative and supply the system with observational data or may request further information of several sorts. When the user relinquishes initiative, PROSPECTOR asks the user to establish by observation the likelihood that a particular geological situation occurs on the prospect. PROSPECTOR selects situations—that is, nodes in the inference network—that will have the most pronounced effect on the probabilities of the model nodes. Thus, PROSPECTOR in effect pursues a strategy of trying to confirm or refute hypotheses about the occurrence of a mineral deposit on the prospect.

A dependency-based modelling mechanism for problem solving

by PHIL LONDON
University of Maryland
College Park, Maryland

INTRODUCTION

The design and implementation of automatic, general purpose problem solvers is a complex task. Although there are several possible methodologies in which to couch a theory of general purpose problem solving, a popular approach in recent AI research has been *problem reduction*. Problem reduction is a technique in which the problem solver's goals are broken down into sets of (presumably) simpler subgoals where the problem solver's task of discovering a solution for each is easier than discovering a solution for the main goal.

Implicit in this assumption of simplicity of subgoal solutions is the requirement that each subgoal be treated independently. Otherwise, the advantage gained by specifying simpler subgoals is defeated by the requirement for continuous interaction among those subgoals' solutions. Thus, an important aim of the research in general problem solving has been to discover schemes whereby autonomy of the subgoal solution process can be preserved.

There are times, however, when interaction among subgoal solutions is inescapable, either because of the order in which the subgoals are specified or because of innate interdependence of subgoal solutions. A promising approach to handling subgoal interaction is to allow the subgoal processes to assume that they are independent of each other and to provide a meta-process which watches the progress of the subgoal solutions. The "watcher" can assure that the currently active subgoal process does nothing inimical to the accomplishments of other completed subgoal processes.

There are several strategies that have been investigated to deal with the interaction of subgoals. I will concern myself in this discussion to the class of solutions that treats the subgoals sequentially, allowing each subgoal process to make use of results of solutions generated for previous subgoals. This approach is typified by the systems of Rieger and London,[1] Tate,[2] Waldinger,[3] and Warren.[4] Several other approaches to subgoal interaction in problem reduction exist. These include what could be called the *parallel* approach (Sacerdoti[5]) in which subgoals are solved independently and then subgoal solutions are merged together, eliminating redundant operations. A third approach could be called the *hybrid* approach (Dawson and Siklossy[6]), a combination of sequential and parallel approaches, in which the plan is expanded by choosing that subgoal to work on next which least interferes with the already existing solution. Finally, there is the so-called *linear* solution of Sussman,[7] which, like the parallel, assumes total subgoal independence at plan time, and corrects for interaction problems at execution time.

In the sequential type of solution, a powerful mechanism for maintaining a world model is required wherein each successive subgoal can determine the effects on the environment which have resulted from the sequence of actions thus far proposed by prior subgoal processes. Each subgoal process is autonomous in that it does not care what particular solution was generated by previous subgoal processes. Nevertheless, it should be aware of the effects those solutions had on the environment. The modelling mechanism must be adequate to represent these alterations to the environment.

Within this setting, I will discuss a modelling technique called *Dependency-Based* (DB) modelling which relies on an explicit representation of justifications for beliefs held by the problem solver. Using these justifications, the DB modelling mechanism is able to determine the relevant lines of inference to pursue during problem solving. Then, I will discuss three particular problem solving difficulties and I will propose remedies which will revolve about the DB modelling technique. The three difficulties are:

1. Subgoal violation detection—the ability to detect that a subgoal whose existence is still required by the main goal has been undone by the solution to a brother subgoal
2. Descriptor binding—the ability to recognize the correct binding in the plan for certain objects which are known in advance only by descriptions of their features
3. Maintaining a consistent world model—when subgoal violations are detected, the ability to relieve those interactions by modifying the sequence in which actions are applied. Demands are made on the modelling mechanism to update efficiently the world model to reflect these changes.

In following sections, I will motivate these problems and

discuss a proposed solution founded on a modelling mechanism based on dependency nets.

BACKGROUND

Maintaining world models for problem solvers is a task which has received much attention. Much of this effort was stimulated by discussion of the "Frame Problem" by McCarthy and Hayes.[16] The Frame Problem points out the difficulty of representing the influence of actions on a problem solving environment.

The modelling mechanism I will describe is based on a representation called *dependency nets*. A dependency net is a graph whose nodes represent beliefs and whose arcs represent logical justifications for those beliefs. Utilization of explicit dependency representations for world modelling is due to Fikes.[8] Dependencies have also been used to represent problem solving assumptions to help control processes such as backtracking.[9]

The power of dependency nets as the basis for modelling mechanisms is derived from their ability to direct the inference processes which draw conclusions from new beliefs about the world. Dependency nets provide a convenient structure for maintaining knowledge about derived relations among assertions. In this way, changes in belief can be efficiently accommodated into the model by allowing already derived relations to direct the propagation of information through the network. Duda, et al.[10] have investigated the propagation of information through networks of relations, although their primary focus was to deal with contributions of justifications with variable confidences to the overall strength of belief of a hypothesis. My model draws heavily on the notion of propagation of information through the network, though these capabilities have been enhanced to deal with problem solving difficulties they did not consider.

A detailed investigation of the nature of dependency structures has been performed by Doyle.[11] While his primary focus was on control issues (e.g., dependency-directed backtracking[9]), mine is on modelling issues. Among the important ideas he developed are the notions of well-founded support and non-monotonic deduction. Well-founded support is justification of a belief which ultimately relies only on fully believed premises. This notion is exercised fully in the theory described in this paper. I have not dealt with his concept of non-monotonicity which states that the justification for belief of some assertions may be based on the non-justifiability of their negations or of certain other assertions. There are many fundamental differences between our systems, though, because of the differences in purpose (control vs. modelling).

Besides dependencies, there are several popular techniques for modelling the state of the world during problem solving. Among these are context-layered databases[14,17] and "plan structure" models.[3,5] They both have advantages in terms of efficiencies for specific operations which are described later. They are both deficient, though, when compared to a dependency-based model in that they do not have the ability to record already derived relations among assertions and to utilize those relations at appropriate times.

THE DEPENDENCY-BASED MODELLING MECHANISM

As described in the Introduction, there are difficulties inherent to the sequential problem reduction approach which arise when subgoals are not independent. Their remedies will be addressed within the DB modelling mechanism for the Commonsense Algorithm (CSA) problem solver.[1]

Dependency nets

The DB modelling mechanism relies on a representation known as a *dependency net*. A dependency net is a network whose nodes are assertions representing beliefs held by the problem solver. The arcs of the network represent relations among the assertions believed by the system. In this way, not only are the system's current beliefs represented, but so are the justifications for holding those beliefs.

The dependency network representation provides the capability to make explicit the interrelationships among facts and beliefs held by the problem solving system. The network's power is derived from its ability to guide inference and deductive procedures when new facts are added to the network or, more importantly, when the truth value of one of the system's beliefs changes. For example, assume the system believes a fact P1 to be true. Suppose then, that an attempt to deduce the believed truth of P2 occurs (e.g., the problem solver wants to know if the goal P2 is already true). The deductive mechanism determines that P2 should be believed FALSE and furthermore, the reason is that a deductive rule was retrieved that stated if P1 is true then P2 is false.* These facts are explicitly represented in the network notation of Figure 1. The truth values required for the relationship between P1 and P2 to be valid (the *schematic truth values*) are denoted on the arc. The believed truth values for P1 and P2 are denoted inside the nodes (e.g., P1:T).

A great deal of flexibility results from the explicit representation of dependency relations. For example, if some event occurs which causes the truth value of P2 to change to TRUE, the system knows it can immediately draw the inference that P1 is false.** If support for P1 is explicitly represented, then those supporting beliefs can be updated in a similar way. In this manner, an alteration in truth value propagates through the network from consequents to antecedents by a process I will call *antecedent propagation*.

Let us consider a slightly more complicated example of antecedent propagation. Suppose, in determining the truth value of an assertion P, the deductive component returns that P should be considered FALSE because P1 and P2 are

* In the context of this discussion, *deduction* will be defined as the process of determining the believed truth value of a specified assertion.

** I take *inference* to be that process which computes the consequences of the assertion of a belief or the change in truth value of a belief.

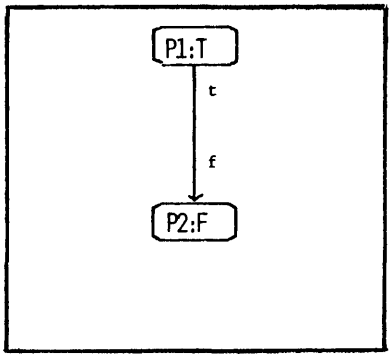

Figure 1

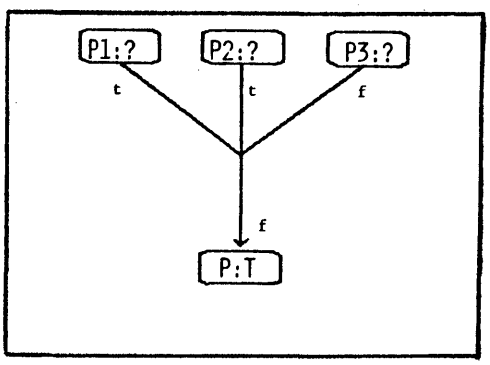

Figure 3

believed TRUE and P3 is believed FALSE. This relation is represented in Figure 2. In this case, if P should change truth value, it is known that at least one of P1, P2, P3 must also change truth value. Deduction could be applied to each to determine which had changed, and this truth value alteration could be propagated backward through the net as before. In order that the model always be consistent, whenever the consequent of a dependency relation changes truth value, deduction must be applied to each of its antecedents.

A great savings in computation could be achieved if the application of deduction to some of the antecedents of an altered consequent is avoided. A reasonable approach is to mark each of the antecedents P1, P2, and P3 as having uncertain truth value (Figure 3), and let this uncertainty propagate through the net. In this way, applications of deduction can be postponed until they are deemed relevant. If uncertainty is ever propagated to an assertion which is considered important, then deduction can be applied at that point and the effect of the result of this deduction can be propagated through the net. What makes an assertion important in a problem solving environment is described later.

Dependency net behavior when an assertion's truth value is altered is not governed solely by antecedent propagation. Truth value alteration can be propagated from antecedents toward consequents (*consequent propagation*), though this is logically different from antecedent propagation. For example, in Figure 2, if P1 changes truth value then little can be said about the truth value of P. The support of belief P has been lost, but it may be that alternate support for the currently believed truth value of P can be derived. When support for an assertion's believed truth value is lost, its truth value becomes uncertain. To determine if there was an alteration of truth value as a result of the lost support, deduction must be reapplied to an assertion whose truth value might not have changed at all. Therefore, all means of support for an assertion should be represented in the net.

For any assertion P whose truth value is desired, the deductive component should not merely retrieve the first applicable rule discovered to provide support for P's deduced truth value, but *all* applicable rules. I will call the application of all valid rules, *exhaustive support*. Although exhaustive support places a heavy demand on the deductive component, it is crucial for some applications to which the dependency net will be applied during problem solving. Having exhaustive support applied to all assertions in the network guarantees the well-founded support which helps avoid the dangers of circular justifications (see Reference 11).

Multiple applicable deductive rules occur frequently and are represented as in Figure 4. In this example, the falsity of P is independently supported by the truth of PA1 and PA2 and by the truth of PB1 and the falsity of PB2 and PB3. If some event should cause PB1 to be believed FALSE, the belief in the falsity of P does not change because of the still valid support provided by PA1 and PA2.

If, as in Figure 2, a fact P has only singular support, then a change in truth value of an antecedent (say P1) signals a change in truth value of the consequent P. The actual support for the new truth value of P must be determined by deduction, but one can hypothesize on logical grounds that P1 has something to do with it.

As with antecedent propagation, the modification of truth

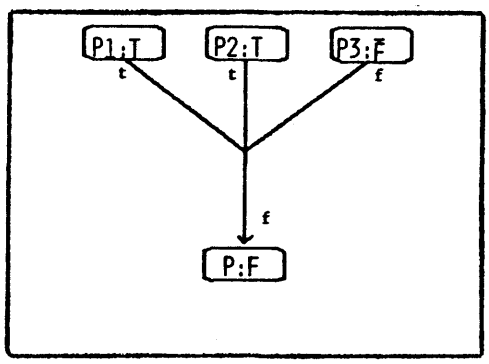

Figure 2

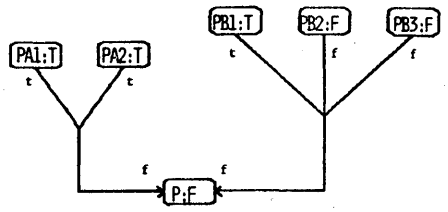

Figure 4

values of beliefs in the dependency net can be propagated along dependency links, though in the direction of the consequent by consequent propagation. Rather than applying needless deduction, assertions whose truth values have become uncertain can be so marked with uncertain truth value until a solid determination of its truth value and new support relations is required.*

A brief system overview

The dependency-based model is intended to serve as a component of a complete problem solving system whose functional modules are depicted in Figure 5. The DB model can be considered as an intelligent interface lying between the planning and deductive components. The planning component frequently requires truth values for various assertions (e.g., goals) and those truth values are determined by the deductive component. The DB model serves as an intermediary who remembers the results of deductions and who applies a highly constrained inference process for the purpose of maintaining a consistent set of beliefs about the problem solving environment. The only facts contained in the DB model are facts which are relevant to the problem solving environment because the model is activated only by assertions passed to it by the planning component. Additionally, a desirable feature of this organization is that the DB modelling component can be studied independently of any particular planning module.

Deduction rules

Dependency relations represented in the network arise from two sources. The first of these sources is the set of assumptions made by the problem solver itself. Such assumptions include the expected consequences of performing actions, selection of objects to participate in plans, and action sequence relations (that the results of an action not only depend on the action but also the context in which the action is performed).

The second source of dependency relations is the deductive mechanism. Dependencies which arise as a result of the invocation of deduction represent logical relationships among beliefs. The schematic examples in the previous section are instances of logical dependencies.

The representation of logical support rules in the dependency-based modelling scheme is rather straightforward. All deduction rules simply are represented as dependency net schemata. For instance, the dependency relation represented in Figure 6 was generated from the deduction schema in Figure 7.

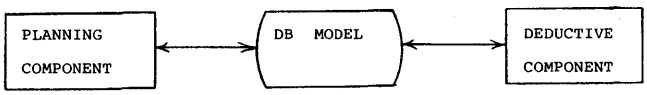

Figure 5

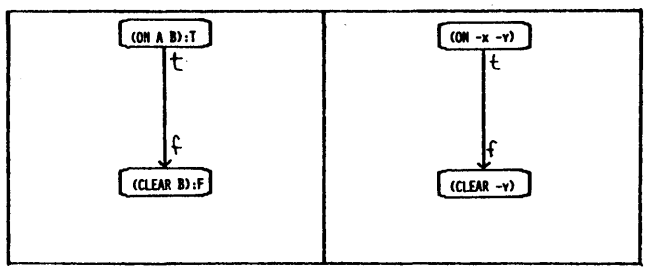

Figure 6 Figure 7

For a logical relation between assertions to be valid, the assertions must be assigned the schematic truth values. The schematic truth values of the support *rule* in Figure 8 represent that if P(x,y) and Q(y) are true then R(x) is false. The instantiation of this rule in Figure 9 illustrates an instance in which the relation is valid; the antecedents represent *actual support* for the consequent. Figure 10 shows an instance of this rule which still describes the same logical relationship among the predicates P, Q, and R (called *potential support*), though the rule is not currently valid since the truth values of the assertions do not match the schematic truth values required by the relationship.

An example of dependency net behavior

The goal of the application of logical support rules is to construct and maintain a richly interconnected network of assertions such that for any assertion P, every other assertion contained in the net which bears a logical relationship to P will be connected to P along some path in the network. These paths connecting logically dependent assertions will be discoverable by antecedent or consequent propagation. In order to maintain a consistent model, all valid alternative means of support as represented in the rules matching the derived truth value for a given assertion must be retrieved. For this retrieval, the particular method used by the deductive search is not significant to the DB model. The intent of this modelling method is to limit the amount of deduction performed during inference while maintaining a consistent model.

Example

Let us now consider an example which describes how the dependency network behaves in order to maintain model consistency. Then, in the next section, we will see how this behavior can be "fine-tuned" to limit the number of deductions to just those that are required.

Consider the set of rules in Figure 11. Suppose that these rules are sufficient to maintain a consistent model in some domain. Suppose also that in this domain, the problem solver possesses a strategy for achieving (making true) the goal predicate P3. This strategy is depicted in Figure 12. The

* Consequent propagation of uncertain truth values is similar to the truth maintenance technique utilized by Fikes.[8]

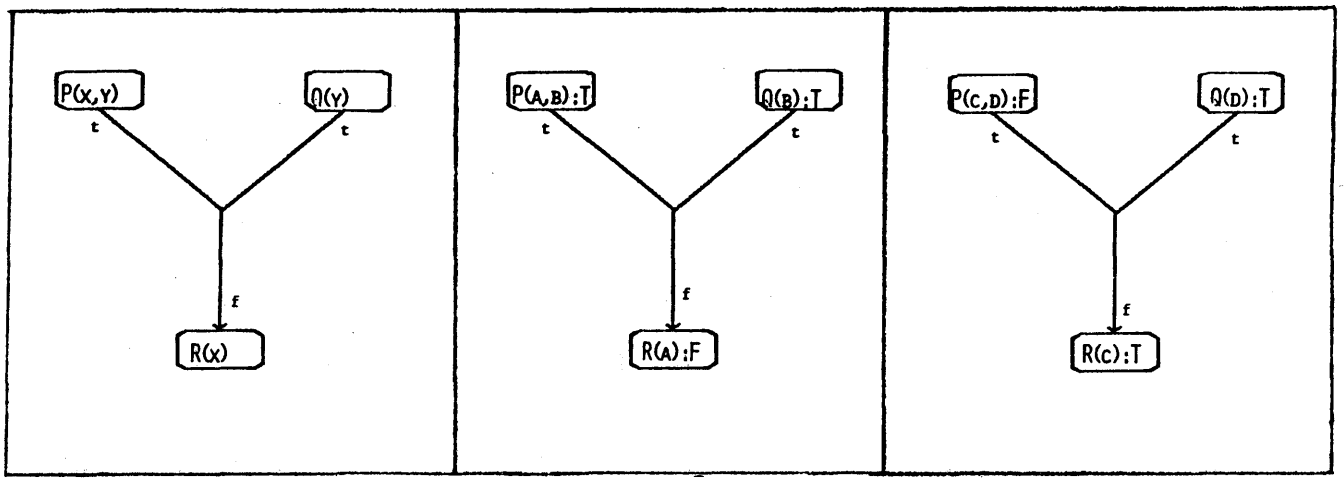

Figure 8 Figure 9 Figure 10

strategy is encoded in the Commonsense Algorithm representation.[1,12] In this case the strategy pattern states that performing the action A causes the predicate P3 to become true (or the goal P3 to be achieved) provided at the time the action is performed that P5 is true.

Now assume that in the initial world (the problem statement) P1, P4, P5, and P10 are true (Figure 13). The problem solver attempts to determine if goal P3 is already true. If so, it need do nothing further. The truth value of P3 is deduced, a value of FALSE is returned, and the strategy of Figure 12 is applied in an attempt to achieve it.

The assertion P3 having truth value FALSE is entered into the existing dependency net and exhaustive support for this belief is determined and drawn into the net (Figure 14). In this case, RULE1 and RULE2 are retrieved since their consequents match P3 and they assert the falsity of P3. The general retrieval algorithm being applied assures that an instantiation of a support rule will be knitted into the net if the consequent and all antecedents which are already in the net match the schematic truth values required of them.

Following the same line, the truth value of P2 should be deduced to determine whether the potential support provided by RULE2 indeed represents actual support for P3:F.

Suppose a truth value of TRUE is deduced for P2. The appropriate support rules for P2:T are retrieved and this process continues until the truth value of all assertions are known and exhaustive support is explicitly represented in the net. This dependency net, which shows P3 and all valid lines of support for belief in P3's falsity, is displayed in Figure 15.

The problem solver now applies itself recursively to P5, the subgoal specified by the strategy. Deduction of the truth value of P5 is not required since it is already explicitly represented in the dependency net. Furthermore, no search for support is required since every assertion in the net is already exhaustively supported. Since the subgoal is solved, the action A can cause the truth of P3, our original goal. This is explicitly represented in Figure 16 by an *action-consequent* link.

Inference behavior spontaneously occurs as the network reacts to this alteration in truth value of one of its assertions. Network inference amounts to an attempt to maintain consistency of the world model. By antecedent propagation, the inference process concludes that P4 must have become false (RULE3 from Figure 11 states this relationship between P3 and P4 explicitly). Similarly, it is concluded that at least one of P1, P2 must have become false. The model update so far is depicted in Figure 17. Let us assume that when deduction is applied to P1 and P2, it is concluded that only P2 has

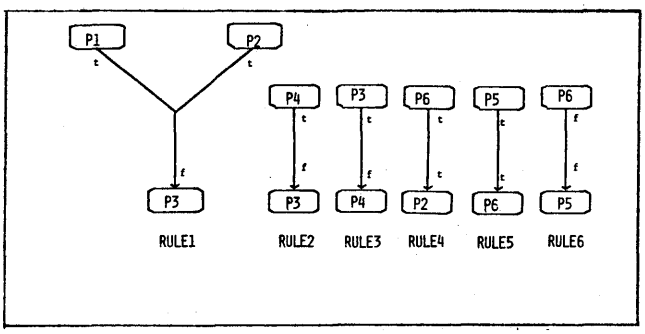

Figure 11

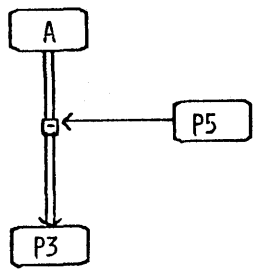

Figure 12

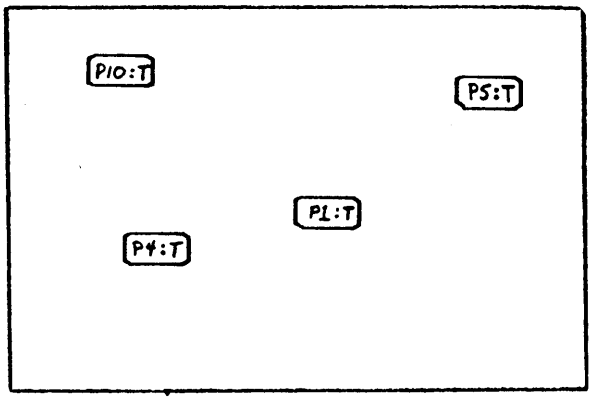

Figure 13

become false. It follows, if P2 is false then so are P6 and P5.

The propagation of alteration of truth values continues until the condition of the network stabilizes. The model is then consistent and the effects of performing the action A will have been accommodated. Every assertion in the net has an associated truth value which can at this point be considered to reflect the current state of the world as modified by the action A. Exhaustive support is required in order to assure that the effects of an alteration of truth value are propagated to every assertion which bears any logical relationship to the assertions which are immediately represented as being altered by performance of the action. In practice, the ability to maintain exhaustive support is limited by the capabilities of the deduction mechanism and the time allotted to search for lines of support.

Application of rules

If it were possible to be more selective about when to apply the deductive mechanism to determine whether a rule retrieved as potential support indeed represents actual support, one could greatly reduce the overhead which would be required to maintain exhaustive support in large dependency

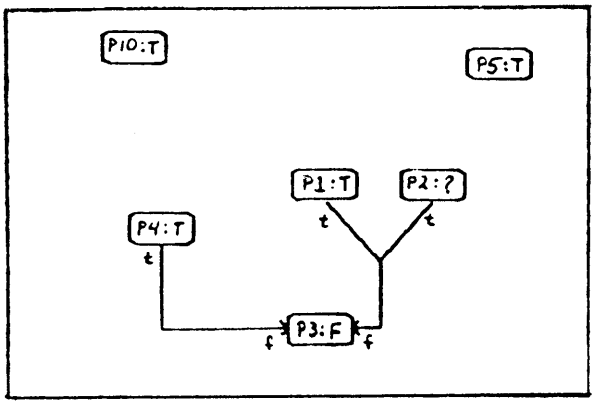

Figure 14

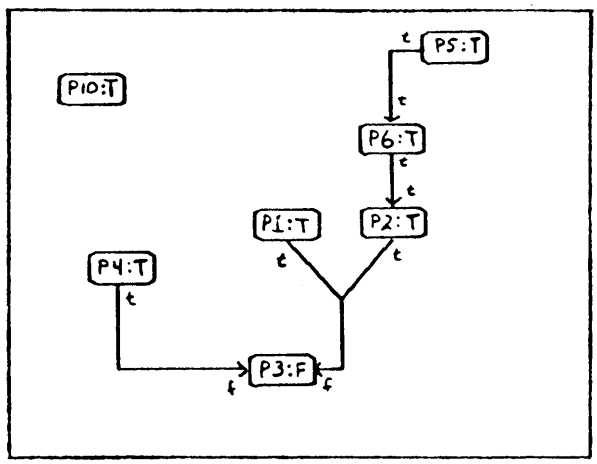

Figure 15

nets. In this section, I will describe modifications to the algorithm for verifying actual support which limit the amount of deduction required to maintain exhaustive support. The method for retrieving exhaustive support locates all support rules which provide potential support for the truth value determined by the deductive component for the consequent assertion. Those rules which do not provide actual support should not be weeded out until the need for actual support arises. This would occur, for instance, if the assertion changes truth value.

Consider the situation in Figure 14. The truth value of P2 is required to determine if RULE2 represents an actual support relation for P3:F. Recalling that the very purpose of exhaustive support is for drawing inferences from an alteration of truth value of an assertion in the net, we note that if P3 were never to change from false to true, there might never be a need to determine if RULE2 is indeed an actual support rule. The decision on the truth value of P2 can therefore be delayed until P3 changes truth value. This will become a key source of efficiency in the DB modelling

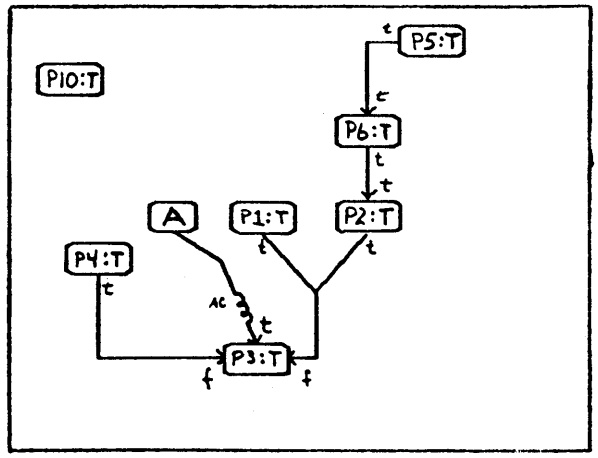

Figure 16

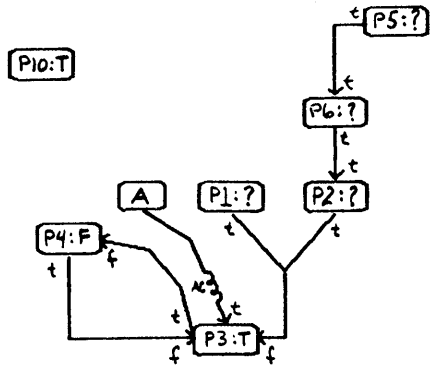

Figure 17

scheme, the efficiency being derived from the ability to focus the deductive process on only those assertions currently considered crucial to maintaining model consistency. In other words, *potential* support need only be verified when *actual* support is required.

To illustrate this point, let us introduce three new rules to the set depicted in Figure 11. The new rule set appears in Figure 18. With this rule set, when RULE2 was applied to support P3:F, exhaustive support for P1:T would have demanded the deduction of truth values for P8 and P9. This would have been a clearly wasteful operation since the truth value of P1 was never altered. In addition, since P8 and P9 were not already in the net the problem solver is not interested in them anyway.*

To realize this idea, the modifications to the information propagation algorithms are as follows.

(1) Exhaustive Support—Knit into the dependency net all support rules whose consequent matches the assertion and its deduced truth value and whose antecedents *which are already in the net* match the schematic truth values of the rule. Mark any newly generated assertions (antecedents which were not already in the net) with '*', meaning that deduction has not been pursued on this node so that this rule provides actual support only if this node has proper truth value.

(2) Antecedent Propagation—When an assertion A changes truth value:

  [1] Change truth value of nodes which are the sole antecedents of valid rules of which A is the consequent.

  [2] In rules which have multiple antecedents mark all the antecedents '?' (meaning that the truth values of these assertions might have changed). If any nodes are now marked '?*' then it is necessary to apply deduction to that node with respect to the net before the consequent was changed for the purpose of determining whether the rule was providing actual support for the altered consequent. If the deduced truth value for the antecedent does not match that required by the rule, then the rule can be discarded because it did not represent actual support. If the truth value of the antecedent matches the rule, then mark the antecedent as having uncertain truth value '?' and put it on the antecedent propagation queue.

These modifications minimize the number of deductions required by inference in accommodating the alteration in belief of an assertion. This inference process determines all relevant effects of a modification in belief of an assertion by the problem solver. Deduction is only performed when required and the network representation is flexible enough to make bookkeeping for the process a fairly simple matter.

* It should be noted that intermediate assertions like P2 and P6 in Figure 16 only serve the purpose of tying "important" assertions together. Important assertions are those stated in the initial world and those for which truth values are explicitly requested by the problem solver (i.e., goals).

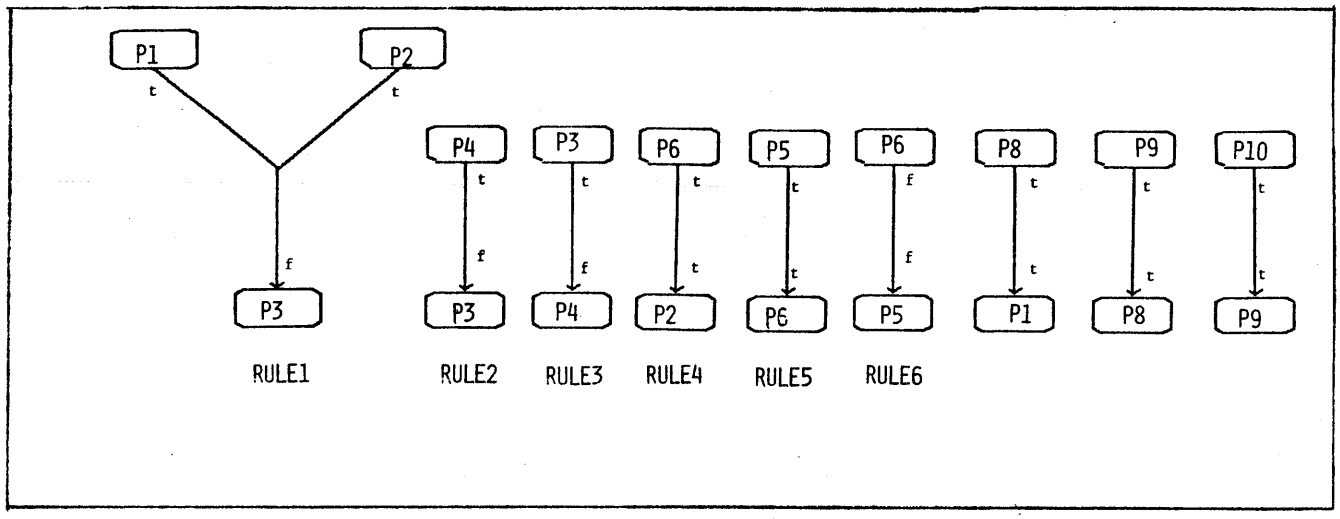

Figure 18

A comment about deduction

My purpose here has not been to propose a new mechanical theorem prover; I have intentionally ignored the problem of deduction entirely. Rather, my purpose has been to demonstrate that the goal structure of a plan and a representation for the justifications of beliefs can be used to guide an efficient modelling technique. Deductions are performed only in response to requests for truth by the problem solver and in determining the actual support relations for believed assertions. One strength of this approach lies in its ability to avoid deduction for the maintenance of a consistent world model until the truth of assertions in that model have a bearing on the outcome of the planning process.

There is an extensive and well-known body of literature on the subject of mechanical deduction.[13] The dependency-based modelling mechanism places no restrictions on the structure of the deductive process. The deductive component could be implemented as a mechanical theorem prover or as a search through the collection of support rules provided. The DB model merely assumes the existence of some deductive capability which can determine the truth value of an assertion with respect to the context established by other known beliefs and that the determined truth value is compatible with that which would be derived if the support rules were applied by some search process for the purpose of deduction.

APPLICATION OF THE DEPENDENCY NET MODEL

In the Introduction, I described three difficulties for general problem solvers that synthesize solutions to conjunctive subgoals by considering the subgoals sequentially. These difficulties arise when the subgoals are not independent. I will now outline solutions to these difficulties within the DB model framework.

Subgoal violation detection

If techniques are to be devised to deal with potential interaction among solutions to sets of conjunctive subgoals, then some method for detecting those interactions must be available. Remembering that one of our aims is to maintain as much autonomy as possible for the solution process of each subgoal, we require a scheme for subgoal violation detection which can run in the background without affecting the activity of the problem solver directly. Subgoals must remain intact until the main goal for which the subgoal has been defined has been achieved. A popular scheme for guaranteeing the temporal scope of a subgoal has been to use protection.[1,3,7]

The violation detection scheme described here utilizes inference as a restricted search process for a general system of violation detection. This violation detection scheme derives naturally from the inferences which occur to accommodate a change in belief in the net. To illustrate, assume a goal G has been solved by the problem solver. A protection violation would occur if, after G is asserted to be true (after it is solved), a consequence of that assertion is to make a protected assertion false. It follows that detecting protection violations can be accomplished by hypothesizing G to be true before actually making it so, allowing the dependency net to react to that assumption, then determining whether a change of truth value propagated to an assertion marked protected. The violation could be eliminated by processes such as described by Rieger and London,[1] Tate,[2] or Waldinger.[3]

It should be noted that this type of processing could conceivably be performed in a "context-based" modelling system. A new (hypothetical) context could be created, G assumed to be true, implications of this assumption determined, and any occurring violations discovered. If no violations were discovered, the hypothetical context could be popped and the implications about the assumption of G true would be discarded.

The dependency scheme never throws away the work it has done in computing the implications of a given truth value for an assertion. When G actually becomes true as a result of some action proposed by the planning process, much of the effort expended by inference to determine the implications of the assumption about G being true can still be used.

In addition to its efficiency, I would argue that this is a more general violation detection scheme than has been proposed before (see References 2, 3 and 5, for instance). It is my feeling that utilizing a general inference process for violation detection allows for application of the problem solver to more complex domains than would be allowed by a detection process which relies solely on syntactic pattern matching. Furthermore, the dependency structure helps focus the search for a violation.

Descriptor binding

It is often necessary during problem solving to defer decisions about the bindings of certain variables. These are variables for which bindings are not explicitly specified when a strategy pattern (Figure 19) is instantiated to satisfy a goal statement (Figure 20). Thus, the "CLEARTOP" strategy has a free variable which should be bound to the

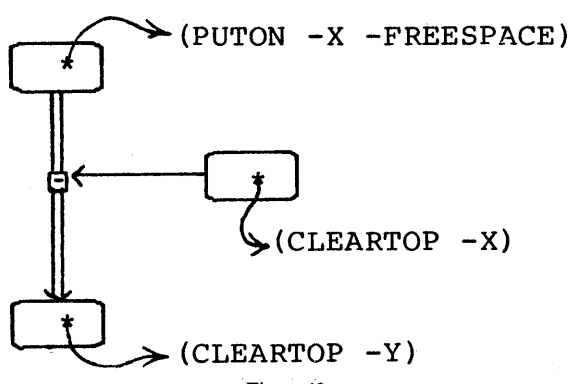

Figure 19

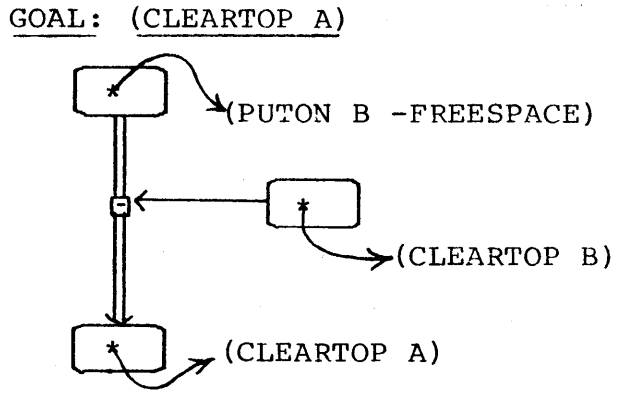

Figure 20

location at which the block on top of the block to be cleared should be placed. One advantage of being able to defer the choice of a binding for this variable is that it may not be obvious at the time the strategy pattern in Figure 19 is instantiated what the most appropriate choice for a binding would be. By deferring the decision, the problem solver can wait until enough information about a suitable binding has surfaced before making that decision.

Consider the problem from Waldinger[3] depicted in Figure 21. For the purpose of synthesizing a reasonably efficient plan, the problem solving system should have the ability to detect that in clearing A, the most suitable location to place B is ON C, thus solving the second subgoal in the process. Problems of this complexity have been handled by defining variables which can be manipulated by the problem solver as objects, and binding those variables to actual objects at the time at which a suitable determination of the correct binding can be made.[5,7]

The solution which I am proposing follows the same line of reasoning by binding variables which can be treated as objects. These variables are called *descriptors* because they can describe semantic restrictions on the eventual referrent. For example, consider the descriptor

```
(*DESCRIPTOR -FREESPACE
    [OR ⟨AND (CLASS -FREESPACE BLOCK)
             (CLEARTOP -FREESPACE)⟩
        (REGION-OF -FREESPACE TABLE)]
    [TABLE-REGION-1] ).
```

This descriptor describes the object on which to place a block which has been picked up for the purpose of clearing another. It is a variable with semantic restrictions on its eventual binding specifying that FREESPACE is either a block whose top is clear or it is some region of table. If no

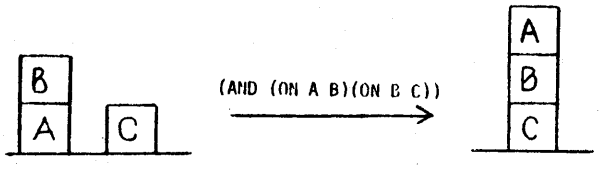

Figure 21

binding can be discovered during plan synthesis, the table is declared as the default.

The relationship of descriptor binding to the dependency network is as follows. All assertions which refer to a descriptor are included in the dependency net. In the example above, the assertion (ON B -FREESPACE):T would be included in the net as a result of clearing A when achieving (ON A B). If the problem solver makes a request for the truth of a goal (e.g., (ON B C)) which matches an assertion in the dependency net containing reference to a descriptor (e.g., (ON B -FREESPACE)), then a candidate for a descriptor binding has been found. The potential binding object (C) must still pass a few tests. If the object which matched successfully against the descriptor also satisfies the semantic restrictions specified in the descriptor, and it satisfies all other assertions in the net which reference the descriptor, then the object can be bound to the descriptor. This binding technique is similar to Sacerdoti's "Use Existing Object" critic.[5] A scheme is currently being considered to allow binding to occur even though not all the restrictions are met, and to allow the satisfying of those restrictions to be solved as subgoals by the problem solver.

Descriptor binding amounts to an assumption made by the problem solver about an appropriate object to participate in the plan. The choice must be carefully determined, and will depend on facts known to the system. As such, the decision can be knitted into the dependency net as a new type of dependency. The advantage of making descriptor binding explicit within the dependency framework is that it allows the descriptor binding mechanism the same flexibility as other inference processes in the system. The choice of descriptor binding is considered best at the time the choice is made. Subsequent problem solving might prove that choice inferior to another. Since the binding is just a type of dependency, these decisions can be "unravelled" as easily as action sequence decisions to be described in the next section. Furthermore, the network treats descriptors as objects and can perform inference based on the features specified in the descriptor as though it were a real object.

Modifying the action sequence

A common operation in problem reduction problem solvers is to modify the partial action sequence as a plan is being synthesized. This modification is most often utilized by "sequential" type systems (those which deal with the subgoals sequentially) and is applied to relieve certain types of subgoal interactions. The particular types of interaction which can be relieved in this way are those which result from an incorrectly ordered action sequence (a possible side-effect of the assumption of subgoal independence).

When subgoals are attacked independently, it is difficult to anticipate the proper order in which they should be solved. Often, in fact, an inherent interdependence among subgoals demands that the solutions that are independently derived for each be somehow melded together. A classic example of subgoal interdependence is depicted in Figure 22. Regardless of the order in which the subgoals (ON A B)

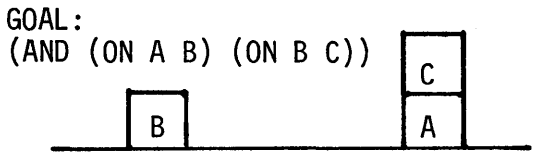

Figure 22

and (ON B C) are solved, a reasonable plan cannot be synthesized by considering the two subgoals independently. A reasonable approach is to allow the subgoals to proceed sequentially and if a subgoal is violated by a subsequent subgoal to modify the action sequence to relieve the violation.*

Operations such as inserting a new action in the middle of an existing action sequence or removing an action from the middle of an action sequence must be acceptable to the modelling mechanism. This is a task which is difficult for chronological "context-based" models to deal with. The purpose of the modelling mechanism is to reflect the anticipated state of the world as it would be when modified by the sequence of actions being proposed by the problem solver. Let us examine an action sequence modification which involves removing an action, Ai, from an action sequence $\{A1, \ldots, An\}$, where $n>i$. The action-consequent links for the actions $Ai, \ldots, An$ can be removed and the inference mechanism can update the network to reflect these changes. The effects of actions $Ai+1$ through An can then again be accommodated efficiently, making use of the already existing network structure created when they were originally introduced.

Frequently the effects of actions are very local in the sense that other actions have little effect on the assertions effected by a particular action.** The power of the DB model for the operation of action sequence modification is derived from the fact that, often, many of the effects of the actions subsequent to Ai are little changed by the removal of Ai from the sequence or the insertion of a new action into the sequence. Since the effects of actions are explicitly represented in the dependency net, much of the effort necessarily expended by a chronological model in recovering to a state of consistency after removal (or addition) of an action from the action sequence can be avoided.

Let us examine some of the problems of using a chronological "context-based" model for these operations. Figure 23 shows a sequence of context frames in a context-layered database (a la CONNIVER[14]) where each frame represents the assertions required to accommodate subsequent actions in the proposed action sequence $\{A1, \ldots, An\}$. An efficient operation for the context-based models is to revert to a prior state, say the state just before inserting Ai on the action sequence (Figure 24). This operation would be necessary if one desired to remove Ai from the action sequence (and its effects from the model). However, if one now tries to include the subsequent actions in the model (excluding Ai), all the work already performed in accommodating $Ai+1$ through An must be reproduced (Figure 25). This is because context-layered databases allow a tree-like structure of context frames (as in Figure 25) while what is ideally required is a graph structure (Figure 26).*

Modelling mechanisms other than "context-based" exist which handle the action sequence modification problem. Most notable are the "plan-structure" schemes of Sacerdoti[5] and Waldinger.[3] Both these schemes make use of the existing plan for computing the model. Both offer no more flexibility than dependency nets for recovering to prior states but they suffer, as do the context models, from being "forgetful" about inferences which have been made since the point at which the action sequence is being modified. In Waldinger's model, this forgetting is deliberate because he does not want the problem solver to be committed to belief in an assertion derived on the basis of the current structure of the plan. The lack of commitment to derived assertions is required since the plan structure on which the derivation was based may be altered by a modification to the action sequence. Dependency nets allow the possible alteration of belief in an assertion due to modification of the plan to be explicitly detectable. Thus, beliefs whose derivations are based on the current structure of the plan can be incorporated into the DB model (whereas in a plan-structure model they cannot) because the dependency net provides a means to detect which beliefs are affected by a modification to the plan.

FUTURE WORK AND IMPLEMENTATION STATUS

The ideas presented here are currently under implementation. Among the immediate problems is that of restricting the bindings of variables for instantiations of selected support rules. It is often possible for the consequent of a rule to match a newly entered assertion, while its antecedent matches no assertion in the net. This can leave unbound variables in assertions for which truth values are believed. For the rule in Figure 27, the consequent (CLEAR B):F matches (CLEAR -Y) and so (ON—XB):* is asserted. I plan to use the descriptor mechanism to specify the range of values the universally quantified variable—X might be bound to. Further, I intend to investigate the possibility of

* There are several schemes for determining an appropriate action sequence modification to relieve subgoal protection violations. See References 1-4.

** See Stallman and Sussman[9] for an analogous discussion of the influence of particular electronic components on the overall behavior of a circuit.

* It should be emphasized that context-based chronological models are more efficient for certain operations than the DB model. These operations are (1) the recovery to prior states (discussed above) and (2) the ability to transfer from one line of reasoning to another. For example, if it is later discovered that it would have been better to leave Ai in the action sequence, a context-based model provides for efficiently returning to that line of reasoning (i.e., transferring from point X in Figure 25 to point Y). These operations cannot be performed as efficiently by dependency net models. A possible compromise (which has not been pursued) would be to implement the dependency net in a context layered database for the specific purpose of making these desired operations efficient within the dependency net domain. It would be, however, a space-wise inefficient implementation, compounding the space-wise inefficiencies of both dependency nets and context layered databases (e.g., CONNIVER).

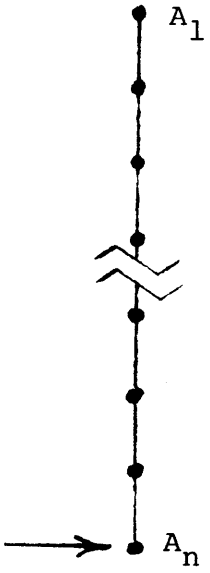

Figure 23

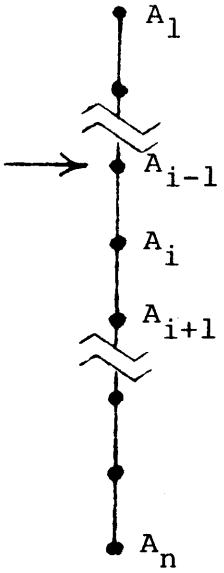

Figure 24

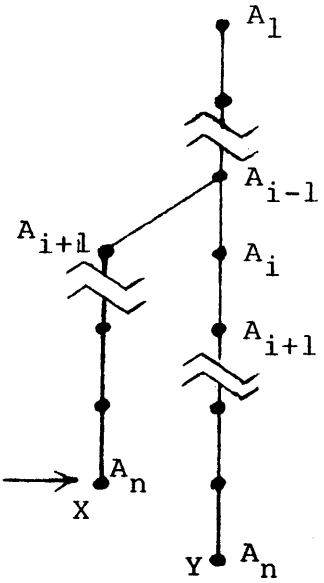

Figure 25

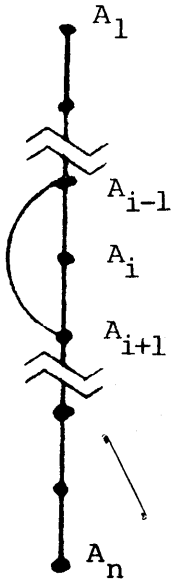

Figure 26

invoking the non-monotonicity assumption of Doyle[11] in order to limit the requirements for redeductions of truth values for assertions which have lost all support.

The implementation strategy I have adopted is to associate with each arc in the net a set of associatively triggered computation units (i.e. demons),[15] whose purposes are to propagate information across the arcs when appropriate. Making the dependency net links be active components is an idea borrowed from the CSA mechanisms simulator.[18] In my case, this technique has the advantage of allowing the implementation of network capabilities to proceed in a very modular fashion. An alternative would be to provide a program which interprets a declarative representation of the network, but would require the integration of all the network capabilities into a single program.

CONCLUSIONS

This discussion has centered on dependency nets as a unified formalism for modelling in general problem solving systems. I have suggested how such a modelling system behaves and how some enhancements to the basic ideas allow them to operate efficiently. Dependency nets serve to limit the amount of deduction required while performing inference for determining the important consequences of acquiring or modifying beliefs.

Various competing solutions have been presented for some of the problem solving difficulties discussed. Most were presented within the context of complete systems with well defined capabilities. I feel that enough has been learned about the problems of general problem solving that some investigations can be initiated to research specific techniques independent of any particular complete problem solving system. This endeavor demands some formalism in which these techniques can be described. I intend to pursue the idea that for many problem solving problems, dependency nets are an important formalism.

Error recovery in robots through failure reason analysis*

by S. SRINIVAS*
California Institute of Technology
Pasadena, California

INTRODUCTION

In performing a task, a robot may encounter a variety of unforeseen circumstances which prevent successful completion of the task. Even simple actions, such as reaching out to grasp a rock, cannot be guaranteed to succeed without dynamic sensory feedback such as visual monitoring. For example, the hand may bump into the rock because of manipulation errors or because of erroneous information about the location of the rock. Failures such as these occur because sensors and effectors are inaccurate, and because the world in which the robot operates cannot be characterized exactly.

Our goal is to design a robot that can recover gracefully and intelligently from failures that occur during the execution of tasks in a static world with no other agents of change. The technique for recovery planning discussed in this paper is based on knowledge about failures—why they occur, what can be done about them, etc. This knowledge is used to determine the cause of a failure and to devise a recovery plan. Similarities and differences between this and other approaches are discussed in a subsequent section.

A computer program called MEND has been implemented for exploring the above concepts. Though MEND only automates recovery from failures in simple manipulation tasks that are performed by the JPL robot,[8,9,17–19] the techniques used in MEND are more widely applicable.

A DISCUSSION OF THE APPROACH

Execution of a task can be viewed as a sequence of transformation that changes the world from an initial state, S_0, into a final state, S_n, which represents the goal of the robot.

Figure 1 depicts the intermediate states of the transformations from S_0 to S_n that result from the execution of a plan of actions, $A_0 \ldots A_{n-1}$. Assume that a failure is detected on execution of action A_i. This means that the robot recognizes that action A_i has not produced the expected state S_{i+1}, but rather has resulted in some failure state S_f.

The problem of error recovery is that of going from the failure state S_f to the goal state S_n. One approach is to treat S_f as though it were some arbitrary state and respond to the failure by replanning to achieve the given goal. In such an approach, there is no essential difference between error recovery [the transformation from S_f to S_n] and planning [for instance, the transformations from S_0 to S_n]. Parts of the old plan can sometimes be reused, as for instance, by replanning from S_f to S_j so that the original plan can be used to go from S_j to S_n.

This paper suggests that by finding an explanation of the failure, i.e., understanding why action A_i resulted in the state S_f, a robot can determine where the problem lies and what can be done about it. With this viewpoint, error recovery is seen as something quite different from traditional planning in that we do not merely ask, "What can be done to go up from S_f to S_n?," but begin by asking, "Why did action A_i result in the state S_f?" in order to recover from the failure.

OVERVIEW OF MEND

Let us consider an example to illustrate the problems involved in recovery from failures, and some of the features of the solution incorporated in MEND. The robot hardware that is controlled by MEND consists of two TV cameras, a laser rangefinder, a manipulator, and a vehicle (Figure 2).

Suppose that the robot is given the simple task of picking up a rock within immediate reach. Performing this task involves locating the rock using the TV cameras, opening the hand, positioning the hand around the rock, and grasping the rock (Figure 3). Assume that the hand bumps into the rock when attempting to position the hand around the rock. In this example, the manipulator system triggers the failure, bringing MEND into action. In other cases, MEND has to make explicit checks of certain conditions to detect failures. MEND's execution monitoring is pragmatic in the sense that only those conditions that are easy to check on the basis of the information available directly from feedback, sensors, etc., are tested. A consequence of this lack of comprehensiveness is that failures can propagate and may be detected only at a subsequent step.

Having detected a failure, MEND is confronted with the

* Now employed at Bell Laboratories, Naperville, Illinois.

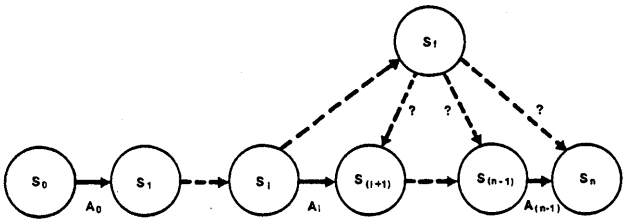

Figure 1

problem of dealing with the unexpected event. A heuristic used in MEND suggests that recovery actions can be found by determining why the failure occurred. The process of finding an explanation for the failure is termed *failure reason analysis*. Knowledge necessary for failure reason analysis is provided through a *failure reason model* associated with each action. The failure reason model represents knowledge about different reasons for failure of an action, how they may be distinguished, and what can be done to recover from a specific kind of failure.

MEND represents possible explanations for a failure in a structure called the failure tree, an example of which is shown in Figure 4. The tree consists of a linked set of failure nodes and action nodes. There are four basic types of failure reasons that are dealt with in MEND; namely *operational errors, information errors, precondition errors,* and *constraint errors*. Each failure node is associated with a failure type and a specific reason for failure. Action nodes are linked to an action in the plan being executed. An example of an explanation represented in Figure 4 is that the goal WITHIN-GRASP (node G) was never achieved by action MOVE-HAND-TO-GRASP, because of an operational SERVO-ERROR (node F1).

Analysis of failures can now be thought of as the process of limiting the set of all possible explanations to the specific one that applies in a particular situation. MEND does this by limiting the set of failure reasons to be considered at each action node in the failure tree. Preconditions and constraints that have been verified on the basis of feedback information and sensor outputs, can be eliminated from consideration as

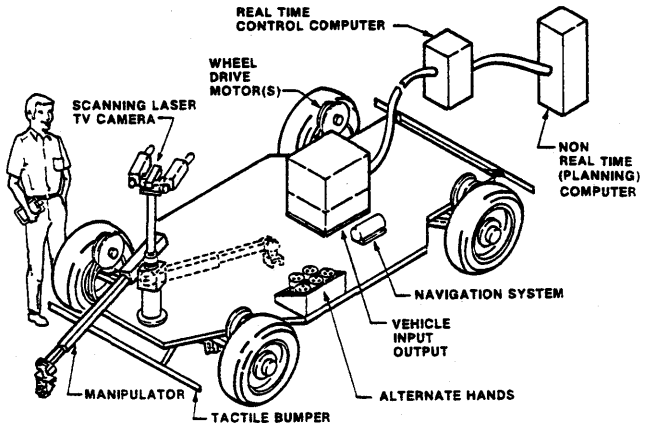

Figure 2

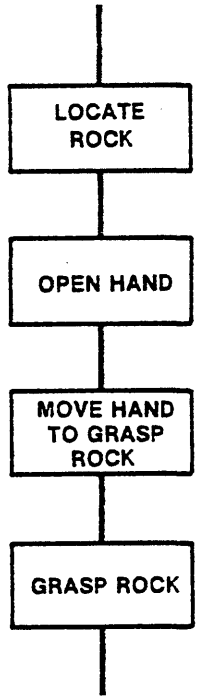

Figure 3

possible reasons for failure. More importantly, the distinctive features of the failure are used to limit the set of failure reasons. Figure 5 shows, for instance, a simple test and the implications of its results in eliminating some failure reasons from consideration.

Once an explanation has been found, recommendations of corrective steps can lead MEND to successfully plan recovery from failures. For instance, if the failure is attributed to an information error (Figure 4) recovery can be achieved by

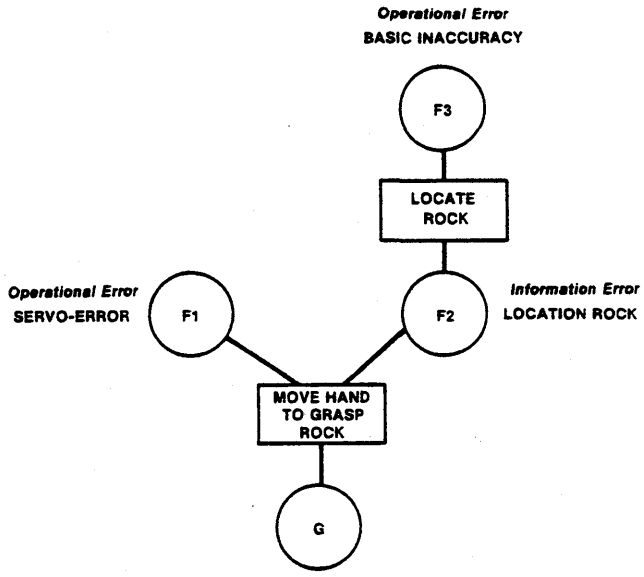

Figure 4

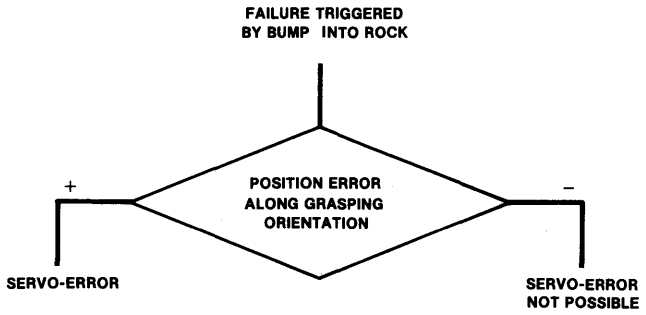

Figure 5

positioning the hand near the rock, determining the location of the rock relative to the hand, and then repositioning the hand around the object (Figure 6).

Other scenarios illustrating MEND's capabilities are described in a thesis[14] that is a more complete documentation of the research study discussed here. The following sections describe the conceptual basis behind MEND and its design.

A CLASSIFICATION OF FAILURE REASONS

MEND's analysis of failures is based on a classification of failure reasons into four categories. These are operational errors, information errors, precondition errors, and constraint errors. Each is discussed in turn.

Actions can fail to achieve their intended result because of certain inherent problems in executing the action. These errors are peculiar to the specific operation being performed and are, therefore, referred to as operational errors. For instance, the manipulator may deviate from the planned trajectory in moving from one location to another. This servoing error will not often have any serious consequences, but in some cases it can cause the manipulator to bump into the object to be grasped.

An inaccuracy in the location of an object is an example of an information error. Though information errors can usually be traced back to operational errors in the process being used to provide the information, they are to be distinguished from such operational errors. As in our previous example of operational errors, information errors will not always cause failures and the robot may successfully complete its task despite such errors.

Before executing an action, MEND will check preconditions and constraints. If any of these are found to be false, it will attempt to make them true before continuing. If all the preconditions of actions could be checked and verified, there would be no reason for failures to occur because of precondition errors.

However, it would be unrealistic to expect a robot to check preconditions exhaustively, since some of them are inherently difficult to check. Therefore, the execution monitoring in MEND does not require that all preconditions be absolutely verified before executing an action. In some cases, executing subsequent steps may be the simplest way of finding out that they were or were not satisfied. For instance, checking to see that an object is truly within grasp before actually grasping the object is unnecessary and expensive, since the very action of grasping will immediately indicate whether this is true or not. Even when previous actions were executed with the intention of making the preconditions true, the robot cannot depend on them being true since these actions themselves may fail. In any case, the consequence of not verifying preconditions is that *after* execution of an action, failure can be attributed to the falsity of preconditions. In this report, the term precondition errors refers to the above interpretation, to be distinguished from precondition failures detected before execution of an action.

Finally, an action can fail because there are some constraints that must be satisfied for successful execution. An example of this is that the object should be movable before the robot can transport it from one place to another. In a sense, these are merely special cases of preconditions that the robot has no way of making true.

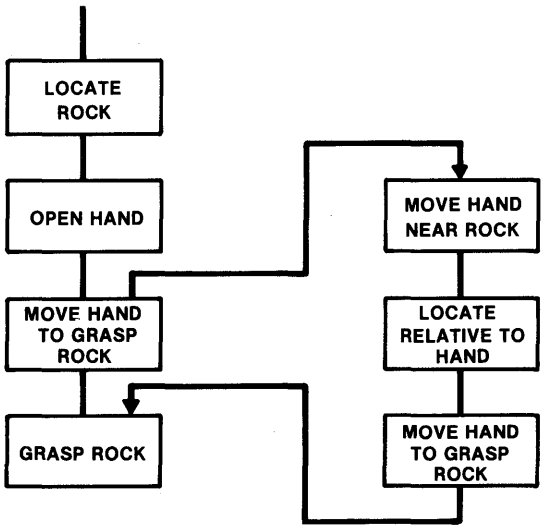

Figure 6

THE FAILURE TREE

The structure of a failure tree, as illustrated in Figure 7, is described next. There are two types of nodes in a failure tree, *failure nodes* and *action nodes*. Failure nodes are represented by circles and action nodes by rectangles. Action nodes are linked to a node in the execution trace through a plan link that is not shown in the preceding figure. Each failure node identifies the failure and its type, and may point to one or more action nodes through one of several kinds of links. The NAB (Never Achieved By) and IPB (Incorrectly Provided By) are two examples of such links. Action nodes point to failure nodes through a PRFF, the "Possible Reason For Failure" link.

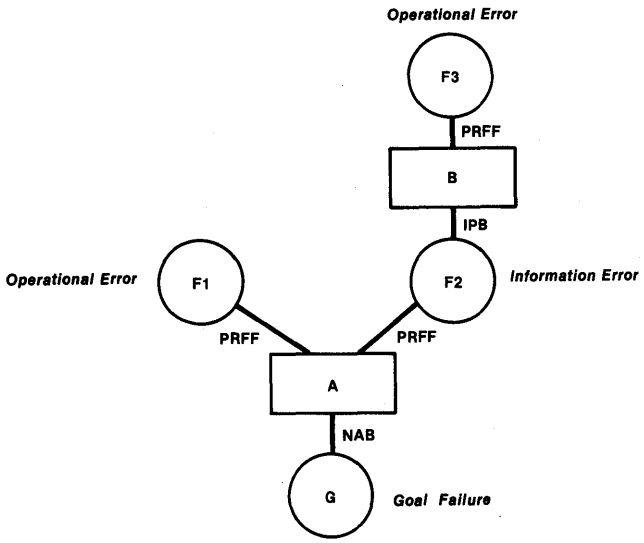

Figure 7

The example in Figure 7 can now be interpreted in the following manner: Goal G was never achieved by action A because of one (or more) of two possible reasons, F1 and F2. F1 indicates that the failure could have been the result of operational error, while F2 represents data incorrectly provided by action B.

The types of failure associated with failure nodes are the ones discussed earlier (operational, information, precondition, and constraint errors) with one addition. There is a special failure type which occurs only at the root of the tree and this represents a goal failure.

Operational and constraint failure nodes do not point to other nodes since they are local to the failure action. Precondition nodes may be linked to action nodes that were intended to achieve the precondition. When such links are missing, it means that no action was executed to achieve this condition. It, therefore, represents an *initial condition error*. Similarly, information failure nodes are linked to actions that provide the needed information, and missing links indicate *initial information errors*.

BUILDING A FAILURE TREE

The idea behind failure reason analysis is to find an explanation of the failure. By *explanation* we mean a chain of reasons represented by a path from the root node of the failure tree to one of its leaf nodes (G - A - F2 - B - F3 in Figure 7). If we consider all possible reasons for failure at each action node, then the failure tree represents all possible explanations for the failure. Clearly, only one or a few will be relevant in any particular situation.

We next investigate what can be done to constrain the set of explanations. An execution trace in which unverified preconditions and constraints are noted provides the information necessary for determining whether failure can be attributed to the falsity of these conditions. Note that a precondition is not considered to be verified merely because a previous action was executed to make this condition true. Instead, it is considered to be true when independent tests verify the truth of the precondition. To consider a trivial example, OPEN-HAND is verified by checking that the joint feedback information indicates that the fingers are fully separated. Typically, other robot systems verify preconditions by looking for explicit assertions in the data base or by deducing the truth of these conditions from other assertions. The result of this is that no distinction can be made between those preconditions that can be verified directly from feedback information and those that are only surmised to be true because of the intended effects of previous actions.

A second important way in which the failure nodes branching from an action can be cut down is by looking at the manifestation of the failure. By identifying distinctive features of the failure situation, some of the reasons for failure can be shown to be impossible or at least unlikely.

Third, the history of actions can show that certain explanations are impossible. If, for instance, no reasons for the failure of action C in Figure 8 can be found, we can conclude that B could not have failed because of F2. If there are no other reasons for the failure of B besides F2, we can conclude further that A could not have failed because of F1. Such reasoning can significantly cut down the set of possible explanations, thereby pointing out the real explanation of the failure.

Failure reason analysis in MEND, i.e., the process by which MEND determines the plausible explanations of the failure by building a failure tree, is outlined below:

1. Find the set of possible failure reasons.
2. Eliminate verified preconditions and constraint failures from this set by looking at the execution trace.

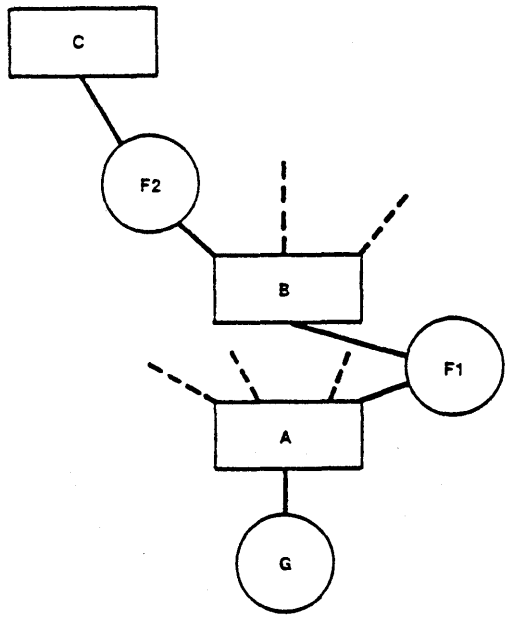

Figure 8

3. Look for distinctive features of the manifestation to further constrain the set of failure reasons.
4. For each of the remaining failure reasons, create failure nodes and link the action node to these newly created failure nodes.
5. For precondition failure nodes, find the previous action responsible for making the precondition true from the execution trace. For information failure nodes, find the previous action that provides the necessary information. Create an action node for each of the previous actions so determined.
6. Repeat the above process for the newly generated action nodes.
7. Clean up the failure tree by eliminating impossible explanations (i.e., apply the process described in connection with Figure 8).

THE FAILURE REASON MODEL

The failure reason model is a model of actions which provides the knowledge necessary to perform failure reason analysis by means of the algorithm outlined in the previous section. First, the model should identify the set of possible failures. Operational failures are represented explicitly through a set of associations as shown below:

(OPERATIONAL-ERROR MOVE-HAND-TO-GRASP(ROCK) SERVO-ERROR)
(OPERATIONAL-ERROR MOVE-HAND-TO-GRASP(ROCK) COLLISION)
(OPERATIONAL-ERROR LOCATE(ROCK) INACCURACY)

Knowledge about other types of failures is implicit in the model of actions used in MEND, which specifies preconditions, constraints and needed information. For instance, any unsatisfied precondition is recognized as a possible reason for failure by MEND. Figure 9 shows the correspondence between the action model and the failure tree.

The knowledge necessary to eliminate some possibilities on the basis of their manifestation is highly domain dependent. In MEND this knowledge is incorporated in a routine called the FRA-ROUTINE which is associated with each action. The FRA-ROUTINEs test for the presence or absence of distinctive features of the failure in the current state of the world. These tests indicate that certain failure reasons are impossible, that others are likely, and so on.

Figure 10 represents the FRA-ROUTINE associated with the action MOVE-HAND-TO-GRASP. At each node in the tree, a condition is tested and the appropriate branch taken. The leaf nodes of the tree specify a list of failure reasons that are considered possible in a specific context.

We note several important points about these routines. As with precondition testing, the conditions being tested are easily computed using the data in the world model and the feedback information. For instance, the condition NEAR-DESTINATION is checked by verifying that the final position of the hand is within a prespecified limit of the planned destination.

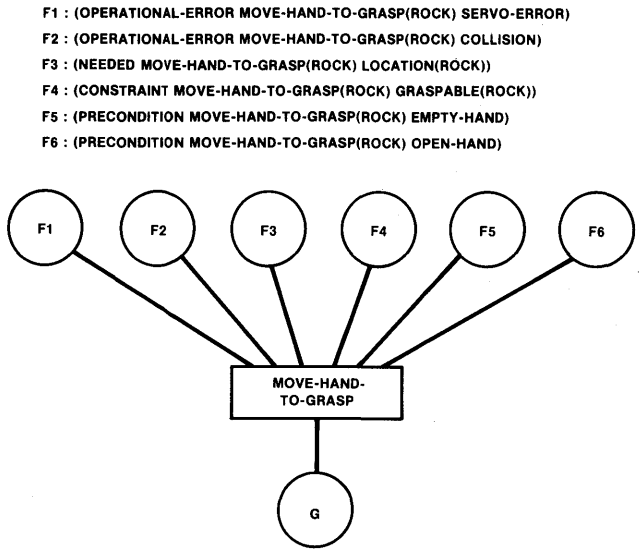

Figure 9

The routine illustrated in Figure 10 assumes that the preconditions EMPTY-HAND and OPEN-HAND have been made true, and does not consider how a failure resulting from the falsity of these conditions will manifest itself. This simplification is possible because MEND's execution monitoring will detect these precondition failures and will not allow execution of this action to continue unless the preconditions have been satisfied. Note that the FRA-Routines represent a procedural incorporation of knowledge about the manifestations of failure.

There is a problem in the use of such routines to limit the set of failure reasons in Step 3 of the algorithm presented in the previous section. This routine requires information about the state of the world in making its decisions, which means that previous states of the world need to be represented. To keep this information around would be quite unrealistic in any large system, even using a stack-like mechanism for representing only the incremental changes.

There are two ways of tackling this problem. Execution monitoring can be extended by running the FRA-ROU-

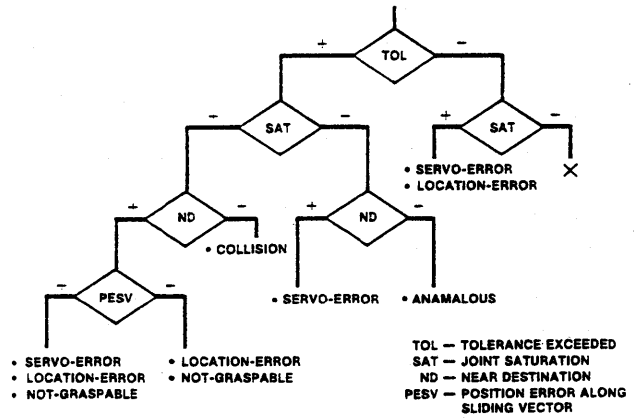

Figure 10

TINEs regardless of whether or not a failure occurred and marking the failure possibilities in the execution trace. Later, if failure reason analysis is necessitated in a subsequent action, this possibility list presents a summary useful for analysis.

A different strategy is to ignore the possibility of failure when there is no explicit triggering of the failure, and to later determine the failures that escaped detection. This is achieved in MEND by the representation of facts such as the one shown,

```
(PTRIG (NEEDED MOVE-HAND-TO-GRASP(ROCK)
  LOCATION(ROCK)) NTRIG)
where  PTRIG=POSSIBLE-TRIGGER
and    NTRIG=NULL-TRIGGER,
```

which says that a location error in the position of the rock could go untriggered when executing MOVE-HAND-TO-GRASP. (The reason for this is that if the location error is sufficiently large, the hand will completely miss the object.) With these facts in hand, MEND can immediately determine the set of failure reasons to be considered in Step 3 of the previously outlined algorithm, without having to run the FRA-ROUTINE for previously executed actions.

An assumption implicit in the latter approach is that any triggered failure has already been handled. The first approach is a more general technique but will perform unnecessary computations in situations where plans are successfully executed.

There is one other aspect of the failure reason model. It provides information about how to correct a particular kind of failure.

Knowledge necessary to correct operational errors is local to an action, and is represented in MEND by facts, such as,

```
(TO-CORRECT (OP-ERROR MHTG(ROCK) SERVO-
  ERROR) MHTG-REC-PLAN1(ROCK))
where  OP-ERROR=OPERATIONAL ERROR
       MHTG=MOVE-HAND-TO-GRASP
and    MHTG-REC-PLAN1=(ROCK)
                      BEGIN
                      MOVE-HAND-TO-
                      GRASP(ROCK)
                      END,
```

which says that an operational error of servoing in MOVE-HAND-TO-GRASP can be corrected by executing the plan MHTG-REC-PLAN1. This plan will attempt recovery by simply repositioning the hand, and this strategy is appropriate for servoing errors. In general, TO-CORRECT steps are provided for each operational error.

Constraint errors on the other hand, have no such "imperative knowledge"[6] about what to do, since the robot does not have the capability of correcting such failures. If failure is attributed to a constraint error, the plan is aborted and MEND seeks human aid.

Precondition and information errors are not directly associated with corrective steps and are treated somewhat differently than operational errors. For precondition errors, the obvious thing is to reachieve the failed precondition before trying the action again. But before this can be done, some of the effects of the failed action may have to be undone. After the precondition has been achieved, other steps may need be redone to get execution back on the right track. MEND implicitly incorporates this knowledge and recognizes that there are three parts to recovery from precondition errors: *undo certain actions, reachieve precondition, and redo the undone steps.* Knowledge about what needs to be undone and what needs to be redone is part of the failure reason model. For example,

```
(UNDO-STEPS (PRECONDITION GRASP (ROCK)
  WITHIN-GRASP (ROCK)) OPEN)
(REDO-STEPS (PRECONDITION GRASP (ROCK)
  WITHIN-GRASP (ROCK)) GRASP(ROCK)),
```

says that if failure in GRASP is attributed to the precondition error of the object not being WITHIN-GRASP, the OPEN undoes the effect of GRASP, and that GRASPing the object needs to be redone after WITHIN-GRASP has been reachieved.

The situation is entirely similar for information errors, and recovery is achieved by undoing certain actions, getting the necessary information, and redoing the undone steps. Facts such as these are used in patching together a recovery plan in a rather simple and direct manner, after that the explanation of the failure has been determined. When multiple explanations remain even after analysis, MEND applies an ad hoc technique using severity codes to identify the more serious failure reason, in the hope that the recovery plan will work even if the explanation is wrong.

PERSPECTIVE AND RELATED WORK

Before summarizing the work described in this paper it would be worthwhile to consider related work and place this work in perspective.

Several studies that have dealt with the problem of planning have adopted the paradigm of devising a simple plan for achieving the given goal, identifying and characterizing the problems in such a plan, and finally correcting the problems in the original plan. It is fairly clear that techniques used in systems adopting such a paradigm have applicability to the problem of error recovery.

Sussman,[15] in his investigation of skill acquisition, characterizes failures in terms of domain-independent goal interactions such as precondition conflict between conjunctive subgoals, and the system corrects these by strategies such as reordering actions in the plan, introducing preparatory steps, etc. Sacerdoti[13] and Tate[16] use similar characterizations of subgoal interactions in their planning systems, but the process by which the characterization is achieved has been improved and made more systematic.

In MYCROFT,[6] violations between the actual performance and the intended line drawing described by a model are determined, and then used in correcting the plan. Similarly, Fahlman[1] uses domain-dependent stability analysis to identify instabilities in blocks world structures, and corrects

these by the use of subassemblies, counter weights and scaffolding.

We note the following points that identify the similarities and differences between MEND and the systems mentioned above.

A. In a general sense all of these systems have the capability of dealing with execution time failures. However, Sacerdoti's system NOAH is the only one of these that deals specifically with error recovery. In aiding an inexperienced human to correct an error, NOAH performs a hierarchical search for more detailed descriptions of the incorrectly performed task to identify the failure.

   In contrast to the above systems, MEND more directly models why actions fail *during execution,* and characterizes failure in terms of operational errors, information errors, precondition errors, and constraint errors. This gives MEND the capability of handling real world problems such as inaccuracies in effectors and sensors.

B. MEND uses a data structure called a failure tree to represent explanations of the failure. From a structural point of view the failure tree is domain independent, and reflects the interrelationships between different steps in a plan. Further, it allows domain-dependent details to be attached to nodes in the tree. This structure should therefore have applicability in characterizing failures in many domains.

C. MEND's domain-independent scheme for failure reason analysis identifies the kind of reasoning necessary for analysis of execution time failures, and shows how this type of reasoning can be incorporated in a computer controlled system that performs tasks in the real world.

D. It identifies the kind of knowledge about the domain necessary for performing failure reason analysis, and suggests how such knowledge can be incorporated in a failure reason model associated with each action.

E. It further shows how knowledge about steps needed to correct failures can be used in conjunction with the results of failure reason analysis to effect recovery by means of very simple planning strategies.

LIMITATION AND EXTENSIONS

Failure reason analysis as it is implemented in MEND can certainly be improved and made more general by including subgoal interaction problems. However, MEND assumes that it has been given logically correct plans and does not need to consider problems arising either from incomplete knowledge about the world or from ignoring interactions in the first order solution to a problem.

Another dimension for improvement in failure reason analysis is in handling mechanism failures. An extension in this direction is possible by using a representation of mechanisms such as the one suggested by Rieger.[12] We could also imagine extending failure reason analysis to handle dynamic worlds, but such extensions are likely to be difficult since we know little about how to deal with activities of other agents who may or may not cooperate in the execution of tasks.

An important problem which MEND does not directly address is that of new information that may invalidate subsequent steps in the plan. Though MEND will fumble along by correcting the failure as it occurs, it is short-sighted in not anticipating failures. Hayes[7] has dealt with this problem by means of a representation of plans which makes explicit the dependency between subgoals and decisions made in arriving at these subgoals.

CONCLUSIONS

The study described in this report has shown that extending the modeling of actions to include a failure reason model allows a robot to address itself more directly to the problem of error recovery. The failure reason model provides a means of representing the knowledge about why actions fail, knowledge about their manifestation, and finally knowledge about what can be done to correct failures.

A specialized technique for performing common sense reasoning, appropriate for planning recovery from failure, is embodied in failure reason analysis. This analysis uses the failure reason model to build a failure tree to represent possible explanations of the failure. Planning recovery from failures by determining the explanation of the failure has proven to be a direct and simple way of handling error recovery, at least in the simple manipulation tasks that have been considered. The effectiveness of this method in more complex problem domains is yet to be investigated and requires a more sophisticated planning ability than the one incorporated in MEND.

Finally, it is important to note that error recovery through failure reason analysis is but one approach to the problem. Another effective approach based on the effects rather than on the causes of failure has also been investigated as part of this study,[12] and can supplement failure reason analysis in planning recovery from failures.

ACKNOWLEDGMENT

I would like to thank Meir Weinstein for getting me started in this area of research, for pointing out the importance of automated error recovery in robot systems and for providing guidance and direction during the course of this work. My thanks to Shriram Udupa and Scott Roth for serving as the sounding board for many ideas and for providing help in topics ranging from implementation details to design concepts. Finally, my thanks to Len Friedman and Bill Whitney for many discussions that led to a better formulation of the ideas and concepts described in this paper.

Design automation

Over the last decade design automation has emerged as an irreplaceable tool for engineering design. The design of today's complex systems such as aircraft, ships, spacecraft, chemical plants, automobiles and computer systems would be unthinkable without extensive computer aids for analysis, simulation and synthesis.

Whereas in the past design automation tools consisted of a collection of loosely connected programs, the current trend is towards an integrated design automation system centered around a common design database.

The last decade also witnessed the emergence of low-cost computer graphics terminals that made it possible to use man-machine interaction in a cost-effective way.

Three sessions explore the various aspects of design automation during this conference. The first session deals with automated design methodologies for large hardware/software complexes. Digital systems have become increasingly complex and new design strategies are required in order to achieve satisfactory designs. The second session deals with the layout of very-large integrated circuits. Due to the explosive development of integrated circuit technology, we are now faced with the problem of efficiently laying out extremely large circuits. The papers in this session explore several ways of solving this problem in an effective manner. Finally, the third session discusses mature design automation systems. In this session we try to look back at some existing systems in order to evaluate their usefulness and impact.

IC design—Misery or magic

by K. J. LOOSEMORE
Pompador Ltd.
Hertfordshire, England

Ever since integrated circuit designers began to put thousands of transistors onto a single chip the cost, in terms of human labor, required to lay out the circuit has been extremely high. If we analyze the layout task we find, in general, that two almost distinct phases are involved. First the designer will design the basic building blocks for the circuit and connect them together. The former of these two phases of design requires considerable expertise and experience, making efficient automation extremely difficult. The second phase, however, only requires lower grade labor, since the efficiency of this part of the layout in terms of size and electrical characteristics is usually less critical. The second phase, none the less, requires a considerable proportion of the design time and it is this fact, together with the need for it to be carried out from scratch for each new design and its lower criticality factor that make it a candidate for automation.

The MAGIC suite of programs has been developed at the UNIVERSITY of EDINBURGH both to address the interconnection problem and to attempt to provide some structuring facilities for the more efficient design of integrated circuits.

The system consists of several programs centered around a main automatic/interactive layout generator. It is this main layout generator which is of most interest but it is worthwhile to give a general description of the rest of the suite in order to see how the system fits together.

The designer begins by taking his circuit diagram and splitting it up into a number of functional modules (e.g., a stage of a shift register or part of a decoder). Specifications for these functional modules are then written in the system's input language. At this stage there are only two requirements, first the rectangular outline of each module must be specified and secondly the positions of the interconnect points (called "pins") to the modules, must be defined. It is not necessary at this point to have the logic internal to the module defined. This is required only at the final output stage of the suite.

Bonding pads around the outside of the chip are designed in a similar manner, however, their positions around the chip are vaguely specified (only side allocations and order are required). These definitions, once produced, would normally be kept in a library file (Refer to Figure 1) and made available for future designs.

After specifying the logic modules the details of their interconnection are defined. For each connection net a list of connections is given and, in order to minimize errors at this point, it is also necessary to include a list of all defined connection points which for this particular design are not connected. This feature allows the program to detect accidental non-connections.

In addition to the definition of the circuit the conductor width must be specified and also an estimate given for the final chip size. When the information is complete the input file and library file are compiled and an internal system file generated from which the layout program will proceed. Because several attempts are normally made to iterate to the best layout, this precompilation phase removes the need for the data to be re-checked for every iteration.

The program builds a chip layout in a series of successive levels working from one edge (bottom) of the chip progressively towards the opposite edge. At each level, an area (slot) at a time is locally optimized; components are chosen for each slot which are most closely connected to the existing portion of the layout and to any other components already selected for the current slot. Placement of components and routing of conductors takes place in parallel allowing a global view of the problem to be used and making it possible to organize the layout very efficiently.

The program begins by taking the estimate of the chip size and assuming a square chip, calculates the side length of the chip. The bottom edge of the chip is then laid down and one of the groups of pads specified in the input file is assigned to this side. The set of pads is allocated by finding the component most closely connected to all the pads then choosing the set of pads most closely connected to this component. This means the first group of pads will, as near as possible, all have a target connection in the first slot thus reducing the amount of routing to successively higher slots until the connection is made.

Once the first group of pads has been allocated, the other groups of pads are assigned to other sides of the chip in the order specified in the input language.

Layout in earnest can now begin. The layout proceeds from this point in a series of rectangular slots, each defined by the lowest level reached in the already completed layout and limited horizontally by obstacles protruding up at either end of the horizontal plateau. (see Figure 2.) Obviously the

first slot is the width of the entire chip and successive slots are generated in much the same way that rectangular stones of varying size are laid when building a stone wall.

An attempt is made to optimize the use of the area in the slot both by choosing the best set of components to fit the area of the slot and by minimizing the amount of interconnection required. In filling the slot with components it is possible to calculate the total width required for a given set of components. This is simply the sum of the widths of the components (with appropriate orientations) and the width required for routing conductors vertically between the components. This latter factor consists of the space required for conductors going straight up through the slot without connecting to anything and the space required for connections to side pins of components. If the order and orientation of the components is well chosen this space requried for vertical routing can be minimized. For instance if a net connects to two or more pins in the slot there are two possibilities; (1) the pins are in different intercomponent gaps, in which case two or more vertical conductors are required and (2) the pins are in the same gap, in which case only one vertical conductor is required to service both of them (see Figure 3).

There are several other features which influence the orientation and ordering of components in a slot. Firstly, it is more efficient, in general, to have components oriented with their largest sides horizontal. This tends to produce a few large plateaus on which to build further slots rather than several small ones thus increasing effective use of area due to reduced fragmentation. Secondly the orientation of components is a critical factor in determining the number of conductor cross-overs required. For electrical reasons it is important to have as few cross-overs as possible so, within the constraints set by the previous requirements the components is a critical factor in determining the number of cross-overs in their connections with the already existing part of the layout. The third factor on which placement depends is the ordering of the components in the slot.

An attempt is made to minimize the horizontal routing required in the slot by taking this into consideration when ordering and orientating the components. There is obviously a trade-off between reducing the space requried for vertical routing and reducing the amount of horizontal routing since

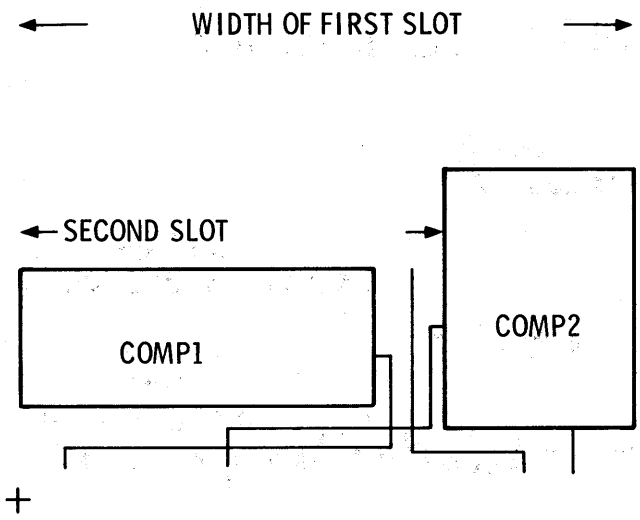

Figure 2

in order to put two pins in the same intercomponent gap it may be necessary to move one of the components further away from its best horizontal position and increase the amount of horizontal routing required.

These processes will have reduced the amount of space required for the current set of components as far as possible. If there is some extra space left in the slot an attempt is now made to find the component which will best use that space. When this operation has been completed the slot will usually be very tightly packed with little unused space. However any unused space is now inserted next to the lowest component in the slot in order to increase the width of what will probably turn out to be the next slot. The x coordinates of the components are now fixed allowing the x coordinates of connection targets to be fixed so that horizontal routing can take place. The y coordinates of the components are left undefined and are only fixed as each component has all routes which need to pass beneath it completed. The component can then be allowed to settle on top of the horizontal routing under it. This delayed fixing of y coordinates is necessary because it is extremely difficult to calculate the amount of space required for routing under a component

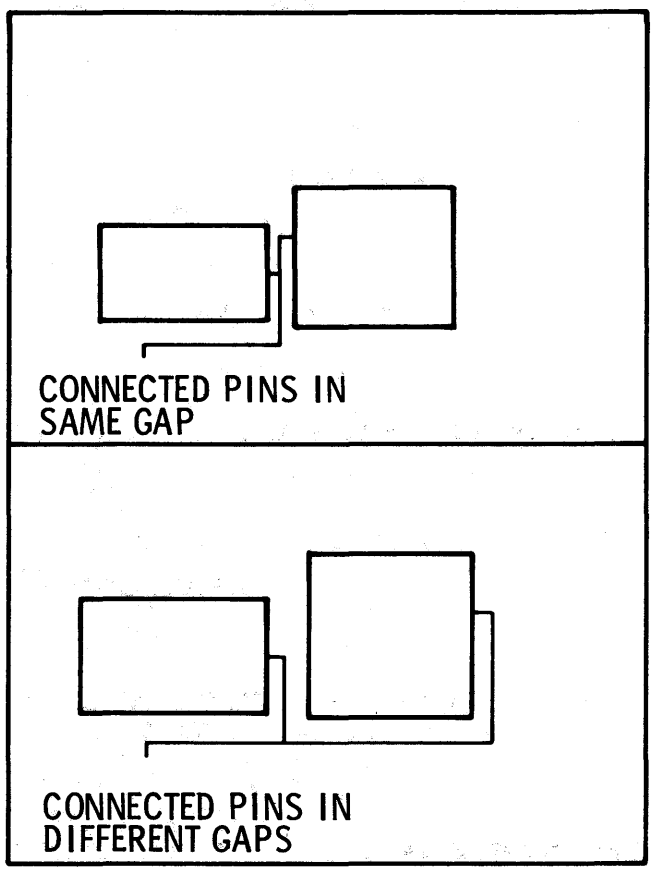

Figure 3

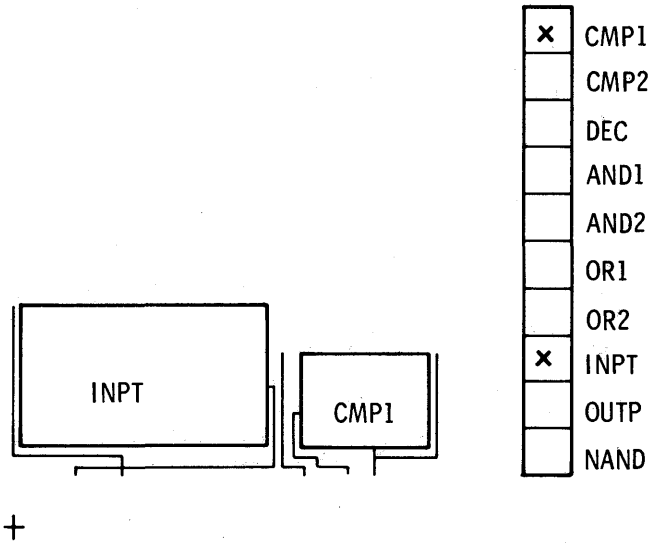

Figure 4

without actually doing it. The next part of the operation is to perform the horizontal routing in the slot. Because all the coordinates have been fixed it is possible to route horizontal segments even though the exact positions of the components are not known. For this routing a system of priorities is used. If there are two or more types entering the slot from below that need to be connected, these are given highest priority so that they are connected as early as possible and do not interfere with the actual intercomponent routing. Next highest priority routes are those which need to pass under components. The effect of completing these is that the components may be placed as low as possible in the slot and take less height. Lowest priority routes are those that only pass from the bottom of the slot to the top, and routes from component sides to the top of the slot. The algorithm operates by performing horizontal routing at increments of one conductor pitch from the bottom of the slot. As many routes and potential routes are completed at each routing level and when no further routing is possible vertical connections are made from the lower ends up to the next level and a fresh attempt is made there. As all routes below each component are completed, the component position is fixed and vertical routing to it is made. In parallel with this activity routes going to the top of the slot for connection in later slots are made and when all the components are fixed and the partial routing completed the processing of the slot is finished. This process continues for all the slots until eventually there will be no more components left to place and all the loose conductor ends will be joined in the final slot. As soon as the layout is finished all the pads are added and an output file is produced containing the details of the layout.

This fully automatic system, when tested on a manually implemented design produced a chip about 1.25 times the linear dimension of the manual design. It was found that there were several instances of awkwardly placed components or densely connected components where the program did not produce an optimum layout. In order to improve the

situation an interactive phase has been added which allows the program and the user to work together. A menu containing the names of all the components in the design is displayed on the right hand side of the display screen on which the design is drawn (see Figure 4). At the beginning of each slot the user is given the chance to choose the component positions and orientations. He may either fill the slot or break off on a partially full slot and instruct the program to fill the rest of the slot automatically or to leave the rest of the slot vacant. Using this facility the program improved on the completely automatic technique giving a result about 1.15 times the linear dimension of the manual layout.

It is worth pointing out the reasons the program does not equal or improve upon the layout produced manually. There are two main reasons. The main one is that the manual designer often designs his components to butt together. The program is unable to detect this fact and will always leave space for, and perform, some routing between the components. Research is under way to test the feasibility of providing some method to butt together some components automatically. In a completely "standard cell"[1] system a different algorithm is used which takes advantage of all the aspects of "standard cells". The second reason why the automatic layout is larger is that designers often generate special versions of modules to fit into local contexts. This has the effect of reducing the amount of connection required had the "standard" version been used. The program, having no knowledge of what is contained within components, is unable to adjust component sizes or shapes and must make do with what is provided. For small numbers of custom designed IC's the design time/chip size trade-off is a good one and will become better for even larger numbers of production units when the new VLSI processes become commonplace and space ceases to be critical.

POST PROCESSORS

The interactive design program produces technology independent output assuming there are two layers available for routing. In order to realize the circuit in the required technology an appropriate post processor is required. Typically the post processor takes the design file produced by the layout program and assigns conductor segments to layers, inserts underpasses where necessary and locates contact windows where interlayer connections are required. It is at this post processor stage that we need to ask the question "What is going to happen to the design from here?" At Edinburgh the design is passed to an independant suite of drafting programs collectively known as GAELIC.[2] The post processor searches the source and library files for the component definitions and extracts from them the details of the internal logic specified in GAELIC manual input language. This is output to a file together with all the interconnections and contact windows in the GAELIC manual input language, thus presenting the GAELIC system with a complete design which looks as though it were produced manually. Using special programs in the GAELIC suite it is possible to automatically generate drive tapes for pattern generators and other mask-making devices. The use of the MAGIC suite of programs in conjunction with GAELIC substantially reduces the time required to design an integrated circuit. Used properly, the system can reduce design time by a factor of ten. This is achieved by storing in the library the complete component specification from the previous circuits; as the library is built up, all that is necessary to perform a new design is to select appropriate items from the library and to specify the interconnections. After this stage everything can be automatic. The chip is laid out by MAGIC and the appropriate GAELIC post processor is used to generate drive tapes for a mask making device. If any interaction is required, the facilities exist, not only in MAGIC but also in terms of the substantial graphic editing facilities in GAELIC.

APPLICATION CONTEXT

The MAGIC suite of programs is applicable to all areas of IC design in which modularity of design exists. Both the rectangular components described earlier and standard cells can be laid out, although the latter layout is not as efficient as if a specialized standard cell program had been used.

The system is most effective when used for irregular designs where patterns are not repeated a larger number of times such as in memory chip designs. In the latter instance, the designer can often produce an optimal circuit design in such a short time that the overhead represented by the extra space requirement using MAGIC is not warranted. The system is applicable to all current IC technologies since sufficient parametrization exists for the details of individual technologies to be included in the design specification. The use of post processors, one for each technology, allows the design to be optimized for each particular technology automatically.

As VLSI techniques become more commonplace the difficulty of laying out a chip by hand is going to be so extreme that unless systems like MAGIC are used, the full potential of VLSI is not going to be realized.

STICKS—A graphical compiler for high level LSI design

by JOHN D. WILLIAMS
Hewlett-Packard Data Systems IC Laboratory
Cupertino, California

INTRODUCTION

The need for good design automation in the area of integrated circuit layout is severe. It is believed that the STICKS system does much to fill that need. STICKS is a computer aided design system which frees the designer from the tedious aspects of IC design and allows him to concentrate on the more creative and necessarily human side of the design process. With STICKS the designer is allowed to divorce himself from the usual precise sizes, spacings, and interrelationships required for an IC layout and, instead, submit his creativity in the form of rough, freehand sketches. The computer makes whatever adjustments are necessary in order to generate an error-free layout. The opportunity is then given to verify and, if necessary, modify the computer's interpretation of the design. An interactive loop is thus formed with the computer doing all of the tedious, detailed work and the human designer providing the necessary inspiration.

Using traditional methods, large scale integrated circuit layout is a tedious, time consuming and error prone process. IC layout is a procedure which results in the placement and interconnection of each of the thousands of components which form the integrated circuit. The designer accomplishes this by drawing several superimposed "mask" layers using a drafting board which together, control the areas where various chemical diffusions and etchings will be made on the silicon wafer that forms the IC. Components such as transistors, diodes, resistors, and their interconnections are formed by various combinations of these masked areas. Unfortunately, the specific sizes of and spacings between components is critical, preventing the designer's job from being an easy one.

There is an overall goal in IC design to pack as much circuitry as possible into a small area. The more circuitry a particular IC contains, the more valuable it is and, consequently, the more marketable it is. The physical size of the chip, however, is a major factor constraining the number of components. Due to a parameter known as defect density, the larger the chip, the less likely it is to work and the more it will cost. Defect density is the number of random material defects per given area which result both from the starting silicon material and from normal losses in the manufacturing process. The solution, one would think, would be to simply make everything smaller thereby increasing component density. Other limitations in the capabilities of the process, however, make this solution impossible. As the components get smaller, the more effect small random defects will have and, again, the less likely the circuits will work.

The absolute minimum sizes and spacings in a layout are embodied in a set of "design rules" which are specific to the particular manufacturing process. They specify in detail the relationships between any two components or, more fundamentally, mask level rectangles. Only when all of the design rules have been met will the circuit be guaranteed to be manufacturable.

It should be understood that the design rules are not necessarily simple width and spacing definitions, they are often dependent upon complex relationships between the mask rectangles and the components intended to be implemented. The number and complexity of the design rules are a major contributor to the difficulties and tedium encountered in the layout process. Each mask rectangle is constrained in two dimensions by several other rectangles on the various mask levels. Indirectly, the placement of every rectangle in every mask is dependent upon the placement of most, if not all, of the rectangles in the entire IC.

The designer approached the generation of the layout by placing the first element and then, sequentially, building elements around it, while trying to leave just enough room for future elements. This is fairly difficult because it is hard to know just how future elements will fit together. The designer generally copes with this problem by adopting a trial and error approach. When the rectangle he is trying to place will not fit without violating a design rule, he must backtrack far enough to correct the problem. This is accomplished by erasing and repositioning any previously placed rectangles which led to the difficulty. Figure 1 shows a simple example of this situation. This particular example is not a serious one but, in actual practice, several hundred structures may have to be erased and redrawn each time a problem of this type occurs. It is virtually impossible for even a highly experienced designer to be able to look ahead far enough in order to avoid having to backtrack.

Traditional layout methods pose additional problems besides those already mentioned. The number and complexity of the design rules make a certain number of design rule violations inevitable. In fact, we have found that approximately ten undetected design rule violations are made for every thousand hand drawn rectangles. This number rep-

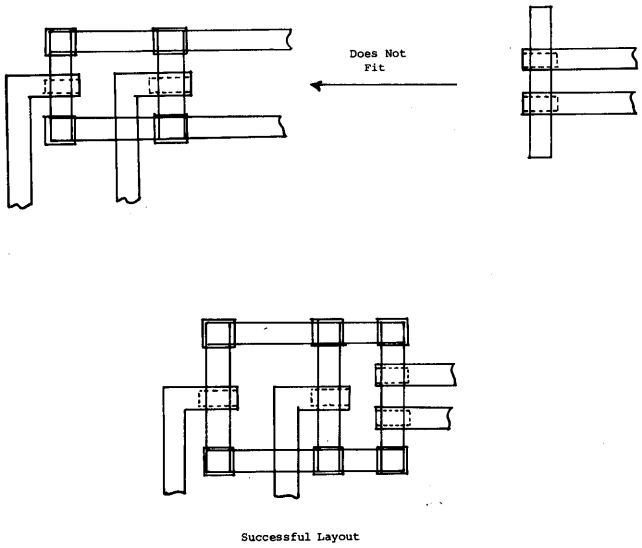

Figure 1

resents only those errors which are found after the layout has been completed. These can have disastrous effects if global design changes must be made to correct them. The problem is that the designer has packed all of the mask rectangles as close as possible together (within design rule constraints) in an effort to maximize circuit density. If a design rule violation is found, it means that the structures were packed too closely together, implying that they must be moved apart slightly. Unfortunately, moving these structures apart would cause additional design rule violations with surrounding structures. The corrections for these errors tend to ripple out to the edge of the drawing, forcing the repositioning of many structures. Since the errors were found only after the entire layout had been completed, thousands of structures could be involved. Then, inevitably, the process of physically repositioning all of these elements could easily produce more design rule violations causing the problem to repeat.

The need to reposition large numbers of circuit elements can also occur when actual circuit modifications must be made such as when logic errors are found after the IC has been fabricated for the first time. This has the same effect as the discovery of a design rule error. Once the layout has been created, it is often very difficult to add any additional circuit elements without moving a lot of rectangles. Again, changes like this are always fraught with the danger of introducing new errors.

With these difficulties in mind, it is easy to understand why layout represents a very costly stage in IC development, both in terms of time and effort.

THE STICK DIAGRAM

The designer's input to the STICKS system, called a stick diagram, is a high level, schematic-like representation of the intended circuit. Circuit elements like transistors, diodes, and contacts (vias) are represented as single symbols instead of as complex sets of overlapping mask levels. Likewise, silicon and metal interconnects are represented by their centerlines. A stick diagram is unlike a schematic, however, in that it includes rough relative positional information in addition to the usual connectivity information. An example of a stick diagram is shown in Figure 2. Like a schematic, the actual distances between the elements in this drawing are completely arbitrary. What is important however, is the relative position between the elements. The fact that a transistor, for example, is "above" a metal interconnect or "somewhere to the left of" a particular diode are the properties which make a given stick diagram unique.

The lack of actual geometrical spacing information is an important characteristic of the stick diagram. In using the stick diagram as a design "language", the IC designer need not worry about the actual location of the circuit elements he places. As a result, his design is nearly as easy to draw, modify, and interpret as a schematic. In fact, it has been found that many designers bypass the schematic entirely and directly translate their logic diagrams into stick diagrams. The use of single symbols for complex structures and centerlines for interconnects as well as the complete absence of specific inter-element spacings makes the stick diagram very fast and easy to draw. The designer does not have to worry about leaving enough room for surrounding structures, there is always room to add them. Unlike designs produced at the mask rectangle level, modifications can be made on a stick drawing without the need for accompanying major global rework. If it is necessary to add a structure, one can always "find" room by simply drawing it smaller and inserting it where desired. Likewise, deleting a structure does not leave a hole since the spacing between elements in a stick drawing is arbitrary.

This arbitrary spacing also means that the designer is removed from the specifics of the particular manufacturing process. He does not have to know what design rules are or where they are applied, nor does he have to know that mask levels like nitride, implant, diffusion, and oversize gate even exist (e.g., a transistor is a single symbol instead of a complex system of precisely aligned, overlapping masks).

The difference between a schematic and a stick diagram (the addition of relative positional information) makes the translation of the stick diagram to a full mask layout a fairly straightforward process. Without this added information,

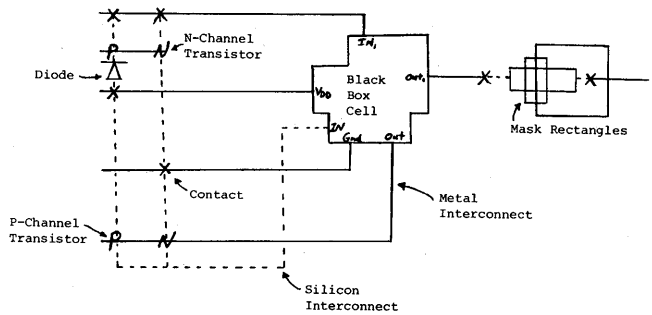

Figure 2

the translation process would have to include component placement; a problem with which computers traditionally have had a difficult time.

The stick diagram is a happy medium between the schematic and the full mask layout. It is at a high enough level to allow the designer to concentrate primarily on the creative aspects of the design yet at a low enough level to completely describe the final geometries in such a way that translation to full mask rectangles can be automated without loss in layout quality.

IC design at the stick diagram level utilizes the capabilities of both man and machine in a very effective way. Humans have very good global perspective; they can look at a drawing and immediately identify how elements should roughly fit together to maximize density. They are very poor, however, at identifying all of the constraints on each element of the drawing and precisely aligning them so that no design rules are violated. The computer, on the other hand, is extremely good at calculating local element separations but poor at making global decisions. By allowing the human to design with stick diagrams and having the machine translate these drawings into full layouts, each is doing what he does best. The human is using his experience and global insight to create the overall plan for the layout while the computer is left to do the tedious, detailed work that it does so well.

In addition to transistors, contacts, and interconnects, the stick diagram may also include mask rectangles and cells (previously designed layouts).

There are two different types of cells available to the designer. The first type, called a "macro," is simply a stick diagram which has been previously stored in a library for future use. When a macro is placed in a stick diagram, it acts as though it had been drawn by hand in its assigned location. It loses any identity it may have once had and, upon subsequent translation to mask layout, is free to stretch, shrink, and mold to its environment depending upon the influenc of surrounding structures. The value of macro cells lies in the ability to pre-define small, commonly used sub-circuits such as gates and flip-flops, eliminating the need for the designer to repeatedly draw them.

The other kind of cell is called a black box cell. It is created by allowing STICKS to generate a layout from a stick drawing (which may, incidentally, contain other black box cells) and then freezing this layout by declaring it to be a new black box cell. This cell may be used in subsequent stick drawings as if it were a logic symbol. It is an outline of the actual layout with labelled ports signifying places where external circuitry may be connected. The cell is also labelled to denote its function. The use of black box cells allows the designer to operate at a higher level than that of transitors and diodes. He can define functional blocks of circuitry and use these in future stick diagrams.

THE STICKS COMPILER

The job of the STICKS compiler is to translate the designer's stick diagram into a complete mask layout which is consistent with design rules. It performs this operation in two main stages. The first stage (called the spacing algorithm) repositions each of the elements in the stick diagram in a way which brings them together as close as possible without violating design rules. The second stage (called rectangle generation) converts the resulting "spaced" stick diagram into a full mask layout.

The spacing algorithm's ability to function properly is due to the fundamental nature of the stick diagram. The stick diagram is composed of relocatable elements wired together by stretchable interconnects. It is this stretchability which provides the added degrees of freedom that are necessary to create an error free design. As long as each element is free to move and any connections to any other elements are infinitely stretchable, a valid layout can be produced. This is true because of the way IC design rules are defined. Design rules prevent any two elements from being too close to each other; all design rules are specified as a minimum distance. This implies that a perfectly valid layout could be produced from a stick diagram with the above properties simply by stretching all of the interconnects so that elements are infinitely far apart from each other. Opposing this philosophy, however, is the desire to maintain the highest possible layout density. The solution then, is to move the elements only as far apart as necessary in order to not violate any design rules. This, in theory, will create the smallest possible valid layout.

The problem, then, is to know in which direction and how far to move each element to produce the optimum layout. The approach the STICKS compiler takes is to divide this two-dimensional problem into two one-dimensional problems. This is accomplished by treating the horizontal structures separately from the vertical structures. In doing so, the algorithm only has to worry about moving each element in one direction at a time. Basically, the spacing algorithm begins by placing all structures which lie on the bottommost horizontal coordinate at the bottom (origin) of a blank work area. The next step is to attempt to place the structures which are on the second horizontal coordinate as close as possible to this origin. This is accomplished by looking up the design rules between the various structures on the two coordinates and deciding where each second coordinate structure must be in order to be as close as possible to the first coordinate structures without violating design rules. The second coordinate structures are then actually moved to these new locations and assigned an actual distance from the origin. The compiler has done two things: it has moved structures relative to each other in a way which tends to increase circuit density and it has also assigned an actual physical vertical spacing between structures.

It should be realized that whenever a horizontal structure is moved to a different coordinate, any vertical interconnections which are attached must be stretched accordingly. This maintains the connectivity of the circuit.

The horizontal pass continues with each subsequent coordinate of horizontal structures moved down as far as design rules permit. When all of the horizontal structures have been spaced, the spacing algorithm is used in the opposite direction. In this pass, the vertical structures are reposi-

tioned while any horizontal interconnects are appropriately stretched.

As soon as both passes have been completed, the designer is given the ability to perform optimization on the stick diagram with the help of the compiler. These techniques will be discussed briefly in the next section. Once the designer is satisfied with the density of the spaced stick diagram, he can ask the compiler to go into its second stage of operation: rectangle generation.

As its name implies, rectangle generation takes the stick diagram which has been spaced to design rule specifications and builds the corresponding mask rectangles. It does this by expanding the interconnect centerlines to their full width and by generating all of the mask rectangles associated with the circuit elements. It also recalls the contents of black box cells from the system library and substitutes the appropriate set of mask rectangles for the cell outline found in the stick diagram. There is no danger of a design rule violation occurring as a result of this procedure since the spacing algorithm took all of this into account when it performed its operation. The product of rectangle generation is a complete mask layout ready to be sent to mask making equipment. Figure 3 shows the results of each stage of the compilation of a simple stick diagram.

One section of the compiler (called the knowledge base) consists of a set of production rules in which are coded the design rules between any two structures. Whenever the compiler is trying to decide how far apart two given structures must be, it consults its knowledge base which, in turn, analyzes the properties of the two structures and reports back the minimum separation distance. Besides the basic design rules, the production rules include additional knowledge which might be called layout heuristics. Layout heuristics are the designer's "tricks of the trade" which he has developed through experience. One example of this would be the fact that a design rule which specifies the minimum separation between two metal interconnects can be ignored if the two structures are electrically connected. In fact, it might be advantageous to completely merge these two structures thus saving area. STICKS has the capability to identify situations like this and make appropriate decisions.

There are several advantages in basing the implementation of the STICKS compiler on the use of production rules. First, the complexity and tremendous number of relationships between IC structures make it very difficult to develop a traditional algorithm which is capable of performing the required tasks. The IC design rules as well as layout heuristics already exist in the designer's mind as a set of rules which are selectively applied whenever the proper circumstances exist. It is natural then, for a computer program to incorporate the same set of rules as its knowledge base. A second advantage is that it is impossible to incorporate all knowledge of IC layout the first time. In fact, it is almost certain that a continuous process of "tweaking" the performance of the system by modifying the knowledge base will exist throughout its usable life. Having to continually rewrite or patch an algorithm is not a pleasant prospect. Modifying a production rule based system, however, means only adding, deleting, or modifying the appropriate rules. Since the rules are virtually independent of each other, this can be done without adverse consequences.

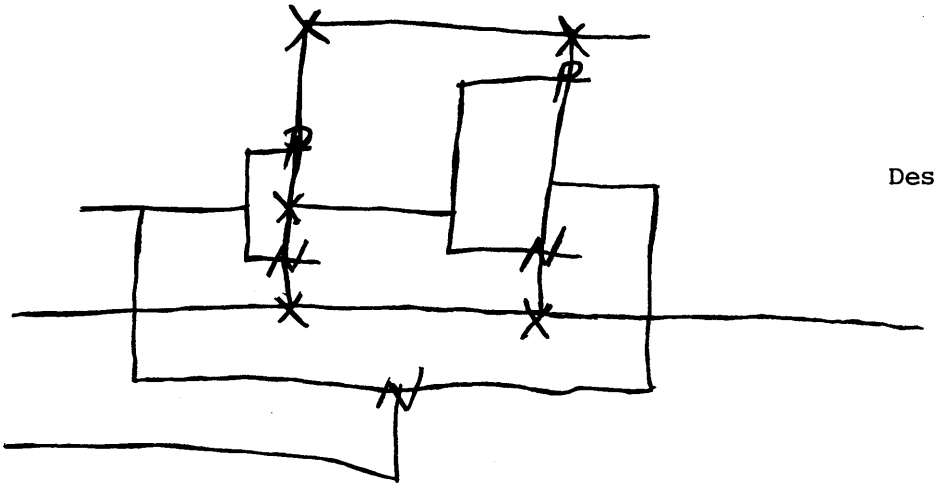
DESIGNER INTERACTION WITH STICKS

An important feature of the STICKS system is that the designer has total control over the quality of the final layout. This control is maintained through several interactive functions which may be invoked after the compiler has performed its spacing algorithm on the entire drawing in both the horizontal and vertical directions. At this point, there are no design rule violations and all structures have been packed toward the lower left corner of the drawing.

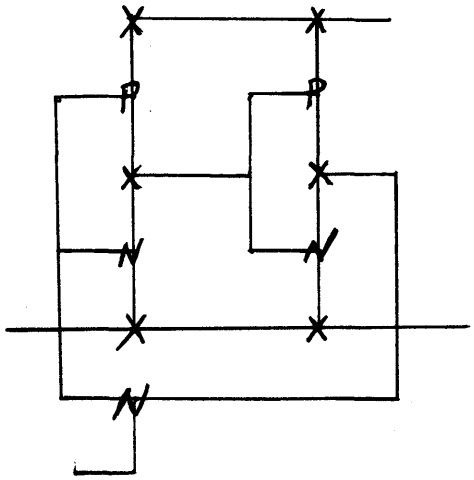
It is likely that this spaced stick diagram will not be as dense as it could be. Although each structure in the drawing will have been positioned as close to its adjacent structures as design rules permit, it is quite possible that unused areas exist. This stems from the fact that the spacing algorithm really is not looking at the global picture. It is assigning minimum spacings between adjacent components but cannot identify the situations when overall density might be improved if a particular local spacing were not set to minimum. This occurs most frequently when compression in the horizontal direction blocks subsequent compression in the vertical direction. Figure 4 shows a very simple example of this situation. In this example, a much more compact layout would have been obtained if the first group of horizontal structures in the center of the drawing had not been moved all the way down to the origin but, instead had been left in its original location. The compiler had no way of knowing this, since it just tries to pack everything toward the bottom left of the drawing. STICKS depends upon the designer to spot problem situations like this and allows him to remedy them through the use of a procedure called local optimization.

Local optimization allows the designer to draw a boundary around any area in the spaced stick diagram and specify a direction in which structures that are included in the boundary are to be respaced. Figure 5 shows how this operation would work to fix the problem in Figure 4. It is done in two steps. First the horizontal group of structures which were originally moved down to the origin are directed to move back up and then the displaced vertical structures are directed to move to the left to fill in the unused area. There is no danger of design rule violations occurring as a result of this procedure since the spacing algorithm always does the actual repositioning of structures. The designer is merely giving it guidance from his global considerations.

A second means by which the designer may interact with the system is through the use of fractures. Figure 6 is a before and after picture showing how fractures can be used to increase the density of a spaced stick drawing. The overall effect of fractures is to allow sections of circuitry which were originally constrained to a particular location by straight interconnects to fill in large unused areas of the layout. The fracture breaks a straight interconnect and allows it to jog in either direction at that point. The designer is actually giving his drawing an added degree of flexibility



Designer Input



Output of Spacing
Algorithm
(Spaced Stick Diagram)

Generation
(Full Mask Layout)

Figure 3

in certain select areas, thereby giving the STICKS compiler freedom to do a better job.

Another problem which can occur involves groups of circuit elements which the designer would like to physically keep together in the layout. It is desirable, for example, to keep all of the flip-flops in a register together in a single row. This is especially important for circuit debugging purposes in the event that the output state of the register must be probed. It would be awkward to search all over the IC for all of the pieces of the register in order to identify its output nodes. This, however, might very well be the case if the spacing algorithm were left unchecked. It has no way of knowing which functional groups of elements should remain together. To prevent the dispersion of such functional groups, the designer is given the ability to enclose all of the elements of the group in a rectangular perimeter called a corral. The corral has the ability to change absolute size; however nothing which is enclosed in it may leave its boundary. This effectively separates those structures from all others in the drawing.

The final way in which the designer may interact with the system is by specifying the absolute micron distance between any two structures in the drawing. This effectively limits the freedom which STICKS has to move structures around, giving the designer considerable control over the

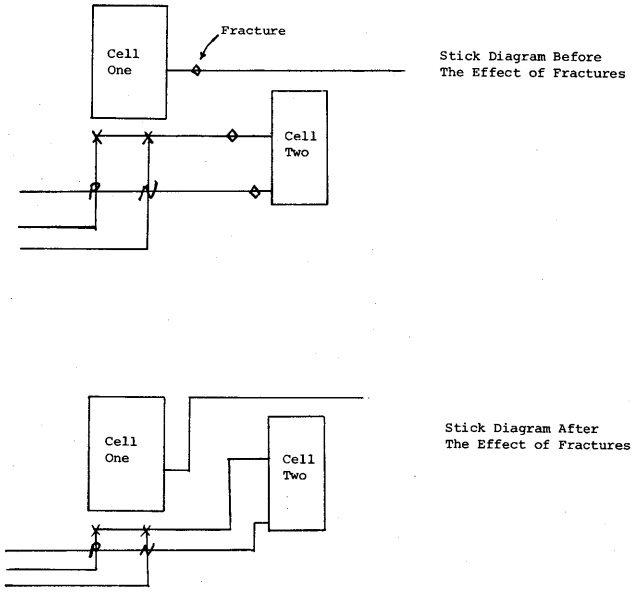

Figure 6

final shape and size of the layout. Of course, there are perils associated with this ability. It is easy to over-constrain a drawing, especially when an absolute constraint imposed by the designer violates design rules. STICKS can identify these situations and inform the designer of the impossibility of his restrictions.

Together, these interactive optimization techniques allow the designer to maintain ultimate control over the quality of his design. This control is believed to be essential in a design automation system of this kind.

CONCLUSION

The STICKS system offers the integrated circuit designer many advantages over traditional layout methods. He designs in a high level, graphical language which is very easy to draw, modify, and maintain. He no longer must worry about design rule violations since it is impossible for him to make any. The layout is built to design rule specifications.

Additionally, the stick diagram possesses a certain amount of process independence. This means that once an IC is designed in the form of a set of stick diagrams, it may be "recompiled" into different mask layouts which are compatible with other manufacturing processes. This feature helps to prevent the obsolescence of expensive IC designs. It is especially advantageous as the original process evolves. The designs can track the process by being recompiled using each new set of design rules.

A final advantage is related to the ease with which the designer can produce a layout. Traditional layout methods are so tedious that even when it is discovered that the layout is poor with respect to circuit density, it is often just too much trouble to do anything about it. With STICKS, on the other hand, the designer is encouraged to try several different layout approaches and try to optimize for density. As a result, it is quite possible to obtain even higher quality layouts with STICKS than with a layout done completely by hand.

Together, these advantages make STICKS an exciting solution to the difficult IC mask layout problem.

A method for the automatic wiring of LSI chips

by NING NAN and MICHAEL FEUER
IBM Corporation
Hopewell Junction, New York

INTRODUCTION

The best known technique for finding a connection between two points is the Moore-Lee algorithm.[1] It is general and thorough, but leads to a long running time. Hightower[2] devised a line-probe wiring scheme which is much more efficient in finding such paths. Variants of this algorithm are probably the most popular means of wiring printed circuit boards at present. However, both of the above techniques suffer from a tendency for the last connections attempted to be blocked unnecessarily by previously wired ones. A more tentative approach to these connections was developed by Hitchcock,[3] whose cellular mazerunner specified connections through cells without fixing their exact location until the end. Schemes which we call line packers for assigning routes to parallel channels have been devised by Hashimoto and Stevens[4] and Kernighan, Schweikert and Persky.[5]

The method described in this paper was motivated by a similar desire to defer final channel selection as long as possible and to give each connnection equal treatment. The method consists of subdividing the wiring space into blocks in a hierarchical fashion, assigning connections to block boundaries by perturbing a global trial solution, mapping the solution to a finer grid and eventually allocating wire segments to channels in the vertical and horizontal directions by linepacking techniques.

The results of an implementation of this method, using a two level hierarchy, have proven very successful in production use at IBM.[6]

THE WIRING PROBLEM

The integrated circuit chip consists of a planar array of devices whose logic terminals (pins) are to be interconnected by metal according to a functional specification. The metal lines are made on two layers separated by an insulating material. In order to maximize wiring efficiency, the horizontal segments of a connection are made primarily on one plane (the horizontal plane) and the vertical segments primarily on the other (the vertical plane). The wiring channels on these planes are organized into horizontal streets and vertical avenues (Figure 1).

In this paper, a net is taken to mean a set of pins which are to be connected by metal wires or those wires themselves. A connection is a pair of pins which are to be interconnected, or the metal path between these pins. A segment is a portion of a net which exists within one street or avenue.

Changing planes can be accomplished by introducing via holes in the insulator between the two planes. These vias are made as needed and are not limited to the fixed patterns typical of printed circuit boards.

HIERARCHICAL GLOBAL WIRING

In the first phase of wiring, the chip is divided into a rectangular array of blocks each of which contains many wiring channels and circuit pins. A straight line segment separating adjacent blocks is called an edge. The function of global wiring is to decide which edges the global nets will cross. Nets whose pins are contained wholly within one block (local nets) are not routed at this phase. For large chips, each block can be subdivided after one stage of global wiring into smaller blocks, and the global solution can be further refined (Figure 2).

Each edge can accommodate a number of crossing wires. This is called the channel capacity of the edge and is largely determined by the number of wiring channels crossed by the edge. Each block is assigned an internal capacity reflecting the ease of wiring past the internal nets or other obstacles within the block. The goal of global wiring is to avoid wiring more nets through blocks or edges than permitted by the available capacities.

PERTUBRATION OF A TRIAL SOLUTION

The global wiring can be done, in principle, by any of the traditional mazerunning or line-probe techniques. An essential advance, however, was made by K. A. Chen[6] and later by J. Lee,[7] which we will call wiring by perturbation from a trial solution. The initial trial solution is built up by wiring each net indepenently. This results in an invalid solution where some regions are over-congested in the sense that wiring demand exceeds edge and block capacity. Nonetheless, this initial solution resembles the real solution much more closely than does a blank wiring image. In addition, the initial solution has the satisfying property of treating all the nets equally.

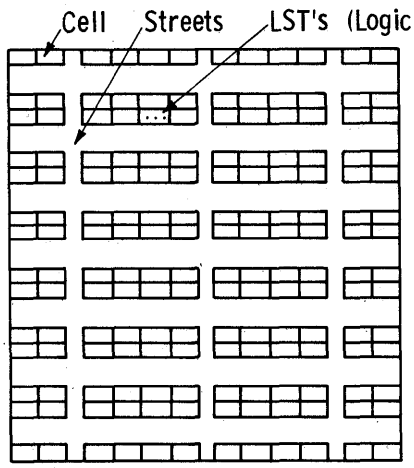

Figure 1—Wiring image

The net configurations, which can be used to build the initial solutiin, vary widely: minimum spanning trees, Steiner trees, biased Steiner trees, chains, source of sink trees, and redundant graphs, such as J. Lee's enclosing grid (Figure 3).

The perturbation consists of moving nets or segments away from congestion peaks. This rerouting can be accomplished by mazerunning, parallel translation of segments or by the deletion of redundant segments. In each case, a net or segment is identified as crossing a congested region and then rerouted in a less congested area at the possible expense of increasing its length.

An illustration of this global wiring procedure on an array of 3×3 blocks is given in Figures 4-8. Each number in Figure 4 represents a pin of a circuit. The same numbers on the chip are to be connected to form nets. All the nets are connected in a Steiner fashion without reference to each other. The initial global solution in Figure 5 is, in general, over congested at some boundaries. The number of nets crossing from one block to another is defined as the *channel demand* at the boundary between the two blocks (Figure 6). Where channel demand exceeds capacity, as outlined in Figure 7, there is clearly a need for rerouting some nets.

The reduction of congestion starts at the worst boundaries. Each net crossing the congested boundary is assigned a weight, which is a function of the congestion in the whole path of the net. The net with the highest weight is chosen first for rerouting. Since only improved paths are accepted in the process, the overall convergence is guaranteed. Figure 8 shows a balanced solution after rerouting.

The process can be visualized as the leveling of hilly terrain by pushing material from hill tops down the slopes. This results in lower and smoother contours with a small increase in total volume of material (net length).

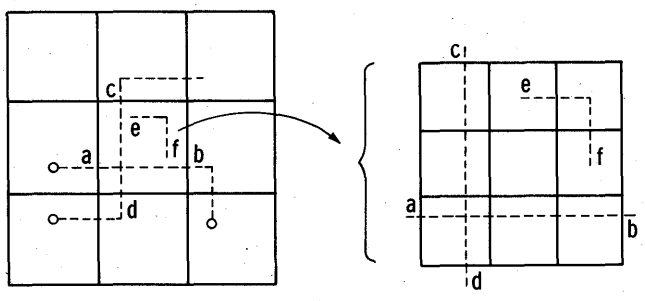

Figure 2—Block hierarchy

PIN SELECTION

During the last stages of global wiring or the early stages of detailed wiring, it is advantageous to reassign nets to pins. The pins to which the nets must attach may often be permuted in small sets without any effect on logical function. For example, the input pins of a NAND or a NOR circuit are all equivalent. The exact choice of these pins has an effect on the number of channels which are available through a block, as illustrated in Figure 9. The objective of the pin selection analysis is to minimize the blockage of the wiring sources.

NET SEGMENTATION

After global wiring, the nets are assigned to certain horizontal wiring streets and vertical avenues for detailed wiring. Each street will contain a number of parallel segments which must be assigned to available channels. The wiring within each street or avenue is dependent on that in all the others. In particular, where a street crosses an avenue, the vertical and horizontal wiring are coupled. Still, this coupling is generally not strong enough to force the detailed wiring to use more channels than would be required for an uncoupled solution.

Figure 10 illustrates the segmentation of a net N, in the vertical direction. X_i's are the net points and a_i's represent the assignment points. After the vertical assignment process, net N is segmented into four independent subnets n_1, n_2, n_3 and n_4.

Figure 11 shows the horizontal segmentation of the same net N. It should be pointed out that only one segmentation is required for a wiring procedure.

CHANNEL ALLOCATION

The most constrained streets or avenues are wired first. The problem consists of a set of parallel segments to be assigned to channels. The constraints come from two sources. The first is that there may be fixed target points (pins) within the street or avenue. The second is that a segment which enters a street, from one side on a specific channel must be wired nearer that side than a segment which enters the street from the other side on exactly the same channel. Constraints of the second kind are called *conflicts*.

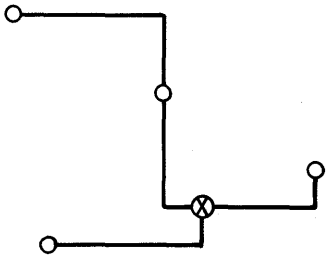
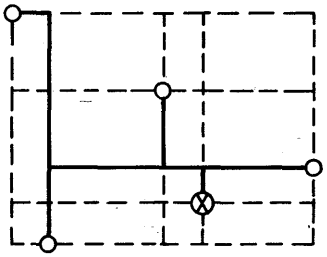
Chain (l=23)



Minimum
Spanning Tree (l=19)



A Redundant Graph

Figure 3—Net configurations

The algorithms used for channel allocation are repeated linear assignment of segments to channels using Munkre's method[8] and an extension of the simple line pack procedures of Hashimoto and Stevens. The former is used when there are pins in the wiring street, the latter when the streets are clear. As mentioned earlier, some pin assignments can be deferred until the channel allocation phase.

An example of line packing in a horizontal street is given in Figures 12 through 15.

Net segments entering a street from above in the same channels used by other segments entering the street from below are in potential conflict. The net segment entering from above has to be assigned to a channel above the one assigned to the segment entering from below. This ordering

relation, (i.e., one segment is required to be wired above another) constrains the linepacking algorithm and, in some cases, leads to a set of constraints which are impossible to satisfy at all. Two such situations, the cyclic conflict and the chain, are illustrated in Figures 12 and 13.

It is clearly advantageous to remove these constraints, if possible, especially to cut all cycles and over-length chains. For this purpose, three straightforward methods are used. The first is to interchange logically equivalent pins of a logic block (e.g., two inputs of a NAND gate). The second is to introduce a short horizontal connection on the vertical plane which had the apparent result of moving the entry point of a segment into the street. The third is to wire a segment in more than one channel. By choosing an uncongested region of the street and dividing one horizontal segment into two segments with a vertical connector, it is possible to wire the two new segments in different channels and thereby satisfy previously impossible constraints. An example of such a solution is given in Figures 14 and 15.

The channel allocation program then scans the wire segments from left to right, filling one channel at a time. When one wire segment ends, the next nearest wire segment is selected to fill out the channel. This selection is conditioned by two considerations: the first is a conflict situation where a candidate segment is required to be above or below a segment which has not yet been wired. If the wiring of the candidate segment in the current channel precludes the wiring of the associated segment in the proper order, then the candidate segment is deferred. The second consideration is the affinity of the candidate segment to the side of the street in which the current channel lies. If two candidate segments are equally suitable from the point of view of linepacking, the one with the greater proportion of connections to that side will take precedence. Figure 16 illustrates the final results for the example shown in Figure 12. A "branch and

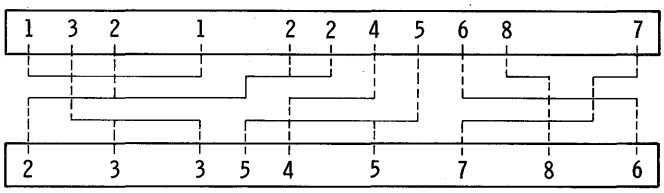

Figure 16—Line pack solution

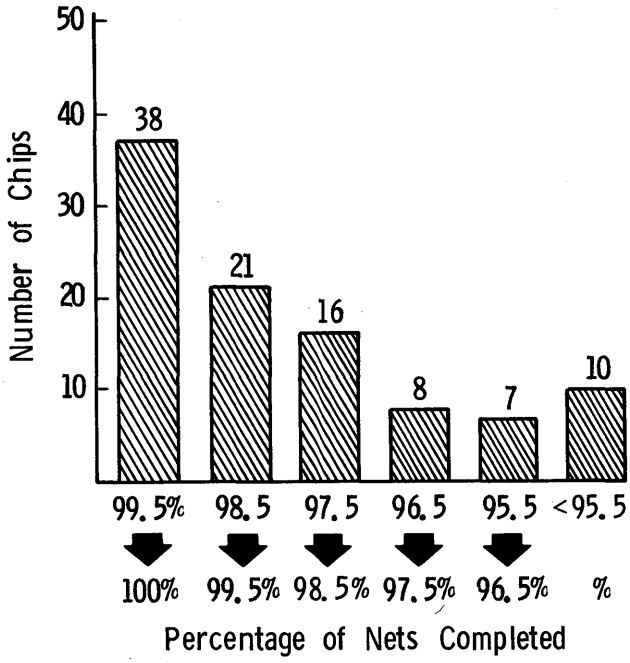

Figure 17—Histogram of completion percentages

bound" treatment of the bilateral channel allocation problem has appeared in the literature.[5]

RESULTS

A version of this method was implemented in 1972 to wire bipolar chips. The results quoted in Reference 6 will be summarized here.

A representative sample of 100 logic chips each containing an average of 125 logic gates and 136 nets. There were 10 vertical wiring avenues with eight channels each and 10 horizontal streets with four channels each. The programs ran in 325K bytes in an average of eight seconds CPU time on a 360/195. The wiring completion percentage in terms of segments, was better than 99 percent. The overall utilization of wiring space varied between 40 and 55 percent of the total length of metal which could be put on the chip.

The wiring programs exist within the framework of a larger physical design automation flow encompassing wirability analysis,[8] partitioning, placement,[9] interactive wire embedding[10] and checking. In almost half the cases, the design is fully automatic (Figure 17). In the rest, the interactive wire embedding program permits a designer to finish the wiring in several hours.

In the years since 1972, thousands of chips have been wired this way. These automatic wiring programs have been a key element in the success of the automatic design system of which they are a part and the chip technology which they support.

A speed-oriented, fully-automatic layout program for random logic VLSI devices

by A. FELLER and R. NOTO
Radio Corporation of America
Camden, New Jersey

INTRODUCTION

This paper describes a low cost, quick turnaround capability for generating high performance, random logic LSI and VLSI devices using the Standard Cell approach. This standard cell approach, described below, utilizes a fully automatic layout capability that automatically maximizes the speed of logic paths identified by the user as critical. In spite of the sophistication and size of the automatic layout program, the system can be run on Midicomputer based systems as well as time shared Main Frame Central systems. During the last 10 years over 1000 custom LSI devices have been fabricated using these techniques.

During this period the basic algorithms used in these automatic layout programs passed through a series of changes due, in no small part, to the needs and demands of a rapidly changing LSI technology. Three fundamental changes occurred during this period.

PLACEMENT, ROUTING, FOLDING PROGRAM

The first was the development of the Placement, Routing, Folding (PRF) program in the 1966-1968 time frame. An early PRF layout is shown in Figure 1. The basic approach used for placement and routing involved the generation of one dimensional geometry. In this algorithm all of the cells were placed in a linear row and optimally placed so as to minimize crossovers and total wire length. Then the array was literally folded by the computer program in a S-type function in order to achieve a rectangular aspect ratio. These algorithms were developed primarily for two phase dynamic PMOS logic.

SINGLE ENTRY TWO DIMENSIONAL PROGRAM (PR2D)

In the 1969-1971 time frame the second major change in the algorithms for the automatic layout programs occurred. This was the development of the single entry two-dimensional placement and routing program developed primarily for static logic. Its first application, and its principal one, was for generating random logic custom LSI devices using the metal gate CMOS bulk silicon technology. An illustration of a chip designed using this approach is shown in Figure 2.

With this program the placement function is based on a two-dimensional pair interchange of cells on the surface. Note, in Figure 2, that except for cells whose input terminals face each other, all connections between cells are routed around the ends of the cell rows in a wrap-around fashion. Because of this routing technique the distance calculation for optimum placement based on the two-dimensional pair interchange concept is based on an end around calculation as opposed to a direct orthogonal calculation.

As shown in Figure 2, significant chip area is devoted to the side channel wiring resulting from the wrap-around interconnections. It is clear that interconnections that passed directly through the cell rows, instead of around them, would result in a smaller, denser, and faster chip. This required far more sophisticated placement and routing algorithms and a more flexible design technique in the layout of the standard cell circuitry. Such an approach was developed in 1973 representing the third major change in the evolution of automatic layout programs for LSI and VLSI devices.

DOUBLE-ENTRY TWO DIMENSIONAL PROGRAM (MP2D)

This new approach is called the Multi-port Standard Cell Approach. This approach uses circuits called Double-Entry standard cells because unlike the previous approaches, connections may be made to these cells at the top or bottom of the cell. Figure 3 shows a silicon gate CMOS-SOS Divide by Two Counter Cell. This approach is particularly compatible with the silicon gate technology. Standard cell families have been developed for silicon gate on bulk silicon as well as sapphire substrates. The most significant advantage of this approach is that it now permits connections between cells anywhere on the chip to be made directly by permitting the connections to pass directly through the cell row. This is demonstrated in the silicon gate CMOS-SOS LSI device shown in Figure 4. Note the significant reduction in the side channel wiring with the resulting improvement in chip den-

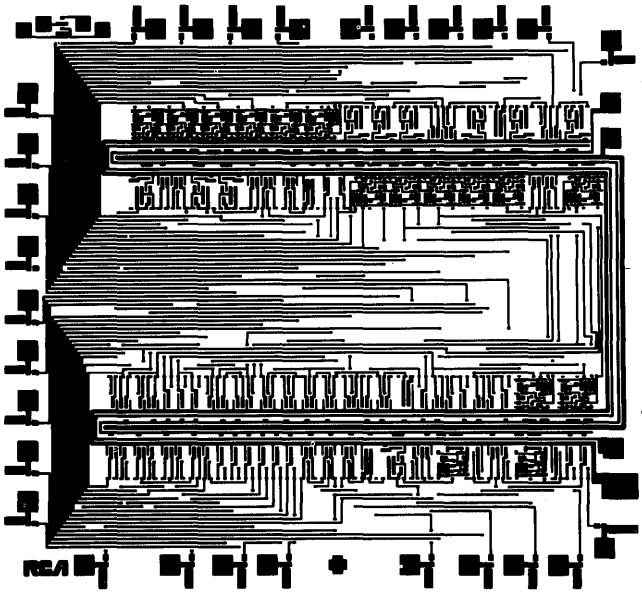

Figure 1—PMOS standard cell array—PRF program

sity and layout efficiency. Since 1973 this approach has been continually improved and is the basic technique that was used in the remainder of the LSI and VLSI devices that will be described or referred to in the remainder of this paper.

APPLICATIONS

Computer oriented applications for which these custom LSI capabilities are applicable include ROM decoders and sequencers, ALU's including special purpose ALU's such as an index register modifier, virtual memory control, dynamic memory management, polling and error detection and correction, general high speed random logic, various I/O functions particularly those associated with I/O computers etc.

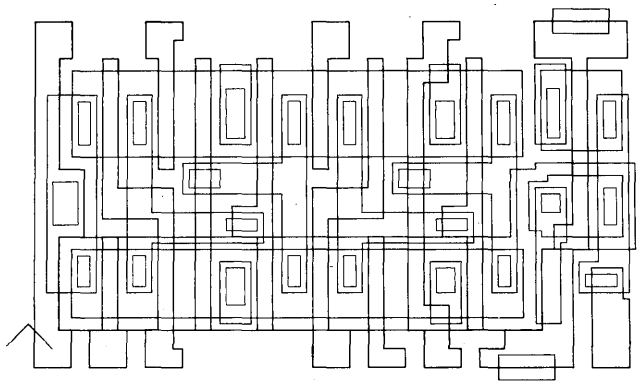

Figure 3—Double entry "divide by two" standard cell

SIMPLIFIED CAD SYSTEM

The block diagram of the CAD system for the Automatic Layout and Checking of LSI and VLSI devices which is shown in Figure 5 is a simplified version of the actual operating system although it does, for the most part, show the principal elements of the system. The only input required for the program is a net list containing some means of identifying the circuit or cell type used and the connectivity. Where there is a speed or propagation delay specification, that portion of the logic so identified will receive, automatically, special attention in the execution of the automatic placement algorithm so as to maximize the speed of those designated circuits.

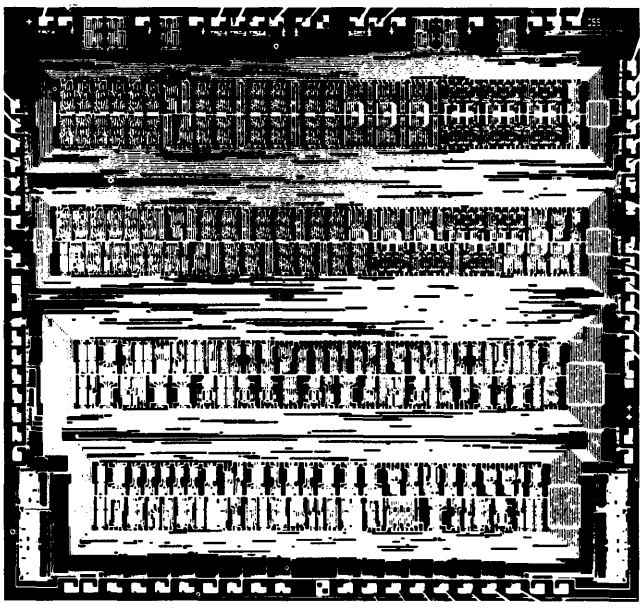

Figure 2—CMOS standard cell Chip—PRZD program

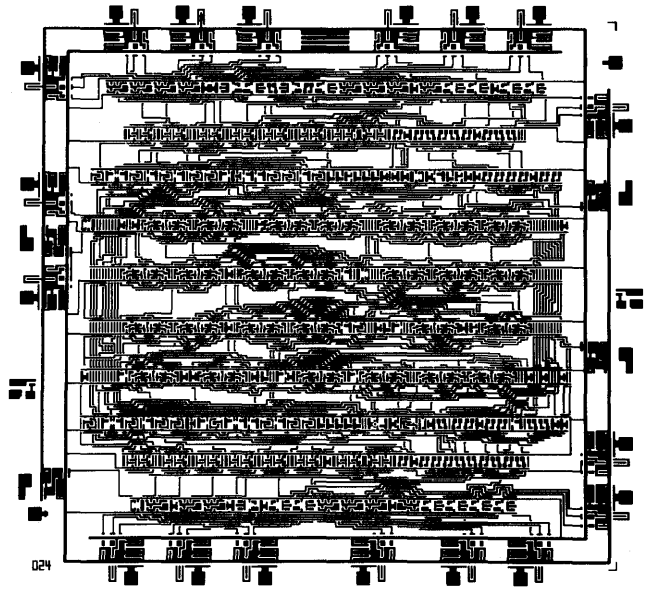

Figure 4—CMOS-SOS standard cell array—MPZD program

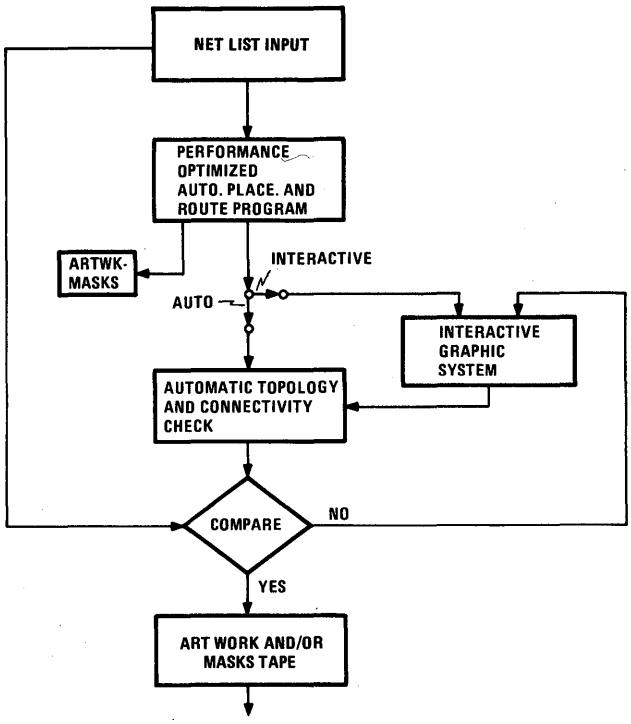

Figure 5—Automatic layout and check system

After the submission of the input data, the chip will be laid out by the Performance Optimized Automatic Layout Program. As shown in Figure 5 the user can exercise one of two options—the Automatic or the Interactive mode.

In the Automatic mode the output of the automatic layout program, as shown in Figure 5, can proceed to the artwork or mask fabrication phase either directly or through a series of topology and logic checking programs. In the interactive mode, the output of the automatic layout program is edited on an Interactive Graphic System (IGS). The designer may choose to edit the automatic layout for a variety of reasons ranging from area optimization to dynamic performance enhancement. The edited layout is then checked for any errors in either the topology or the logical connectivity. After validation, the system will automatically generate a magnetic tape to generate the final artwork and/or working masks.

STANDARD CELL LSI APPROACH

The standard cell LSI approach for generating LSI devices begins with the design, layout, and validation of a group of custom circuits called standard cells. The divide by 2 counter cell, whose topology is shown in Figure 3, is a typical example of a standard cell. Within the framework of the standard cell topology, all the inherent efficiency of a

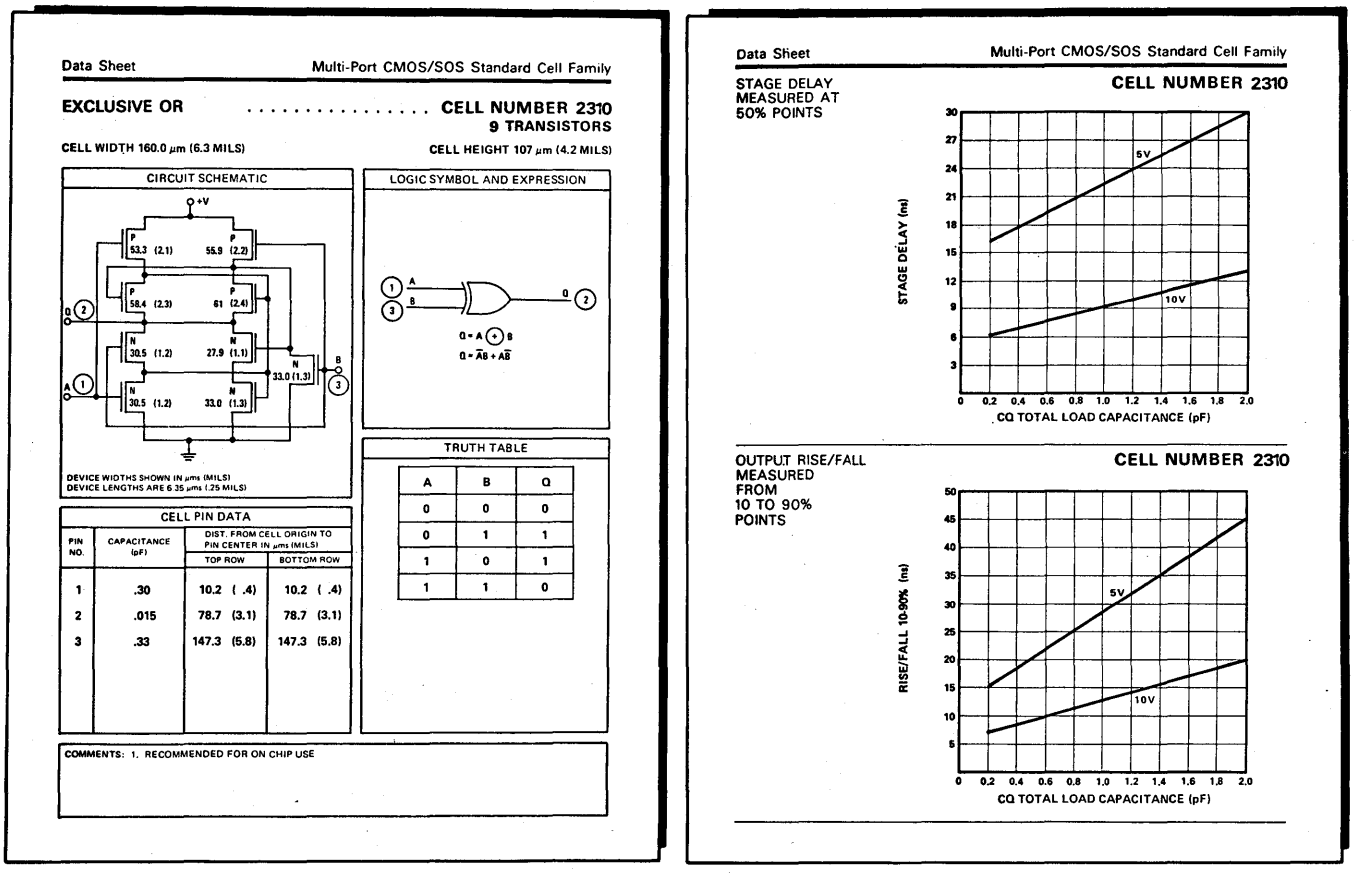

Figure 6—"Exclusive OR" standard cell data sheet

custom design may be incorporated into these individual circuit cells. Once validated, these cells are given an identification or pattern number and permanently stored. To use one of these cells in a logic design, the user calls for these cells by pattern number. To aid the logic designer in selecting the appropriate cells for optimum logic implementation, each cell is completely characterized and documented in standard cell data sheets such as that shown in the exclusive 'OR' function in Figure 6. The computer, under automatic program control, retrieves the cell data from the stored library in a way such that individual cells are represented by a collection of polygons corresponding to the various mask levels. The automatic layout program then places and interconnects the cells in accordance with the prescribed logic function.

DESIGNING LSI DEVICES WITH THE STANDARD CELL APPROACH

Designing LSI chips with the standard cell approach involves only the partitioning of the logic into standard cells, the identification of the selected cells and the generation of the net list or logical connectivity. This input data is expressed in a free-formatted, user oriented language called the Common Data Base specifically developed such that the input data can be programmed by a technician or design coordinator. Normally this is the only input data requirement. If, however, there are specific logical nets or paths whose speed or propagation delay are critical to the proper performance of the chip, such paths are identified in the input data. The placement algorithm will automatically ori-

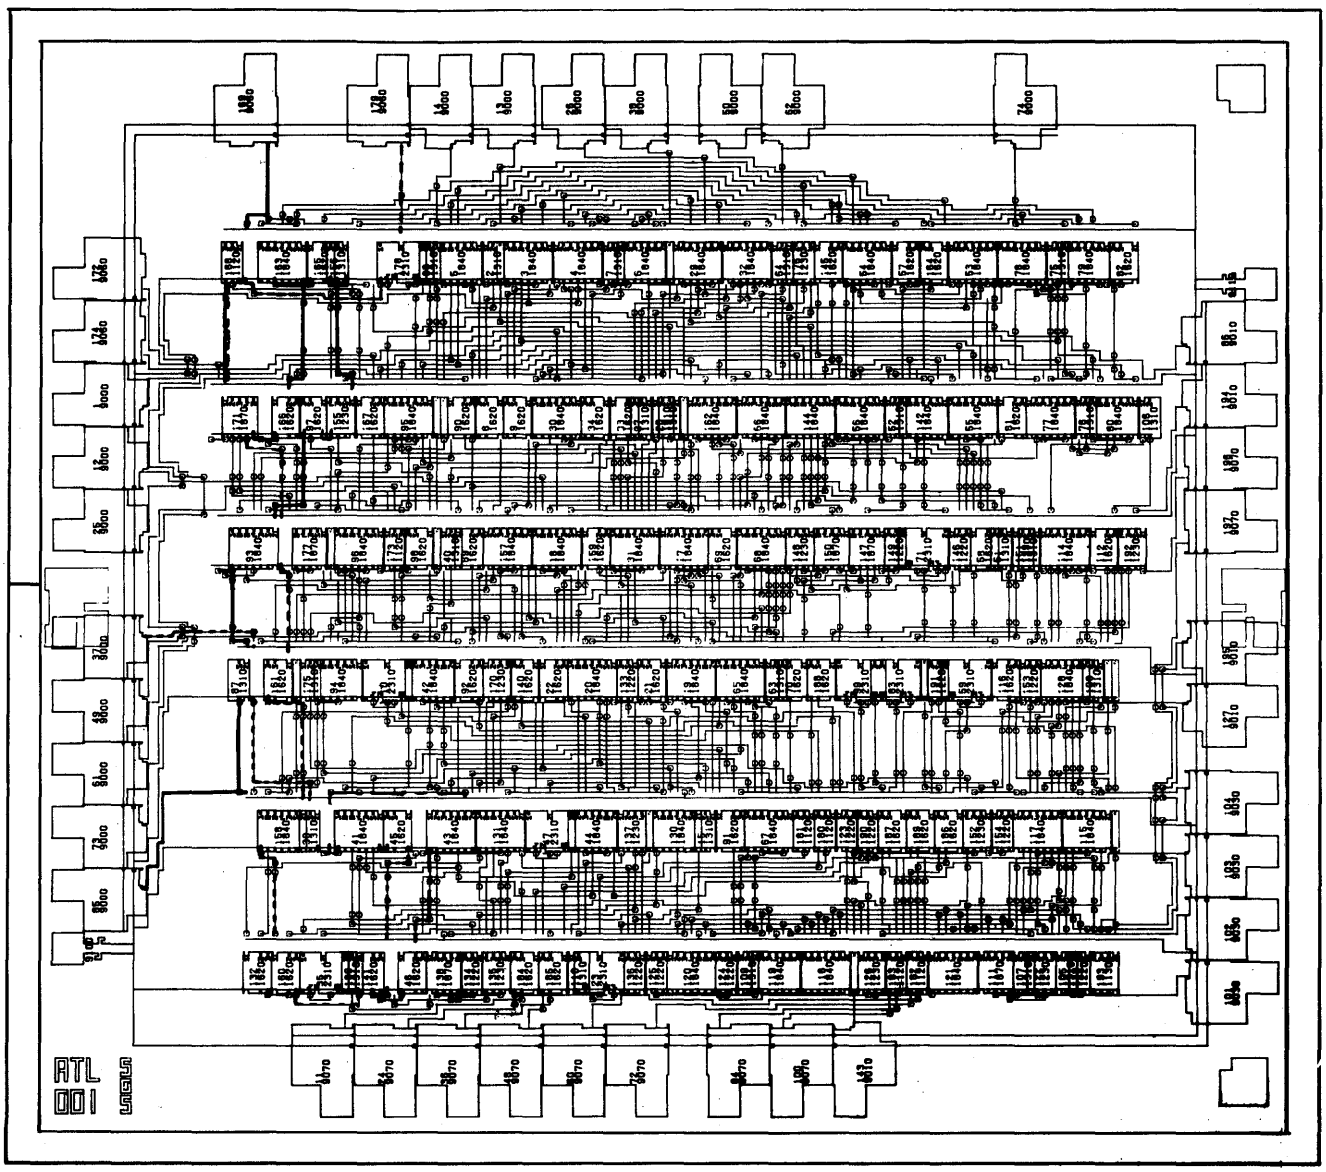

Figure 7—Critical path optimized automatic layout

ent the logic cells of the identified critical paths so as to minimize the delay associated with the interconnection parasitics. This is described in more detail in the following section.

PERFORMANCE AND SPEED OPTIMIZED CAPABILITY

As indicated earlier, a new capability of the LSI automatic layout program is its ability to minimize the propagation delays of logic paths identified by the logic designers as "critical" logic paths. Figure 7 illustrates this principle. This figure shows the computer generated layout of an 8-bit ALU with the critical paths highlighted. The closer spacing of the cells that form the critical paths results in reduced interconnection parasitics and hence shorter propagation delay. In addition to minimizing the delay of the selected 'critical' paths, the program also computes and generates a detailed listing of the parasitic resistances and capacitances associated with the interconnections. In the very high speed MOS technologies, such as CMOS-SOS, these parasitics are a determining speed factor. This information can be used to update the circuit simulation program or the 'race' and 'timing' computations of the Logic Simulation Program.

TABLE I—Improvement in Automatic Layout Program

Year	Size (mils)	Area ($mils^2$)	Density ($mils^2$/device)	Computer Cost	
				Minutes	Dollars
1974	146 x 121	17,666	18.2	Not Available	Not Available
1975	129 x 120	15,480	16.0	13.4	344
1976	115 x 111	12,765	13.2	5.4	132
1977	100 x 117	11,700	12.1	Not Available	Not Available

DENSITY AND EXECUTION TIME

In absolute terms substantial improvement has been made in increasing the density and reducing the execution time of automatically laid out standard cell LSI devices. This improvement in the speed and efficiency of the automatic placement and routing program is shown in Table I. Table I

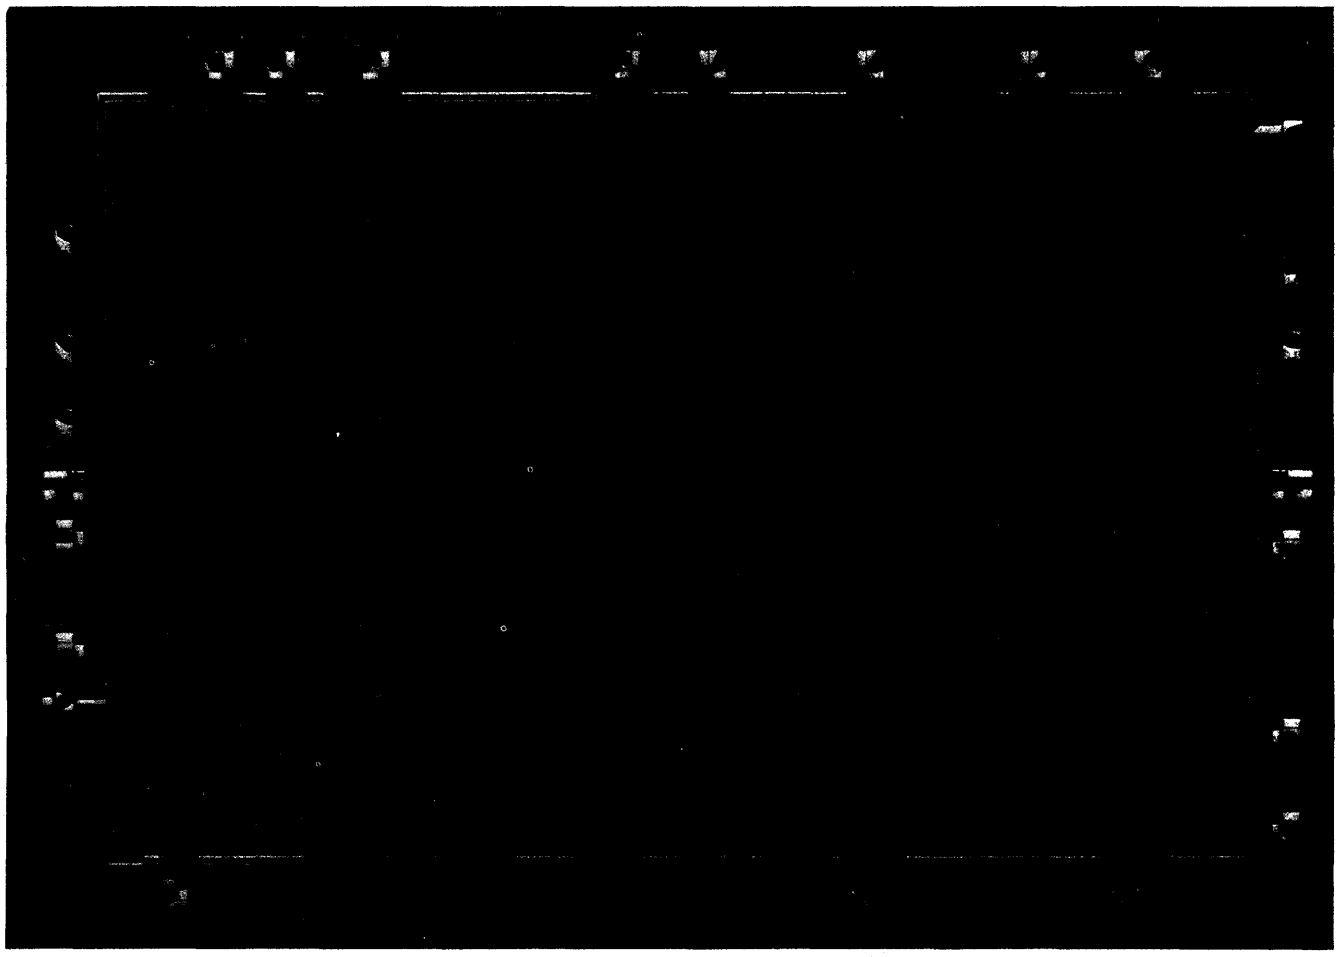

Figure 8

	AVERAGE GATE DELAY (nsec)				TOTAL INPUT TO OUTPUT (A to B)(nsec)				MAXIMUM COUNTER OPERATING FREQUENCY (MHz)			
	5V	10V	12V	15V	5V	10V	12V	15V	5V	10V	12V	15V

*EXTRAPOLATED

Figure 9—CAD generated LSI performance

shows the reduction in area (or increased density) and reduced execution time associated with the layout program since 1974. As shown in the table the area of the chip was reduced by 33 percent, while the execution time was reduced by 60 percent. These improvements are due entirely to improvements made in the efficiency of the placement and routing algorithms. The LSI device used as the test vehicle in Table I is a random logic device which is generally the type selected for implementation by the standard cell LSI automatic layout approach.

LSI AND VLSI APPLICATIONS

LSI application

Figure 8 illustrates a recent LSI application of the standard cell approach using the CMOS-SOS cell family. This chip, which was laid out with the automatic layout program, with virtually no manual editing, contains about 550 gates (2200 transistors) and has a chip size of 235×166 or about 17.65 square mils/device. Note that virtually all interconnections between cell rows pass directly through the cell rows. There are two basic methods which the layout program automatically uses in interconnecting cells on non-adjacent rows. If in a particular row there is a cell which is part of the same node or net as the source gate the program will use the polysilicon gate of the cell as a means of crossing the cell row. In this case, the polysilicon gate serves a dual purpose—that of a control element and a means of crossing a cell row. If there is no such cell on a particular cell row, the program will automatically move the cells in the appropriate area and provide a feedthrough cell to cross the intermediate cell row. As shown in the figure considerable area is associated with the large tristate drivers and protective devices in the pad area around the perimeter of the chip. The active area of the chip, essentially contained within the two parallel bus lines around the inside perimeter of the bonding pad area, measures about 202×132 square mils or about 12 square mils per device.

Although this chip is essentially a random logic device, it does contain sequential circuits such as ripple counters. Figure 9 shows the ripple path through a six stage counter in a form in which the path was analyzed by a circuit simulation program. The table in the lower half of Figure 9 gives not only the measured performance of this portion of the chip, but also the correlation between measured and computed performance. For example at 10 volt operating level the average predicted stage delay, based on conservative model parameter values, is 6.2ns while the measured average delay is 4.9ns.

VLSI applications (ATMAC microprocessor)

Two of the VLSI (>1000 gates) devices generated by the Standard Cell Automatic Placement and Routing program are shown in Figures 10 and 11. In addition to illustrating the VLSI capability of the standard cell approach, these chip types, which form the basic chip complement for a high

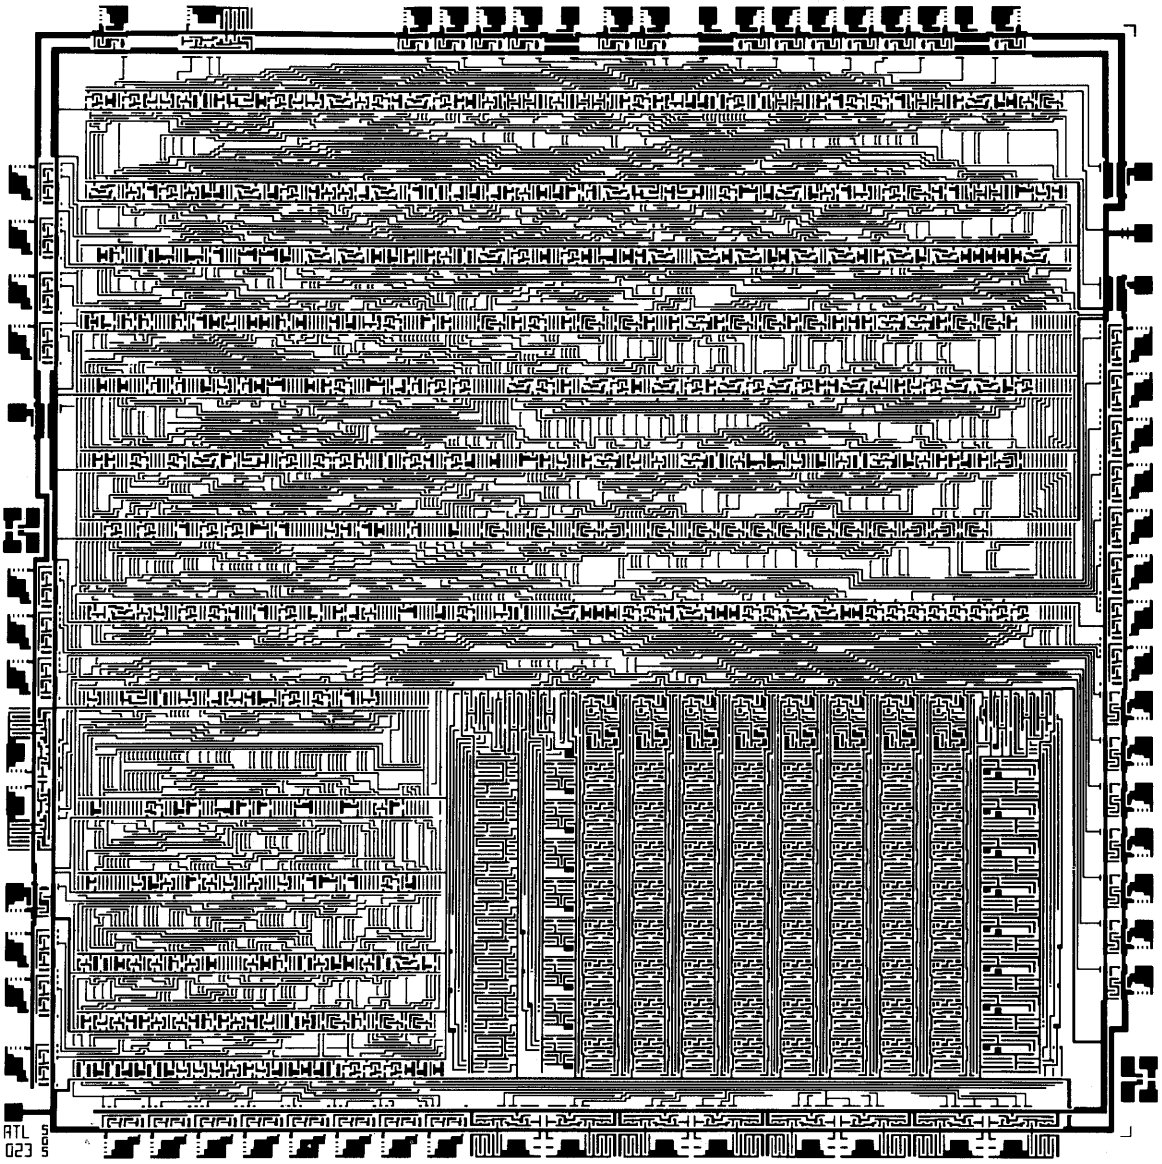

Figure 10—VLSI CMOS-SOS microprocessor chip #1

performance CMOS-SOS microprocessor, the ATMAC, were selected because they both illustrate a new capability of the Automatic Layout program called the Subchip Option. With the subchip option the program will accept a functional design, which may have been remotely designed by conventional manual techniques, (this includes designs on interactive graphic terminals) and automatically make all connections to it while simultaneously laying out the remainder of the host chip. The subchip option recognizes that certain logic configurations, such as memories, registers, counters, ROMs, and PLA's characteristically are regular and repeatable structures with a relatively simple interconnection matrix. As such it is not excessively costly and time-consuming to achieve a high density layout using conventional layout techniques as would be the case for complex, random logic devices.

The net effect of incorporating the subchip option into the standard cell automatic layout problem is to combine into this computer aided design capability the high density and optimization associated with handcrafted design devices with the low cost, quick turnaround capability associated with automatic layout programs such as the standard cell automatic placement and routing capability.

Each of the VLSI devices shown in Figures 10 and 11 contains about 5000 transistors, the equivalent of 1250 gates. Each chip contains both random and regular logic. The Data Execution chip, which performs the arithmetic processing and contains the data portion of the microprocessor, in-

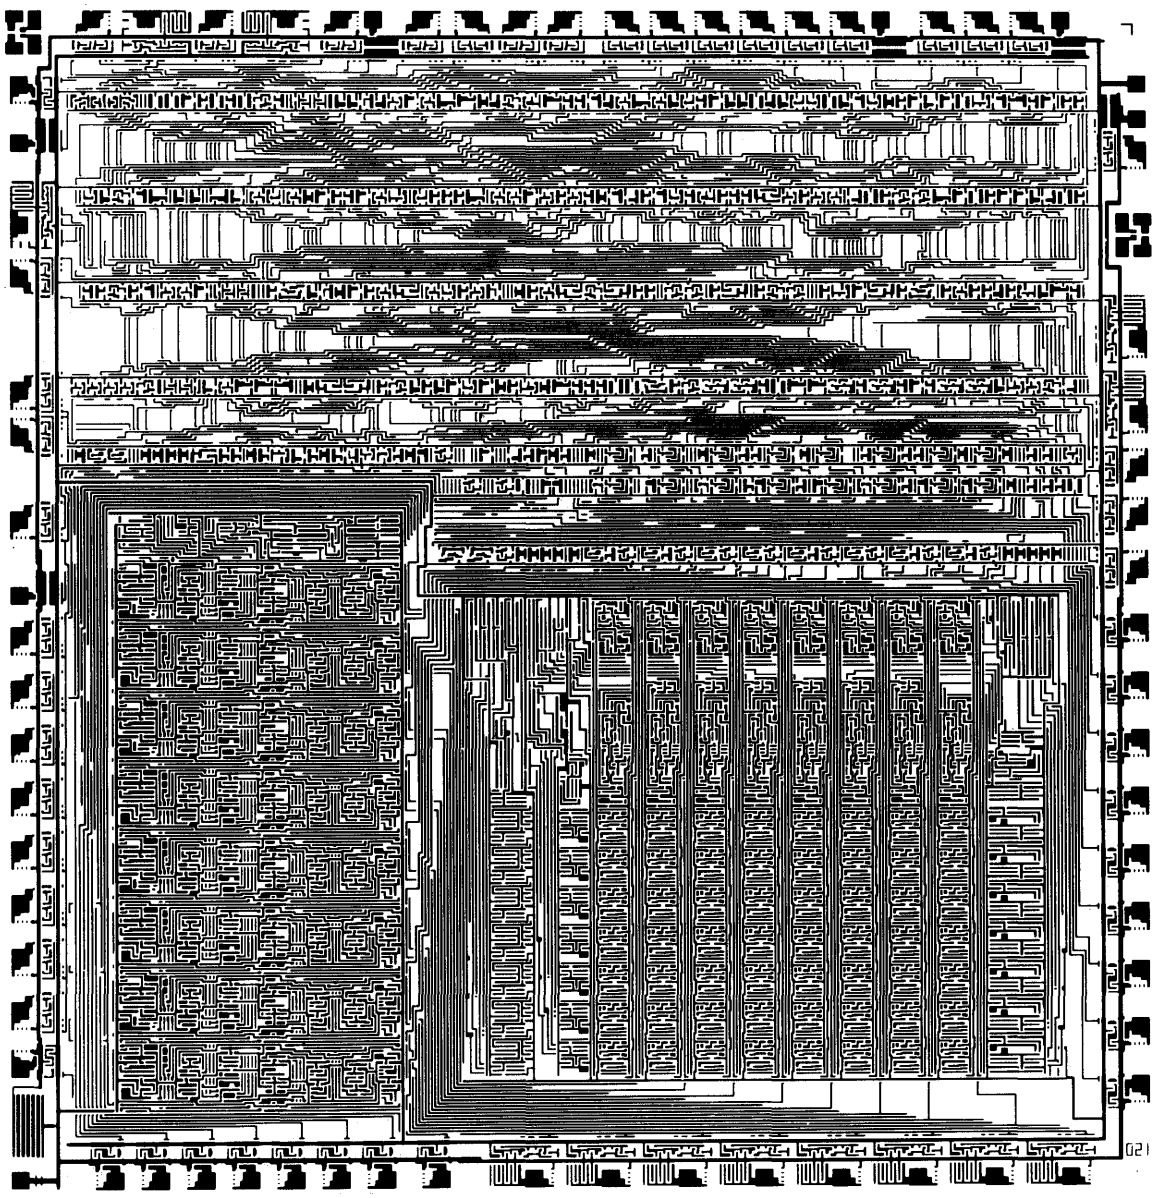

Figure 11—VLSI CMOS-SOS microprocessor chip #2

cludes one subchip function, an 8 word by 8 bit register stack. This function contains about 1200 transistors. The remainder of the chip, the random logic portion, which contains about 3800 transistors, was fully and completely laid out by the automatic layout program.

The other microprocessor chip, shown in Figure 11, is the Instruction and Operand Fetch (IOFU) chip, which functions parallel to the Data Execution chip. It is the control element of the system and operates control timing, program sequencing, operand accessing and array address updating.

As shown in Figure 11, this chip contains two subchip funcitons. Although one of these subchips is an 8×8 register stack, it is a different design from the one in the data execution chip. The other subchip is a 4 word by 8 bit Last In First Out (LIFO) register stack. Together these two handcrafted custom designs contain about 2000 transistors. The remainder of the IOFU chip, which contains about 3000 transistors, was automatically laid out and interconnected by the automatic layout program which automatically and simultaneously made all interconnections to the subchip functions as well.

The block diagram for this two chip 8 bit modular and expandible microprocessor is shown in Figure 12. It complements the CMOS/SOS technology with advanced parallel architecture to optimize its performance in signal processing applications. Its high speed/280 ns and 350 ns instruction times is enhanced by many architectural and programmable parallelisms that provide an effective throughput of greater

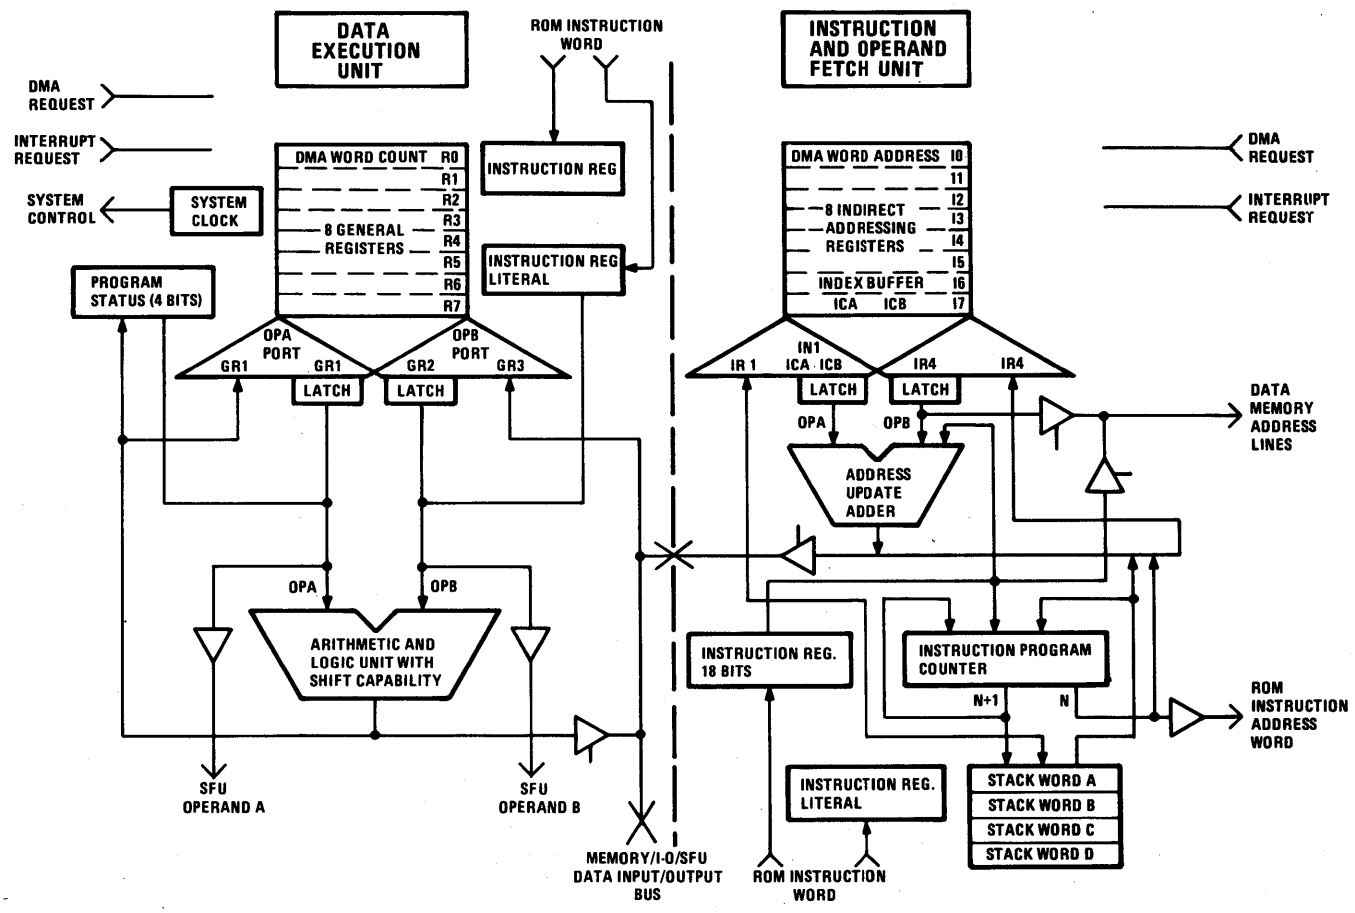

Figure 12—CAD generated CMOS-SOS microprocessor block diagram

than 10 million instructions per second in many array-type computations.

CONCLUSIONS

Because the standard cell approach for generating random logic custom LSI and VLSI devices is based on a completely automatic layout capability, it has proven to be a low cost, quick turnaround means of generating random logic custom LSI and VLSI devices, particularly for the larger and more complex devices.

With its low design cost and quick turnaround capability established, emphasis during the last few years has focused on improving its high speed performance. Two major improvements were made in the program affording higher density. One was improved placement algorithm that has resulted in a 30 to 40 percent improvement in density. The other was the introduction of the subchip option which combines into the standard cell approach the high density and custom optimization of handcrafted custom approaches with the low cost, quick turnaround capability that characterize the automatic layout capability.

A methodology for design of digital systems—Supported by SARA at the age of one*

by GERALD ESTRIN
University of California at Los Angeles
Los Angeles, California

INTRODUCTION

There are many practical forces at work which encourage improvement in design methods. "Structured programming," "hierarchical design" and "modularity" are terms which have become commonplace. However the frequency of their use does not mean that design methods now exist which can guarantee that a particular complex system, whose programs are shared by many users, will have no design errors. Nor do design methods yet exist which can guarantee that a digital system, "simple" enough to be integrated into one device and reproduced in the millions, will have no design errors. It is well-known that almost all digital systems have so large a set of possible sequences of states that great ingenuity must be applied to achieve any meaningful degree of partial verification of their behavior. Theoretical advances continue to be made in verification. Those deriving from concepts of abstract data types[1] are incorporated in new languages[2-4] and have a lasting influence on the way we think about systems.

Despite those advances it is a source of great embarrassment to computer architects that semiconductor technology has created a capability which we cannot now exploit with proven design methods. A number of interesting approaches to design of concurrent systems are being actively pursued. However we do not currently have the languages, operating systems and design methods needed to effectively employ the new LSI devices which can now be produced. We would like to be limited only by economic factors, not technical or theoretical factors.

One hope is that there will evolve effective methods for composing such systems from defined, well behaved building blocks whose composite behavior can be shown to meet prestated requirements. A second hope is that starting from well formulated requirements and an initial abstract solution system, there will evolve helpful guidelines for structural partition and effective algorithms for behavioral refinement. The refinement procedure should conserve desirable properties through as many levels of abstraction as the design needs. A third hope is that a new dimension for architecture of computer systems will emerge from these design methods and permit us to effectively use the outpouring of large scale integrated devices.

Realization of these hopes and their joint use are the goal of the methodology discussed in the first part of this paper. The second part of the paper describes the state of the system implemented to support a designer attempting to use the methodology. A companion paper[5] illustrates application of our methods to design of software.

The System ARchitects Apprentice, SARA, is only one year old. The roots of this work were reviewed in short by the author in one of a set of presentatons[6] which announced SARA early in 1977.

We are not so simplistic as to think that we have THE only right way to design computer systems. We do feel that our methodology makes some significant advance in approach to design of concurrent software and hardware systems and has great promise for incorporation of previously verified models of software or hardware systems. In fact it has long been recognized that methods for design of concurrent systems are also important to good sequential system design. The models used to represent desired concurrency can also be used to model a set of processes which are mutually independent. Sequence can then be imposed on them after appropriate analysis rather than by chance.

As verification methods become more effective and succeed in avoiding combinational explosion[7] we hope to combine them with the UCLA design methodology and move closer to effective use of semiconductor device capability.

The UCLA design methodology

We tersely characterize the UCLA design methodology as being requirement-driven and supportive of self-documenting design of modular, concurrent, hardware and software systems. Figure 1 displays a high level flow chart of the design procedure. We will proceed through each step discussing what is done with particular attention to implied analysis or value judgments made outside of the stated procedure. In this first part of the paper the reader need make no assumption about the nature of automation aids but rather should focus on the systematics.

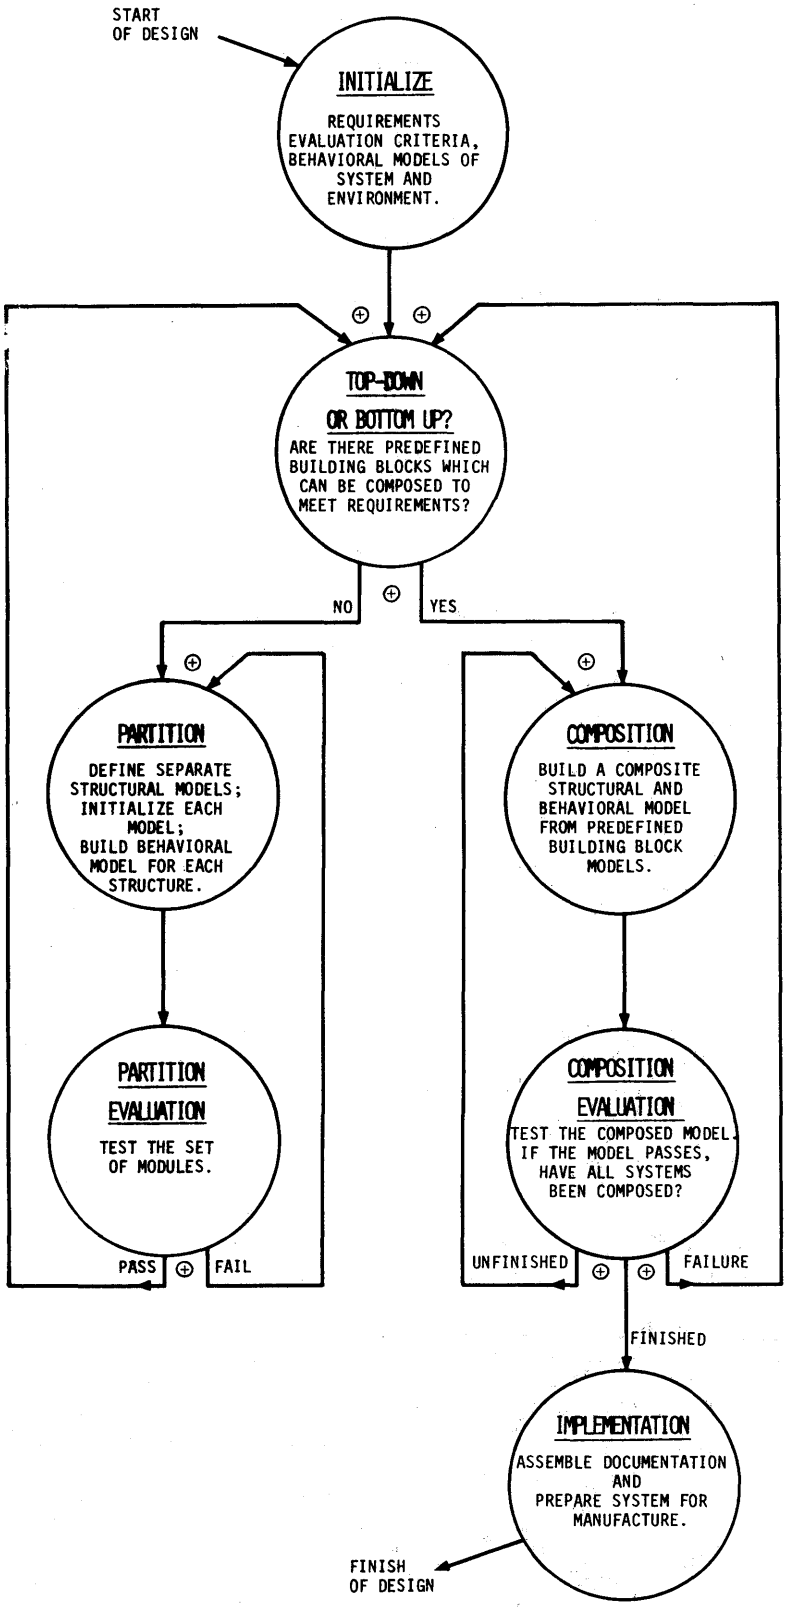

Figure 1—UCLA design methodology

Initialization of a design

This design methodology is characterized as requirement driven. Given a set of requirements and assumptions about the environment, the designer conceives of a system to satisfy those requirements. The bulk of our discussion is about a procedure which develops sufficient detail about the system behavior to determine which of the requirements are not satisfied.

Requirements are not God-given and there continues to be extensive study of disciplined analysis techniques[8,9] leading to well formed requirements. When design costs get too high it is often necessary to reconsider the requirements themselves. For purposes of this paper we will assume that requirements have been carefully generated and that we are to make our best effort to design a system which satisfies them. It is generally recommended that requirements be made at a sufficiently abstract level that they do not prematurely commit to particular implementation methods. However, many designers make certain implementation decisions early for practical reasons. For example, a manufacturer may restrict implementation to a small prescribed set of well tested, well understood building blocks, in order to minimize inventory and training costs. These must then be carried through the rest of the design process and not be compromised.

Requirements fall into different classes with respect to their use in this design procedure.

Some requirements carry quantitative design constraints, such as real time response to a stimulus, which lead directly to use of analytical methods or to generation of experimental tests. These are the most straightforward requirements to deal with, with the exception of two problems:

- A numerically stated requirement often implies more precision than was intended and it is sometimes tedious and difficult to introduce tolerances or to manage tolerances during evaluation.
- When a high level system design is partitioned it is necessary to determine the set of subsystems which are involved in satisfying a quantitative requirement and, where possible, to estimate a new quantitative subrequirement for each subsystem. Such estimates can turn out to be quite arbitrary and to produce undesirable distortions of the design. This is a poorly understood art.

Many requirements are qualitative. In some cases their satisfaction is determined by delegating the responsibility for judgment to individuals who can then record approval or disapproval. In other cases qualitative requirements are simply passed on to the fabrication phase because they cannot be evaluated until manufacture. Qualitative requirements deserve careful attention because they are often the focus of user dissatisfaction. When tradeoff analysis can be made to show optimality of a design response to a qualitative requirement it can save a great deal of misunderstanding and expense.

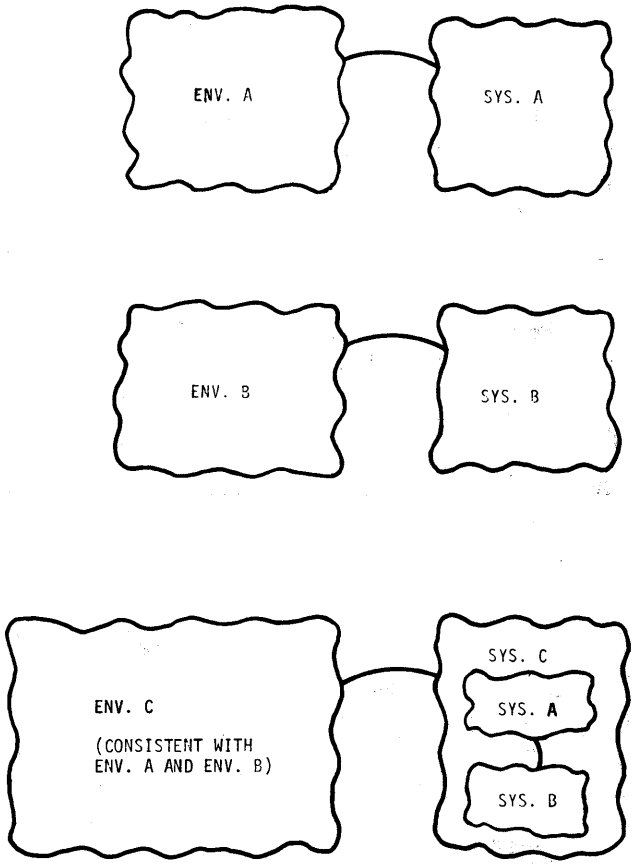

Figure 2—Composition of systems and environments

An integral part of our design methodology requires initial behavioral modeling of the system under design and its assumed environment. The environment model displays only those properties necessary to constrain the system design and is constructed using the same primitives as those used for models of systems being designed. Therefore when two independent designs are composed, a designer must test the consistency between each subsystem and the others' environment, as informally shown in Figure 2.

Partition or composition decision

The decision to compose a model of the system directly out of predefined models or to go through another stage of top down partition depends upon the availability of predefined building blocks and the designers understanding of their behavior. A designer may have a number of building block models, which seem to fit a particular design jigsaw, but be missing one type of building block. Rather than pass through a uniform top-down partition, which always entails some overhead, the designer may choose to move aside into

an independent design phase. There the designer would establish requirements for the new building block, successfully complete its design and validation using existing building blocks, and then return to complete composition along the original design path.

It is of value to add to our intuitive acceptance of what building blocks are by the following definitions:

By building blocks we mean physically realized systems with:

—constrained environments, and
—predictable input-output behavior,

such that, given:

—two or more such compatible systems, and
—connectivity constraints between them,

then the combined input-output behavior is predictable. Whenever a combined system is also a building block we call it well behaved.

Building block models are representations of building blocks if:

—each model has one or more defined physical realizations satisfying the definition of a building block, and
—when building block models are interconnected consistent with interconnection constraints, then combined corresponding physical realizations form a physical realization of the combined model.

Composition

In the composition step the full set of selected building block models in interconnected—to each other and to the assumed environment model. Attributes, associated with the inputs and outputs of each building block model, provide the basis for consistency and completeness checks. These checks must include an environment check as noted above for Figure 2. The complete model is then analyzed or experiments are conducted in a simulation environment.

If implementation decisions have not been made earlier they are introduced in the composition step building block models.

Composition evaluation

The evaluation step consists of a combination of analysis and experiment. If the behavior of each building block has been verified, it may be possible to verify a system requirement which has been formally stated. For example, if one of the requirements states that a concurrent system must satisfy "proper termination" then it is possible that analytical tools[10,11] can be used. More generally the designer will generate experiments in a simulation environment and choose the most stressful conditions for test.

Partition

A partition procedure is used when a set of requirements cannot be met directly by composing known building blocks. There are different strategies for guiding partition of a system into subsystem modules.

- Parnas[12] has noted that modular decomposition may be done according to independent user functions which need to be implemented or according to system functions which are needed in carrying out every user function. The former approach may make mapping of requirements more direct. The latter approach generally leads to better utilization of shared resources.
- One module may be separated from another because both design and observation of the included operations are considered vital to performance, reliability or cost. The module is a system element which is most easily observed because its interface with the outside is made explicit.
- A set of modules may be selected because it is estimated that they all have about the same complexity, thereby providing a design balance.
- A set of modules may be selected because it is estimated that they all have approximately equal influence on performance and therefore represent an educated guess of a balanced system.
- Modules may be selected because they are readily composed from known building blocks and therefore will avoid another partition step.
- Modules may be selected because they simplify refinement of higher level behavioral models in a manner which guarantees preservation of desired properties. Thus, consistency with invariants established in higher level proofs of data flow or control flow properties would be example criteria.

Whichever combination of guidelines are practiced leads to the creation of two or more structures and their interconnection. For each named subsystem there is then an initialization step identical to that carried out at the previous level with the exception that the higher level requirements must be mapped onto the new structures. For each named subsystem a behavioral model is developed which seeks to meet the subsystem requirements and hopefully to join in meeting full system requirements.

Partition evaluation

The set of subsystem models are evaluated by inspection, by analysis or by simulation. If any evaluation fails, the design is returned to the partition phase for modification or re-creation by the designer. If all evaluation steps pass then the design is returned to the part of the process where, for each subsystem, it is decided that composition can take place directly or else that another partition is needed.

Implementation

When the compositions succeed in passing all tests for all subsystems, the design moves into an implementation phase to prepare the design for fabrication. The following operations are generally needed:

- Documentation is prepared. If there have been careful records kept during the design process, they provide the best description of intended functions, predicted behavior, and the usually critical interfaces between subsystems. This documentation is important for those who will evaluate the fabricated system. However other kinds of documentation are generally needed to facilitate fabrication, maintenance, marketing, training and distribution. Wiring lists, microprograms, bit maps for read-only memories, higher level language programs and test programs are examples.
- Changes may have to be made to remove artifact introduced by the modeling and design process. For example, instrumentation may have been integrated with a model to determine whether performance requirements were met but the measurements may themselves deteriorate performance and not be deemed necessary. This excision must be done very carefully in order not to alter desired behavior and sometimes it will force another pass through evaluation of the altered model.
- The simulation environment may have mechanisms which cannot be directly fabricated and are replaced by "equivalent" mechanisms. This too must be done very carefully lest the modeling and evaluation process be invalidated.

THE SARA (SYSTEM ARCHITECTS APPRENTICE) SYSTEM

The groundwork for SARA was set by Gardner*[13] at the beginning of 1975 following several years of collaboration between Gardner, Potash and Estrin. The design of SARA was begun during the summer of 1975. Implementation of structural and behavioral modeling tools continues through the present. SARA's birth was announced at the beginning of 1977[6] and a one year old version now marks SARA-reborn at MIT-Multics, a more permissive environment than UCLA's IBM/TSO. The infant version of SARA provides a collection of modeling tools, at both UCLA and MIT, for which some care has been applied to the design of the user interface. The sibling SARA's are reachable by authorized users through the ARPANET.

The current view of the structure of the SARA system is shown in Figures 3 and 4.

* In addition to R. I. Gardner, major contributions to the design and implementation of SARA were made by D. Berry, I. Campos, C. Carper, J. Drobman, B. Fenchel, W. Overman, R. Razouk and W. Ruggiero.

User interface

All communication between a designer and the SARA DESIGN SYSTEM as well as output to FABRICATION are done through IO.[14] The IO system creates a flexible and powerful user-interface and achieves uniformity of interface with the various tools in SARA. Moreover it serves as a place to contain all machine dependent routines, easing any move from one PL/1 environment to another. SELECTOR[14] is then used to move between language processors at different levels as illustrated in Figure 5.

Structural and behavioral modeling tools

The most fully tested tools are those contained in the modules named STRUCTURES and BEHAVIORS.

- STRUCTURES holds a language processor called SL1 which lets a designer interactively describe the structure of a system using three primitives (see Table I): modules, sockets and interconnections. Multilevel structural models can be constructed using fully nested modules as in Figure 6. Multilevel interconnections, can be expressed simply, as displayed in Figure 7. In general interconnections may be refined as complete systems.
- BEHAVIORS holds several language processors used to create different kinds of models of named structures. The principal behavioral modeling tool is the Graph Model of Behavior (GMB). The GMB provides a small number of primitives (see Table II). The control graph primitives allow a designer to interactively create a graph explicitly modeling flow-of-control among processes including synchronization of concurrent processes. The data graph primitives allow a designer to display flow-of-data, interpreting the processes in the control graph at an abstract level. Furthermore a preprocessor, called PLIP[15,16] allows a designer to concretely interpret each data processor and dataset primitive using the full power of PL1. The topology of both the control and data graphs is fixed and they are used to model pseudo static aspects of system behavior. The PL1 interpretation (PLIP) models dynamic behavior within each processor and causes changes in control and data flow along the prescribed data and control arcs. Two other tools have been built for analysis of the GMB model. An interactive simulation environment[16] permits experiments to be executed, observed and analyzed. The simulation environment is used to check predictions of results and estimate timing. Moreover, the GMB simulator is effective at detecting deadlocks, detecting contention for datasets and detecting contention for processors. One reduction program is used to analyze the control flow graph and this analysis can determine that a system is "properly terminating", i.e., that it is deadlock free and reentrant.

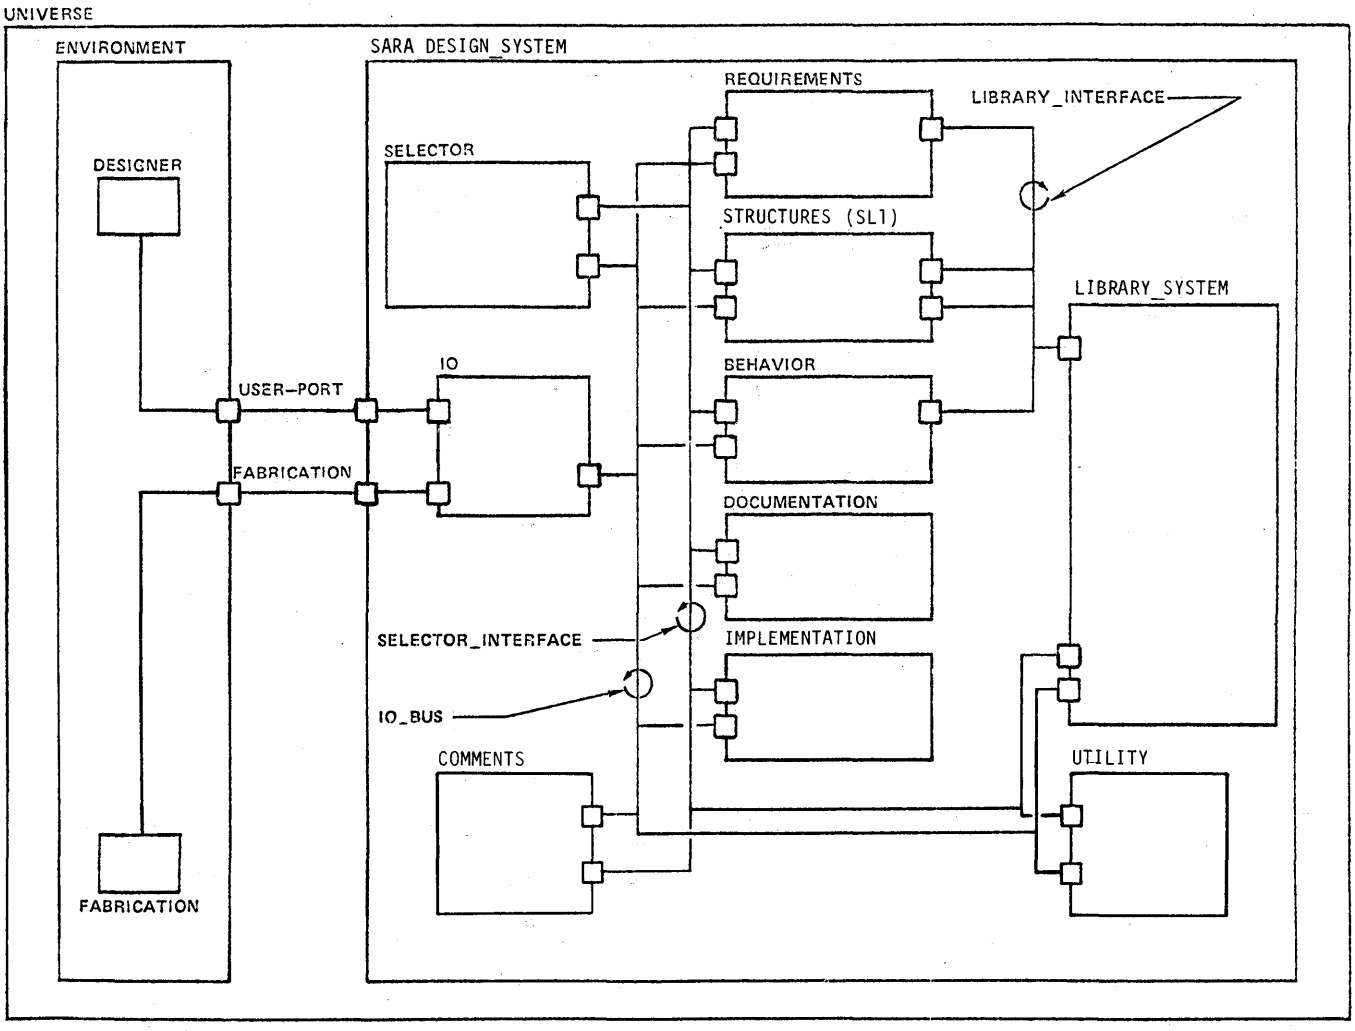

Figure 3—Structure of SARA

TABLE I.—Modeling Primitives

TYPE	GRAPHICAL	MACHINE PROCESSABLE
STRUCTURAL PRIMITIVES		NOTE: SL1 STATEMENTS MAY BE MADE IN ANY ORDER. THEY CAUSE CREATION OF IMPLIED STRUCTURES.
A NAMED MODULE REPRESENTS AN OBJECT WHOSE INTERNAL, FULLY-NESTED STRUCTURE IS HIDDEN FROM THE OUTSIDE. A MODULE'S ONLY POSSIBLE COMMUNICATION WITH THE OUTSIDE IS THROUGH A SOCKET. OTHERWISE, A MODULE'S NAME IS KNOWN ONLY TO THE STRUCTURE WITHIN WHICH IT IS NESTED. EXAMPLE: THE MODULE, CALLED "NAME_C", IS COMPOSED OF MODULES "A" AND "B".		NAME_C (A,B,C)
A NAMED SOCKET IS PART OF A MODULE BUT THE SOCKET'S NAME IS KNOWN BOTH INSIDE AND OUTSIDE OF ITS HOST MODULE. EXAMPLE: THE MODULE "NAME_C" IS COMPOSED OF MODULES A WITH SOCKET SA, B WITH SOCKET SB AND C WITH SOCKET SC.		NAME_C (A@SA, B@SB, C@SC)
A NAMED INTERCONNECTION IS A STRUCTURE WHICH CONNECTS TWO OR MORE SOCKETS. EXAMPLE: AN INTERCONNECTION CALLED "LINK" CONNECTS THE SOCKETS A@SA, B@SB, AND C@SC.		LINK + (A@SA, B@SB, C@SC).

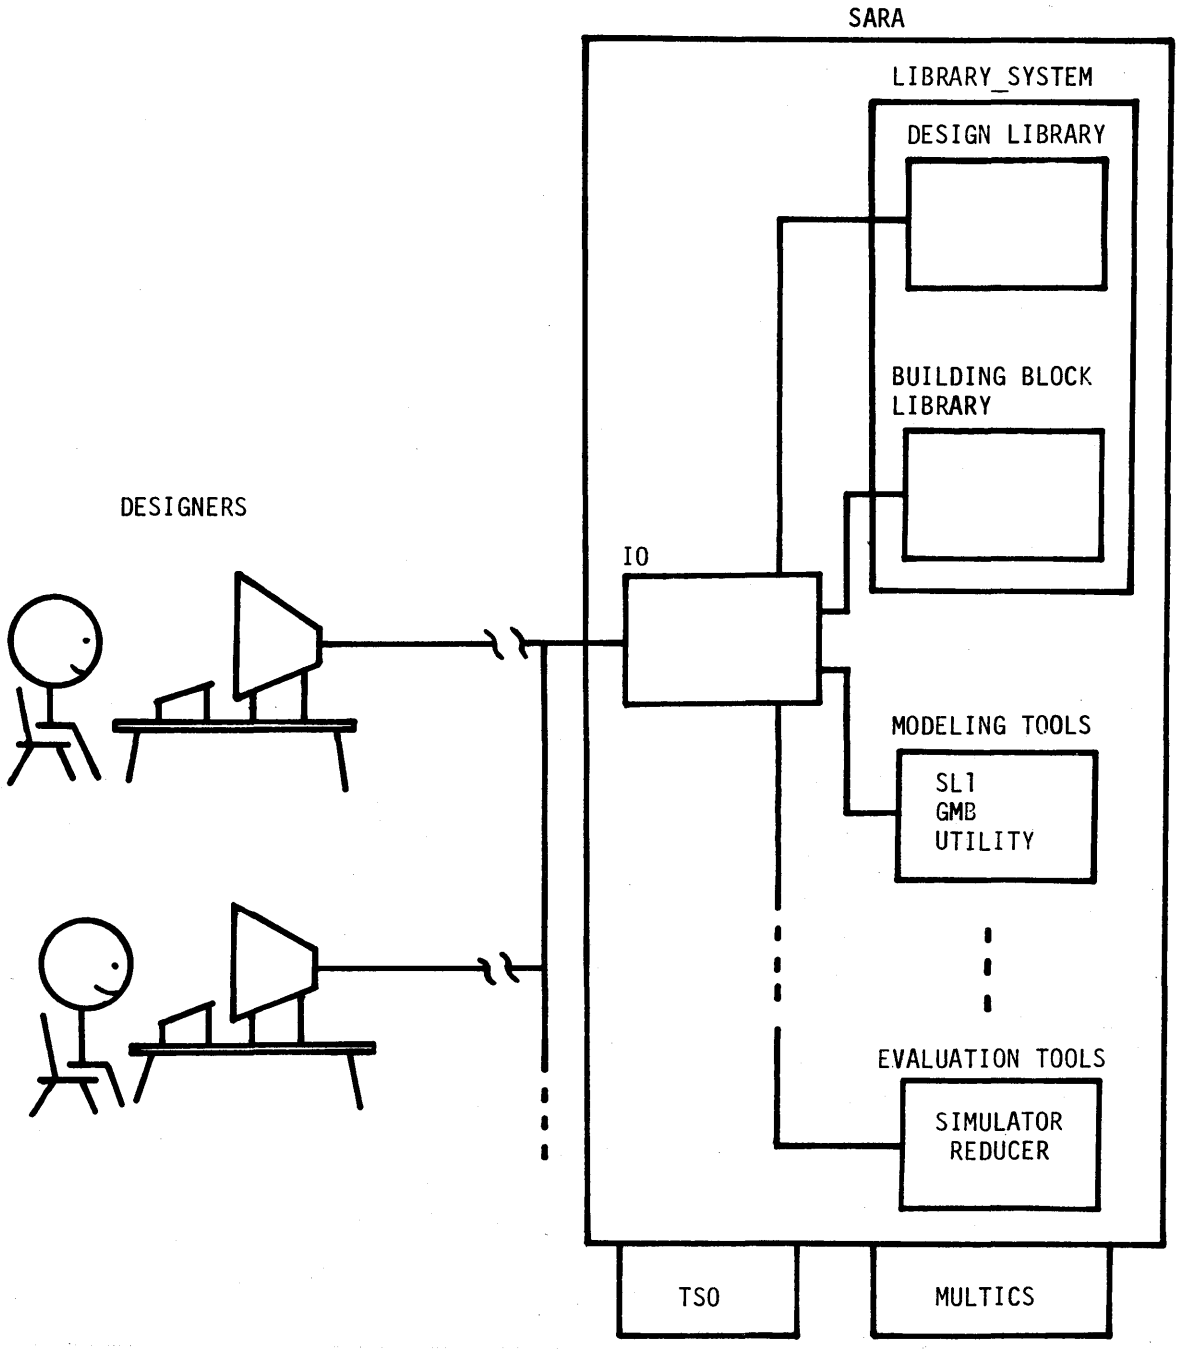

Figure 4—Designers view of SARA

Three other behavioral modeling tools are in various stages of integration in SARA.

A simulation system called DCDS (Digital Control Design System) was implemented in 1969[17] and improved in the early 1970's. DCDS is not interactive but allows a designer to richly describe a system in terms of logic nets, in terms of microprogram sequences or in terms of algorithms. A fourth sublanguage called DECLARE is used to combine models described separately in the three languages: LOGIC, MICROPROGRAM and PL1. DCDS is not integrated into the set of interactive SARA tools. Models are translated in a batch mode and simulations run in a batch mode.

The Instruction Set Processor (ISP) modeling language created by Bell and Newell[18] has attracted widespread interest. Buliding upon work by Crocker[19] a translator from ISP to PLIP was created. One complex machine model was built and is still undergoing test.

The Simulation Oriented Language (SOL) of Knuth and

TABLE II.—Behavioral Modeling Primitives

TYPE BEHAVIORAL PRIMITIVES	GRAPHICAL	MACHINE PROCESSABLE
A NAMED CONTROL NODE REPRESENTS A STEP IN A PROCESS BEING MODELED. A CONTROLLED DATA PROCESSOR (SEE BELOW) MAY BE ASSOCIATED WITH A NODE TO PROVIDE INTERPRETATION OF THE PROCESS. EXAMPLE: A NODE N1 HAS A SINGLE ENTRY ARC S AND A SINGLE EXIT ARC X.		@CONTROL_GRAPH; @NODES N1; @ARCS S,X; N1 (S:X); @END;
A NAMED DIRECTED CONTROL ARC REPRESENTS NON-VOLATILE PREDEDENCE RELATIONS BETWEEN SETS OF NODES. IF THERE IS MORE THAN ONE SOURCE NODE OR DESTINATION NODE THE ARC IS CALLED COMPLEX; OTHERWISE IT IS CALLED SIMPLE. AN ENABLING TOKEN IS PLACED ON AN ARC EITHER AS A STARTING STATE OR UPON TERMINATION OF ANY OF ITS SOURCE NODES. WHEN A NODE IS INITIATED, ITS ENABLING TOKENS ARE ABSORBED. EXAMPLE: A2 AND X ARE SIMPLE CONTROL ARCS. A1 IS A COMPLEX CONTROL ARC WHOSE SOURCE SET IS NODES N1, N2 AND N4 AND WHOSE DESTINATION SET IS N5, S, IS AN INCOMING COMPLEX ARC WHOSE DESTINATION SET IS N1, N2 AND N3.		@CONTROL_GRAPH; @NODES N1,N2,N3,N4,N5; @ARCS S,A1,A2,X; N1 (S:A1); N2 (S:A1); N3 (S:A2); N4 (A2:A1); N5 (A1:X); @END;
INPUT CONTROL LOGIC A LOGICAL RELATION AMONG THE INPUT ARCS TO A NODE SPECIFIES THE PRECEDENCE CONDITIONS THAT MUST BE SATISFIED BY TOKEN STATES FOR THE NODE TO BE INITIATED. TOKENS FROM THE INITIATING ARCS WHICH SATISFY THE INPUT RELATIONS ARE ABSORBED BY THE TOKEN MACHINE. TOKENS ARE ABSORBED FROM ONE OF AN INITIATING ARC SET GOVERNED BY AN OR RELATION IN A MANNER ESTABLISHED IN THE TOKEN MACHINE AND FROM ALL MEMBERS OF AN INITIATING ARC SET GOVERNED BY AN AND RELATION. EXAMPLE: IF ENABLING TOKENS EXIST ON EITHER A1 OR A2 AND ON EITHER A3 OR A4 THEN N1 CAN BE INITIATED. OUTPUT CONTROL LOGIC A LOGICAL RELATION AMONG THE OUTPUT ARCS SPECIFIES WHICH ARCS HAVE TOKENS PLACED UPON THEM WHEN A CONTROL NODE IS TERMINATED. WHEN AN EXCLUSIVE OR OUTPUT RELATION HOLDS, A DATA PROCESSOR INTERPRETATION MUST DECIDE WHICH ARC RECEIVES A TOKEN. WHEN AN AND RELATION HOLDS ALL OUTPUT ARCS RECEIVE TOKENS. EXAMPLE: WHEN N1 TERMINATES, ITS ASSOCIATED CONTROLLED DATA PROCESSOR WILL HAVE DECIDED WHETHER TOKENS ARE TO BE PLACED ON B1 AND B2 OR ON B3 AND B4.		INPUT:OUTPUT CONTROL LOGIC @CONTROL GRAPHS; @NODES N1; @ARCS A1,A2,A3,A4,B1,B2,B3,B4; N1((A1+A2) * (A3+A4): (B1+B2) * (B3+B4)); @END;

McNeely[20] was implemented in PL1 by the Defense Communication Engineering Center under the name SOL/370. It has been installed but not fully tested and integrated. It is proposed for use as one of the SARA behavioral model analysis tools.[21]

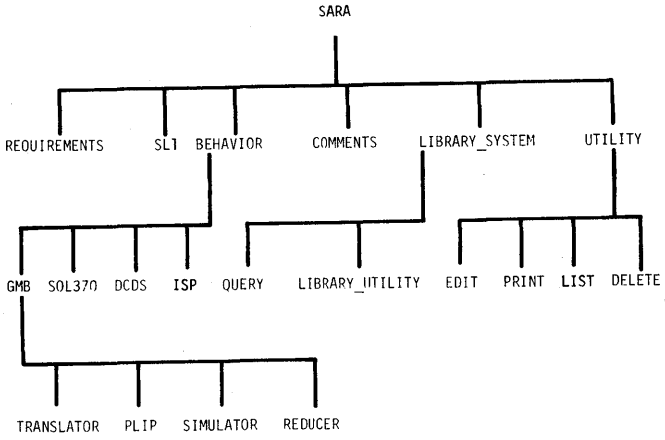

Figure 5—SARA—Multilevel view from the selector

The design library

Every tool in the SARA system makes use of LIBRARY SYSTEM for storing and retrieving models. There are two essentially different parts of the LIBRARY SYSTEM.

- One part contains the public building block library which holds models of hardware and software subsystems that have been extensively tested or verified. These models have a great deal of value added and are assumed to be called upon strongly enough to make the investment pay off. Extensive controls on entry and modification will be exercised by a library administrator. Drobman has considered the nature of the library system with respect to hardware system design and has proposed generic building block structures for LSI based systems.
- A second part provides facilities for storage and retrieval of private building block models and private partial system designs.

LIBRARY SYSTEM is still in an early stage of development. At present we use basic facilities of the

TABLE II (Continued)

TYPE	GRAPHICAL	MACHINE PROCESSABLE
A NAMED CONTROLLED DATA PROCESSOR REPRESENTS A DATA TRANSFORMATION OBJECT WHICH IS ACTIVATED WHEN AN ASSOCIATED CONTROL NODE IS INITIATED. E.G., PROCESSOR P1 IS INITIATED WHENEVER EITHER N1 OR N2 IS INITIATED. WHEN PROCESSOR P1 TERMINATES IT CAUSES TOKENS TO BE PLACED ON OUTPUT ARCS OF THE CONTROL NODE WHICH INITIATED IT. AN INTERPRETATION OF THE DATA TRANSFORMATION AND OTHER PARAMETERS SUCH AS TIME DELAY OR RESOURCE REQUIREMENTS CAN BE ASSOCIATED WITH THE DATA PROCESSOR. EXAMPLE: PROCESSOR P1 HAS A RANDOM DELAY ASSOCIATED WITH IT.		@DATA GRAPH; @PROCESSOR P1 (N1,N2); @END; PLIP INTERPRETATION @PROCESSOR P1; DCL IRAND ENTRY(FIXED BIN(31) FIXED BIN(31))RETURNS (FIXED BIN(31)); /*RANDOM # GENERATOR*/ DCL NUMBER FIXED BIN(31); NUMBER=IRAND(1,2) /*PICK AN INTEGER: 1 OR 2*/ IF NUMBER=1 THEN @OUTPUT_ARCS='B1,B2'; ELSE @OUTPUT_ARCS='B3,B4'; @DELAY=IRAND (10,100); /*PICK RANDOM DELAY FROM 10 TO 100*/ @END PROCESSOR;
A NAMED UNCONTROLLED DATA PROCESSOR REPRESENTS A DATA TRANSFORMER WHICH PROVIDES, AT ITS OUTPUT, STATED FUNCTIONS OF ITS INPUTS INDEPENDENT OF CONTROL NODE STATES. IN THE DATA GRAPH AN UNCONTROLLED PROCESSOR IS IDENTIFIED BY PROVIDING AN EXPLICIT DECLARATION. AN INTERPRETATION OF THE DATA TRANSFORMATIONS AND OTHER PARAMETERS MAY BE ASSOCIATED WITH IT IN AN IDENTICAL MANNER TO THE CONTROLLED PROCESSOR.		@DATA_GRAPH; @UNCONTROLLED_PROCESSORS U1; @END;
A NAMED DATA SET REPRESENTS A PASSIVE COLLECTION OF DATA. DATA STRUCTURE MAY BE ASSOCIATED WITH A DATASET. ALL PL/1 DECLARATIONS NOT CONTAINING SCOPE OR STORAGE CLASS ATTRIBUTES ARE ACCEPTED AS DEFINITIONS OF DATA SETS. CHARACTER STRINGS CANNOT HAVE THE VARYING ATTRIBUTE. EXAMPLE: THE DATASET D1 IS A SIX-DECIMAL-DIGIT COMPLEX FLOATING POINT NUMBER.		@DATA_GRAPH; @DATASETS D1; @END; PLIP INTERPRETATION @DATASET D1 COMPLEX FLOAT DECIMAL(6);
A NAMED DATA ARC STATICALLY BINDS DATA PROCESSORS AND DATASETS. A DATA PROCESSOR HAS READ OR WRITE ACCESS TO A DATA SET IF THE ARROW POINTS TO OR FROM THE DATA PROCESSOR RESPECTIVELY. EXAMPLE: PROCESSOR P1 IS INITIATED BY CONTROL NODE N1. P1 READS DATA FROM DATASETS D2 AND D3 AND WRITES THEIR SUM INTO DATASET D1.		@DATA_GRAPH; @PROCESSORS P1(N1); @DATASETS D1, D2, D3; @ARCS DA1, DA2, DA3; DA3 (D3:P1); DA2 (D2:P1); DA1 (P1:D1); @END; PLIP INTERPRETATION @DATASET D1 FIXED BIN(31); @DATASET D2 FIXED BIN(31); @DATASET D3 FIXED BIN(31); @PROCESSOR P1; @READ(D3); @READ(D2); D1 = D2+D3; @WRITE(D1); @END PROCESSOR;

interactive operating systems. There has been a great deal of design thinking and actual DBMS design but the results are too speculative to include here.

Behavioral—Structural mapping

A fundamental aspect of the SARA system is the mapping of behavior on the structural primitives i.e., modules, sockets, and interconnections. The mapping funcitons are currently under development. It is only after such mapping that SARA tools can detect enought cases of inconsistency and incompleteness to repay the designers for the structured thinking and excess description that they are forced to provide when they follow the prescribed methodology. Behavioral attributes are mapped to sockets[5] and focus the designers attention on interface problems, the source of most design errors. Then if two sockets are linked via an interconnection and an inconsistency in attributes is discovered, it is known that either an error was made or else the interaction must have a more complex behavior designed into it.

Multilevel modeling

As indicated in the first part of this paper the strength of support for multilevel modeling procedures and the consequent management of complexity will be the principal test of SARA's reason for existence. During the partition phase, the role of SARA is to support evaluation of a refinement proposed by the designer and to accept it if the higher level abstraction is not contradicted. If the designer insists on the refinement, despite contradiction, then a procedure to weaken the abstraction is needed. Similarly in the composition phase, the role of SARA is to compose given building blocks into a model and to help discover inconsistencies with respect to the next higher level model.

The behavioral models are clearly more complex. Campos and Ruggerio[22] have proposed formal replacement algorithms which retain equivalencies between two graph models of behavior. Whenever a single control or data graph primitive is to be refined or whenever a sub-graph can be abstracted by a single primitive, the replacement algorithm guarantees that changes are localized. In general a refine-

SL1 CODE

S3(S4,S4@L2); S3.L2(S4@L2,S3@L2);
S1(SUB1,SUB2,SUB3,SUB1@L2,SUB1@L1,SUB2@L1,SUB3@L1);
S1.L1+(SUB1@L1,SUB2@L1,SUB3@L1);
S1.L2+(SUB1@L2,S1@L2);
```

NOTE: THE "." IS USED TO DESCRIBE NESTING IN A FULLY QUALIFIED NAME, E.G. S2.S1.SUB1 IS THE FULLY QUALIFIED NAME OF SUB1 IN FIGURE 6.

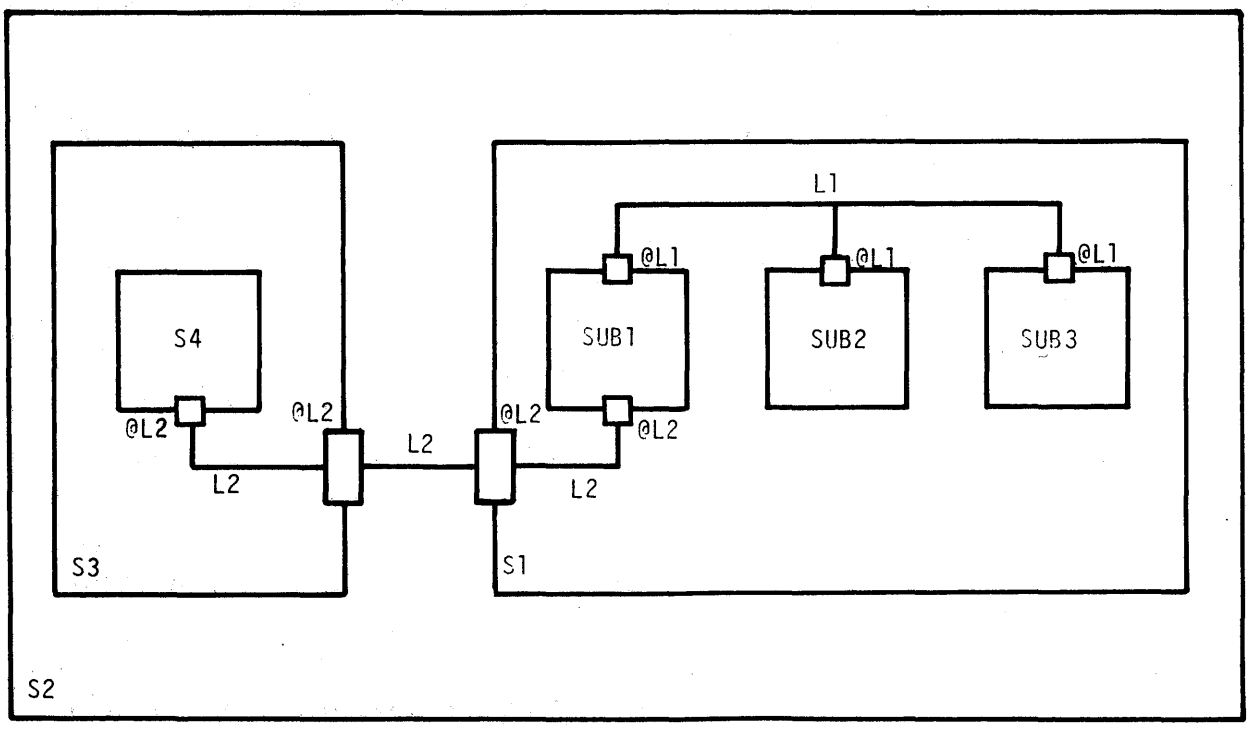

Figure 6—Multi-level modules

ment of (or abstraction into) a data graph primitive implies modification of the associated control graph—and vice versa. Furthermore it is possible to retain "well-behaved" properties like proper termination during these replacements. These replacement algorithms are restricted in the sense that we do not have an algorithm yet to permit replacement of an arbitrary sub-graph by another sub-graph. However they add considerable strength to SARA in support of the designer.

In the same vein, our models of concurrent systems provide a context in which to embed verified processor interpretations and seek algorithms to prove partial correctness of a full data graph including interpretation.

For effective multilevel modeling, the "bottom line" is the accuracy, clarity and richness of the building block models available to the designer. No matter how late or early implementation decisions are explicitly made, the design process must be goal oriented and the designer must either understand the elements or have faith in the models reinforced by successful use of them. For hardware building block models, we find ourselves giving a great deal of attention to detail in order to convince ourselves that our models can accurately represent manufacturers specifications.[23] Drobman[24] has been able to generalize such study by defining "generic" as well as specific building blocks. There are other ways to harness rich populations of building blocks.

SL1 CODE - HIGH LEVEL MODEL

SVB2@L1 (SUB2@L1.WIRE3,SUB2@L1.WIRE2);
SUB3@L1 (SUB3@L1.WIRE2,SUB3@L1.WIRE1);
L1.WIRE1 + (SUB1@L1.WIRE1,SUB3@L1.WIRE);
L1.WIRE2 + (SUB1@L1.WIRE2,SUB2.@L1.WIRE2,SUB3.@L1.WIRE2);
L1.WIRE3 + (SUB1@L1.WIRE3,SUB2@L1.WIRE3);
```

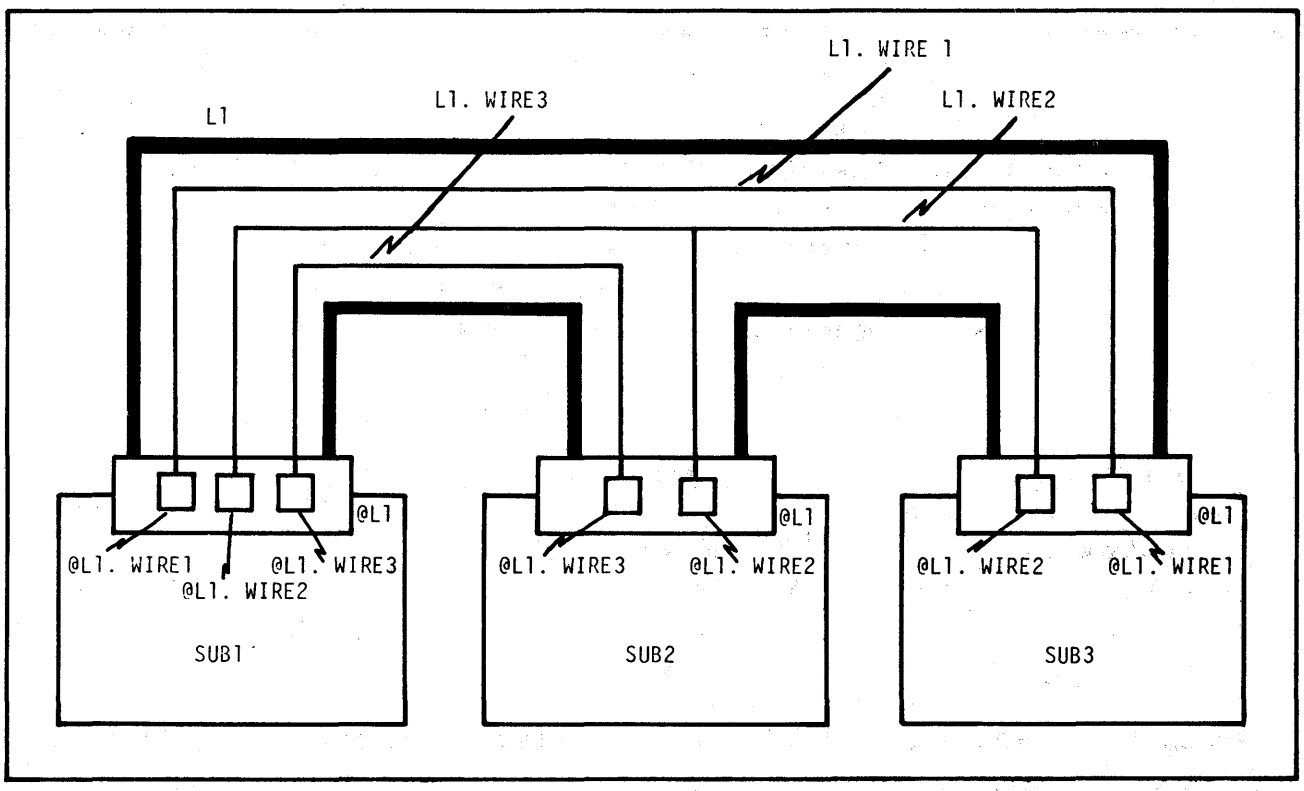

Figure 7—Multi-level interconnection

For example we have a path for translating ISP descriptions into PLIP interpretations but we do not yet fully understand limitations imposed by efficiency issues.

In the companion paper,[5] a software example is taken all the way from programming-in-the-large to programming-in-the-small or PL1 code. In that case the PL1 language definition provides the building blocks and the transition is smooth because the entire SARA System is written in PL1. When concurrency exists, the transition is not completely smooth because the "token machine" is an integral part of the SARA environment and there must be equivalent machinery wherever a SARA model is expected to execute. In fact we are exploring new architectures in which SARA models would run with no alteration of the designed and tested model.

SUMMARY AND CONCLUSION

The UCLA design methodology has been elaborated in an attempt to indicate its requirement-driven and self-documenting properties for modular, concurrent, hardware and software systems. The need for implementation in hardware, for example, may show up explicitly in initialization or finally appear in composition.

Those goal characteristics which distinguish this design philosophy are:

- Explicit modeling of environments using the same primitives as the systems being designed.
- Separate but related static and dynamic models.
- Separate but related control and data flow models.

- Separate but related structural and behavioral models.
- Support for both top-down and bottom-up design.
- Implementation decisions forced in composition but retained when they are entered earlier.
- Supported "well-behaved" properties in multilevel modeling and analysis.
- Supported simulation of concurrent processes.
- Supported fabrication.

SARA is useful now as a collection of tools which help structured design of concurrent systems. SARA has been tested in a number of design problems. As a result of its recent move to MIT-MULTICS, it is soon to be tested on larger system problems. To the extent that support of the requirement-driven multilevel design methodology is increased and detected "errors" are reported to the designer, SARA's value will increase significantly. A number of problems with the current methodology and its support are discussed in the companion paper.[5]

We believe that SARA is unique in the support it gives to design of concurrent systems. We do not look on this methodology as being in competition with other active work in, for example, dataflow architecture or sequential software design. We are constantly alert to incorporation of other maturing synthesis techniques, particularly when any of our designs reach the stage of incorporating sequential programs.

The number of poorly understood problems which have been pointed to in this paper is very large. They give credence to the author's philosophy which rejects completely-automatic design at this time and seeks to support the designers injection of value judgments and decisions. Automated design procedures should be introduced selectively and patiently. Sarah begat Isaac when she was ninety years old [Genesis]. It is possible that, with the help of SARA and the help and the wisdom of many researchers and machines, we will know enough before 2067 to beget a powerful ISAAC (Information System Automatic Architect Computer). We do know how to beget an ISAAC but also know that a 1978 ISAAC would be fired for incompetence long before tenure could be achieved.

SARA aided design of software for concurrent systems*

by IVAN M. CAMPOS** and GERALD ESTRIN
University of California at Los Angeles
Los Angeles, California

INTRODUCTION

In the past several years it has often been noted that software is the major cost component in designing, implementing and maintaining computer systems. Unreliability and associated debugging and maintenance activities are among the main elements responsible for this increase in cost. Most bugs are "born" in the design phase, i.e., the design itself is usually faulty,[1] and when a bug is uncovered some changes are likely to occur. Whenever modification is made, it is generally difficult to keep track of all consequences that it may provoke. Poor design often shows up as a high degree of connectivity among subsystems.[2,3] Interconnections may be "hidden," representing unstated assumptions that a subsystem makes about other subsystems and leading to unforeseen side effects when seemingly harmless changes are made.[4,5]

In an attempt to improve software, extra effort tends to be invested in design. Considerable attention is being given to issues such as stepwise refinement,[6,7] structured programming,[8] modularity,[9,10] and composite design.[3] Data abstraction concepts have been introduced into languages such as CLU,[11] EUCLID,[12] and ALPHARD.[13] Active research continues to uncover more effective methods for analysis and synthesis of verified programs.[14]

Since the early 1960's, Estrin and his colleagues have been involved in the development of models of computational algorithms, models of interpreters, and procedures for mapping one on the other. The UCLA Graph Model of Computation;[15–21] the development of a methodology (DCDS) for design of hierarchical hardware and firmware systems;[22] and the revelation of difficulties in evaluation of unstructured computer systems[23] led this UCLA group to concentrate on synthesis of structured systems, in which one might manage complexity from the outset and prepare for further analysis.

The major direction of work at UCLA on methodology of synthesis is to complete a set of tools which support a structured multilevel design procedure for software or hardware development.[24] This interactive computer-aided system called SARA (Systems ARchitect's Apprentice) provides languages to help a designer form useful abstractions which can be manipulated and tested in a disciplined way,[25–28] and which may be forced to retain good properties.[29]

SARA supports both a bottom-up composition (abstraction) procedure and a top-down partitioning (refinement) procedure. In both cases, however, the procedures are requirement-driven so that attention can be focused on the gap between a designer's declared intent and the current approximation of the system's behavior.

Models are created using a small number of primitives* whose manipulation are supported by SARA interactive translators and a simulator (see Tables I and II in the companion paper[24]).

Modules, sockets and interconnections are structural modeling primitives which allow creation of a hierarchical name space for a fully nested system. Named modules permit interaction only through sockets. Socket names are known both inside and outside of modules, thus supporting declarations of interfaces. Named interconnections support interaction among modules.

Explicit control flow behavior can be expressed by control nodes, which span initiation and termination of associated processes, and by directed control arcs, which are used to express precedence conditions. Control conditions and thresholds can be prescribed to condition process initiation. Control consequences can be prescribed to take effect following process completion. Tokens mark the state of control flow and a token machine governs progress of the state of a model. Data flow is described by graphs composed of controlled processors, uncontrolled processors, datasets and data arcs.

All of the above primitives are currently used to form models which are static in the sense that the topology currently does not change during execution. Interpretations can be associated with the data flow primitives (processors and datasets) and provide the semantics for modeling of dynamics. Currently, a pre-processed PL/I (PLIP) is the interpretation language. An interactive simulator supports experi-

* The authors chose not to provide, in this paper, the full detail of syntax and semantics implemented in SARA. The interested reader can find such information in Refernce 26. We have tried to include enough detail to follow examples. Note that the "@" symbol is used for many purposes: to identify a socket name or a declaration or language processor.

ments on models. Extensive discussion of SARA modeling may be found in the references noted above.

The objective of this paper is to expose the SARA methodology as applied to software. The central problem is the set of tools and procedures to be brought to bear on building possibly concurrent software systems which reliably carry out the designer's intent.

We also wish to propose a role of SARA models not only as design and evaluation tools, but also as the basis for a superstructure to be overlaid on the actual code of a designed product as redundant information for the operating system. One consequence of imposing such a superstructure on source code modules is that it provides its operating system and its user with a "live" documentation whose objective is to enforce consistency between requirements, structure, function and behavior of the software system.

In the body of the paper below, we take the reader through the key steps of two example designs and try to generalize the procedure through commentary. We chose the design of a synchronized sender-receiver process and an abstracted FFT. They are relatively simple examples which are of some importance and serve to bring out many properties of our design method and the SARA system.

Following an informal statement of need, the design universe is partitioned into the system to be designed and its environment. An initial behavioral model (of the system and of the environment) fixes all assumptions under which the design is to proceed. Requirements establish evaluation criteria for the system. Following "top-down" levels of designer-created behavior, there is a final composition step to produce PL/I code. In the models below, comments will highlight SARA conventions. In all other cases PL/I conventions will be assumed to hold.

A DESIGN EXAMPLE—A SIMPLE MESSAGE TRANSMITTER

The informal statement of our design problem is "design a system whereby a process produces and sends a sequence of data to another process, if the latter is not busy.

DEFINING THE STRUCTURE

The initial design steps in the SARA design procedure[24,27] lead us to partition our UNIVERSE into two SL1 modules, MESSAGE TRANSMITTER, the system to be designed, and ENV, its environment. The machine processable SL1 code, its graphical representation and the requirements for both ENV and MESSAGE TRANSMITTER are shown in Figure 1. Parentheses establish nesting level so that the second line of SL1 code is read "ENV" is composed of three sockets, called @INFILE, @HERALD, and @OUTFILE." Identifiers starting with the character '@' are socket names. The symbol '+' indicates that the system to its left is an interconnection which connects the sockets whose names appear between the parentheses that follow it. Thus the third SL1 statement says that "within UNIVERSE there is an interconnection named SL1 which connects the socket ENV @INFILE to MESSAGE TRANSMITTER @INFILE."

The three interfaces between the modules that constitute ENV and MESSAGE TRANSMITTER are called HERALD, INFILE and OUTFILE, respectively, as shown in the sockets.

SL1 CODE FOR STRUCTURAL MODEL OF UNIVERSE

```

on arc S. The expression in parentheses after node names contain arc expressions separated by a colon. To the left of the colon one specifies the input logic expression to the node (precondition for its activation); conversely to the right of the colon one specifies the output logic expression (postcondition to its deactivation). Any well-formed logic expression can be used. If the designer is restricted to using the operators AND ("*") and OR ("+") then analysis of control graph properties is made easier. Let us now consider evaluation of the model with respect to the requirements. RE1 and RE3 are satisfied by the first two PLIP dataset interpretations. RE2 is satisfied by the control graph description. RE4 is satisfied by the first DCL in the process P2 interpretation. RE5 is implied by the interpretation of processor P2. RM1 is satisfied by inspection. RM2 is satisfied because the Sender and Receiver processes are done sequentially. RM3 can be tested in the SARA simulator environment and, finally, on a PL1 machine when the program is composed.

The above model is read by the SARA translator and simulated, even at this high level, by providing test messages in INFILE and observing at the end of simulation that they appear in OUTFILE in a manner that satisfies the requirements.

CODE SYNTHESIS—BOTTOM-UP COMPOSITION

This design example is so simple that we directly go bottom-up in the design process.

A few observations are in order. The fact that PLIP is an extension to PL/I via a preprocessor places us in a privileged position to directly synthesize PL/I code. We will try to treat each PLIP statement as a building block model of the corresponding PL/I statement. We assume that we have validated MESSAGE TRANSMITTER with respect to requirements and are therefore ready to directly synthesize the code. This can be seen as a "fabrication phase" after the modeling has been completed, and we assume that future development of SARA might make this process automatic.

We compose the MESSAGE TRANSMITTER procedure by declaring as internal variables all those datasets that have been mapped separately on ENV in the GMB-to-SL1 mapping (in this case INFILE and OUTFILE). We concatenate them with the declarations of the internal variables found in the PLIP code of P2.

The next "cleaning-up" step consists of deleting all the @READ and @WRITE statements from the code, since they are only used by the SARA GMB simulator. The final code is shown in Figure 3 next to the original PLIP code (taken from the upper right box in Figure 2).

This was, of course, a trivial example but served to illustrate the methodology. Our second design example is more complex.

A SECOND DESIGN EXAMPLE—A FAST FOURIER TRANSFORMER[30]

In this example we wish to focus the readers attention on the composition procedure, which is our name for a bottom-up design procedure.

A signal processing problem which has received extensive attention can be informally stated as "design a system which receives sequences of complex numbers; calculates the Fast Fourier Transform of each of those sequences; and makes it available to the environment that issued the original complex numbers." For purposes of this paper we consider a reduced problem for sequences of 8 complex numbers. It is of some importance that the reader extrapolate the application of the method to larger problems.

In this design example we get a little more formal in our discussion. We use a specification of the problem (which we call our invariant) whereby a description of the desired in-

```

Figure 3—Original PLIP interpretation and final composed PL1 code for message_transmitter

teraction between the system to be designed (FFT) and its environment (ENV) is produced. This invariant is composed of:

- A structural model which splits the design universe into two subsystems, ENV and FFT, and shows their structured connections by means of interconnected sockets.
- A list of requirements for both the system under design and its environment.
- A graph model of behavior (GMB) of the desired interaction between ENV and FFT.
- An interpretation associated with the GMB, which shows in procedural form which input/output transformations are to be performed by both ENV and FFT, with particular attention to interface issues.

THE STRUCTURAL MODEL

The machine processable and graphic SL1 model of our design universe is presented in Figure 4 where we distinguish two subsystems of UNIVERSE, namely ENV and FFT.

Structurally, ENV and FFT are connected through interconnections XI and FI, each of which interconnect a socket in ENV to a socket in FFT. These interconnections support both control and data interactions between the two subsystems. In Figure 4 we have chosen to show both a top level structural model and a more detailed socket model. We are anticipating modeling concurrent programs. Eight of the interconnections support flow from ENV to FFT, and the other 8 support flow from FFT to ENV.

REQUIREMENTS

The requirements are superimposed on the structural model in Figure 4. They are separated into two sets, one mapped onto ENV and the second onto FFT.

THE BEHAVIORAL MODEL

The flow-of-control and the flow-of-data graphs are shown in Figures 5 and 6 respectively, mapped onto the ENV and

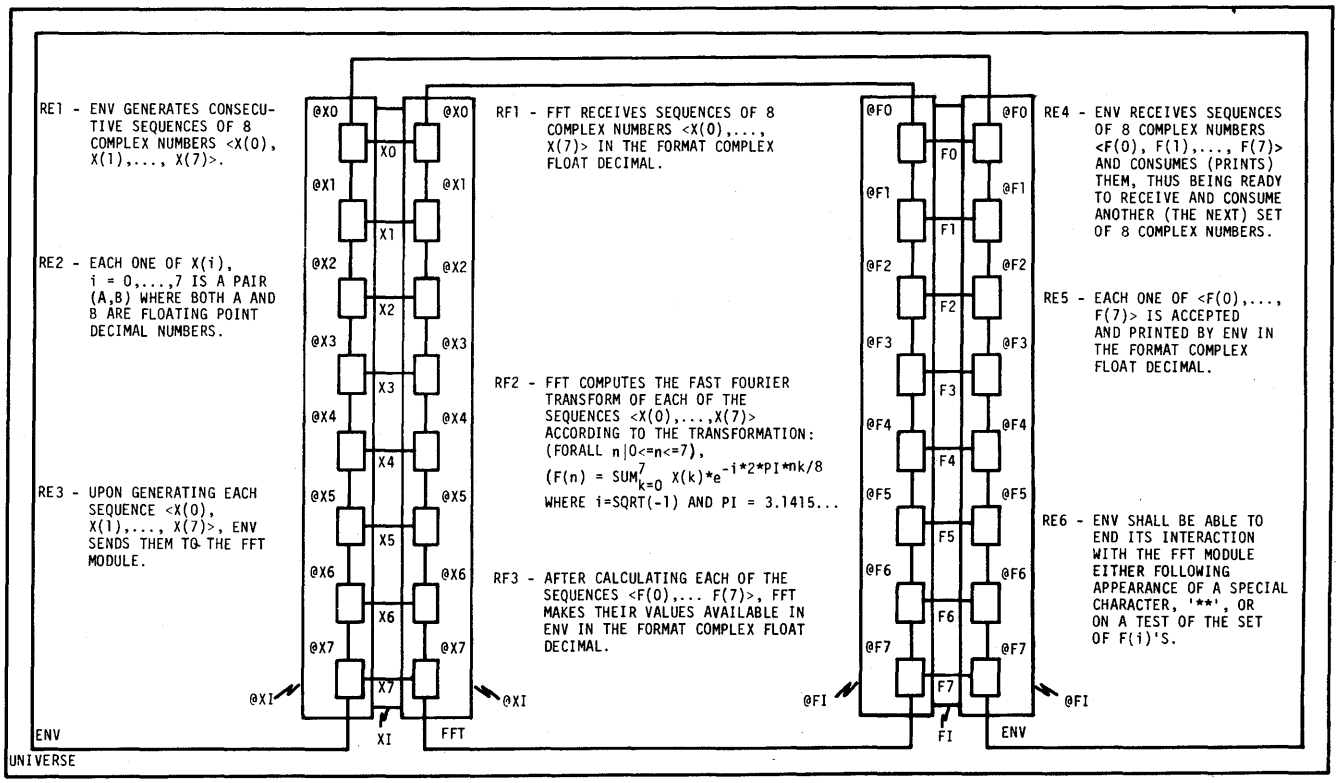

Figure 4—Structural model and requirements for FFT system showing SL1 for both abstract and refined socket levels

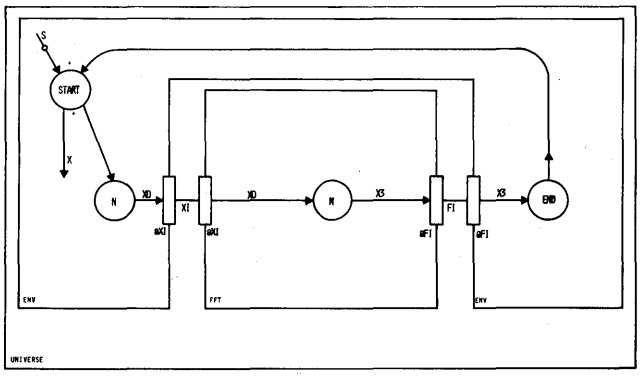

Figure 5(a)—High level FFT control graph

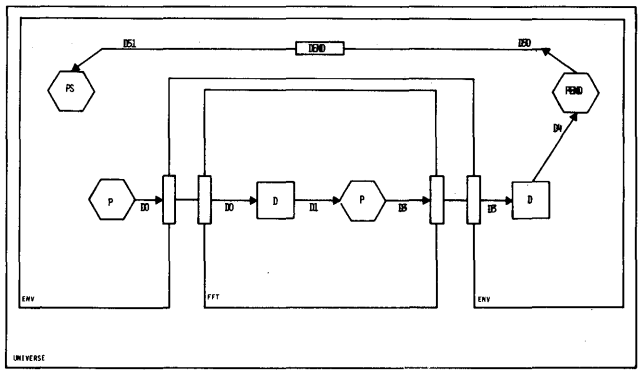

Figure 6(a)—High level FFT data graph

FFT structures. Figures 5A and 6A show the top level models. Figures 5B and 6B show more refined models. The machine processable representation of the GMB, the GMB to SL1 mapping, the PLIP interpretation and the socket attributes are generated in the same manner as for the design example MESSAGE TRANSMITTER. The detail is not included in this paper but is available on line at MIT-Multics. These high level models can be reduced to PL1 code in the same manner as the earlier example.

Let us assume that our tests check that the simulation model is proper and we consider composition utilizing a "butterfly" building block.

THE BUTTERFLY BUILDING BLOCK

The following description should give the reader a firmer idea of what is meant by a software building block in SARA. We continue our discussion with some informality in order to conserve space and to be readable. A building block model includes a name-set, an attribute set, structural models and behavioral models.

The name set provides a place to list all alias library names. In this case we call our building block FFT BUT. However the library might also respond to aliases like FFT BUTTERFLY or FFT BMOD.

The attribute set includes an informal description and comments about interpreters and versions. For this case the attribute set reads:

Informal description

The FFT "butterfly" whose non-procedural model and code are shown below in PL/I-like syntax is a software module designed to run in a multiprocessing environment (concurrently with other such computations) and perform one complex multiplication, one complex addition and one complex subtraction. The latter two operations are done in parallel within the butterfly.

Its usefulness is based on the existence of highly parallel algorithms that can be composed by binding several such procedures together in ingenious ways in order to compute the Fast Fourier Transform of arrays of complex numbers.

The input and output assertions for the Butterfly are

10**(−70)⇐abs(X0)⇐10**70
10**(−70)⇐abs(Y0)⇐10**70
X1=X0+WPY0, where WPY0 is a complex constant
Y1=X0−WPY0, where WPY0 is a complex constant
10**−70⇐abs(WPY0)⇐10**70

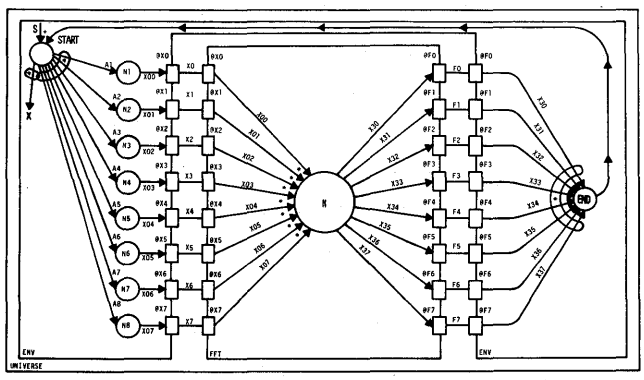

Figure 5(b)—Refined control graph

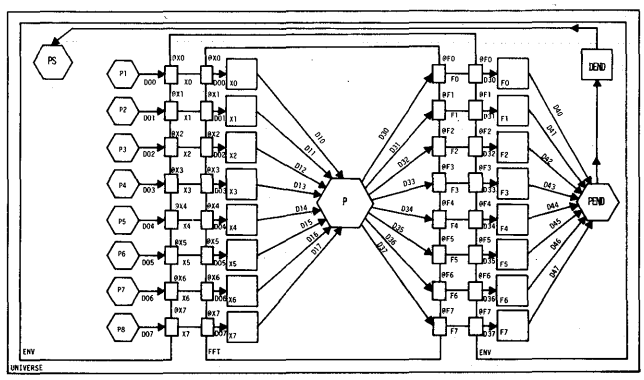

Figure 6(b)—Refined FFT data graph

```
FFT BUT: PROCEDURE;
      DCL (X0, Y0, X1, Y1) COMPLEX DECIMAL
    FLOAT (6)
  EXTERNAL;
      DCL (A3, A4, A7, A8) SEMAPHORE;
  DCL WP COMPLEX DECIMAL FLOAT(6) INITIAL(*);
  DCL WPY0 COMPLEX DECIMAL FLOAT(6);
  .....
  WAIT(A3 & A4)
  WPY0=WP * Y0;
  COBEGIN
  X1=X0+WPY0;
  Y1=X0-WPY0;
  COEND;
  SIGNAL (A7 & A8);

END FFT BUT;
```

Interpreters and versions

This procedure runs in PL/I multitasking environments, provided the availability of the following Concurrent PASCAL[31,32] constructs:

```
cobegin . . . coend
signal (semaphore expression)
wait (semaphore expression)
```

An ingenious implementation of Brinch Hansen's semaphores as an add-on to the PL/I machine is given in Reference 33.

We notice here that the construct cobegin . . . coend can trivially be implemented with semaphores. For each concurrently initiated task we issue a "signal(semaphore)", having a unique semaphore per task. Inside of each of those tasks, the first executable statement is a "wait(semaphore)" which waits for the appropriate semaphore. Upon completion, each task issues a "signal(completion semaphore)", one semaphore per task. The "coend" construct is then substituted by a set of "wait(completion semaphore)".

We shall use the cobegin . . . coend for it is syntactically more pleasing.

The structural and behavioral models are in the same form as used in our top down system design descriptions.

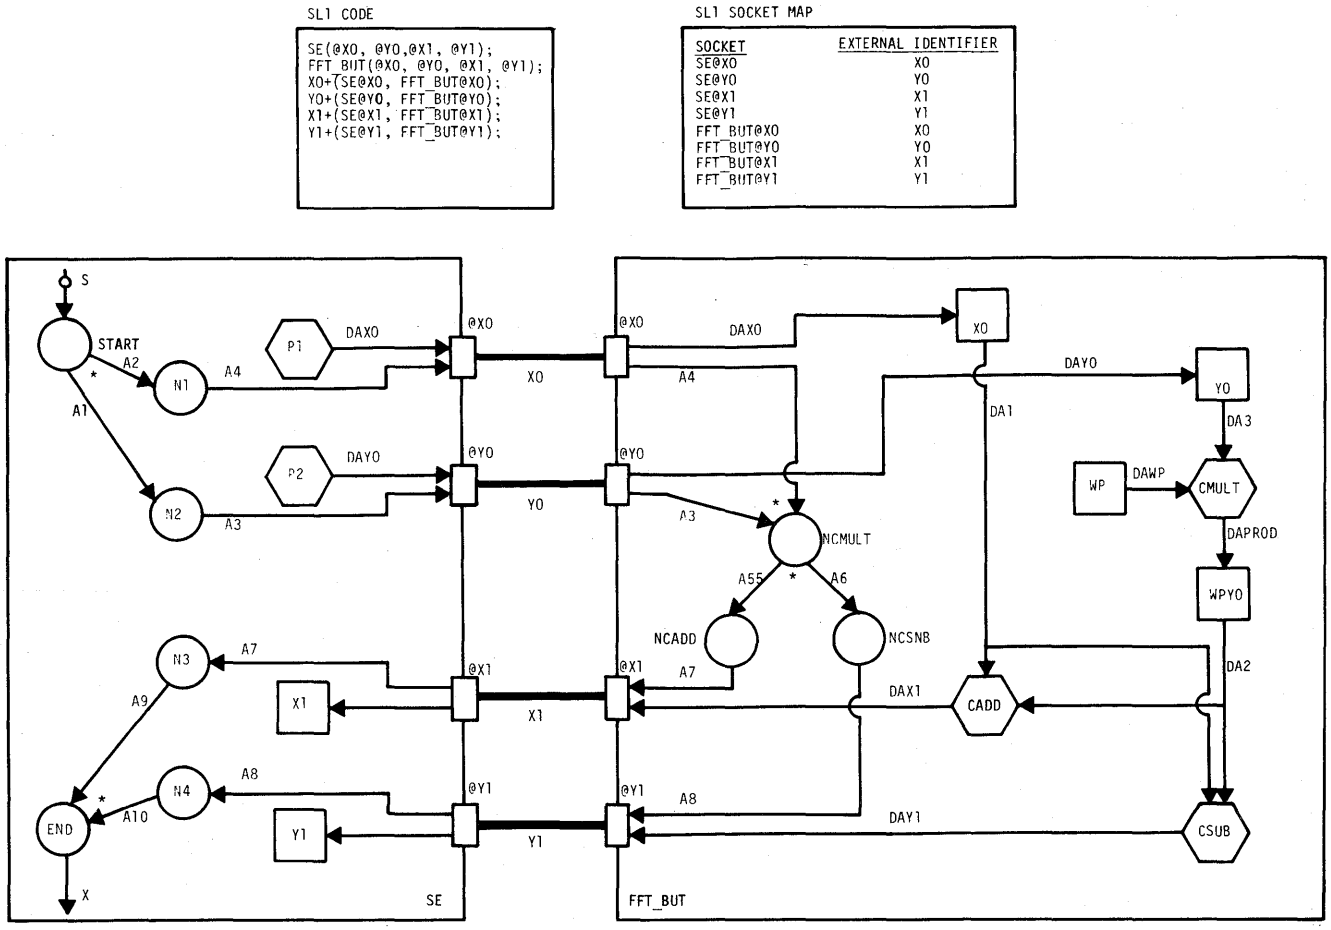

Figure 7—SL1 mapped graph model of FFT "butterfly" building block with its standard environment

MACHINE PROCESSABLE SL1 MODEL

Figure 7 shows a graphical representation of the GMB model of FFT BUT and of its standard environment SE. The structural model SL1 code and the socket to external identifier mapping are included in the figure.

MACHINE PROCESSABLE BEHAVIORAL MODEL

In similar fashion to the MESSAGE TRANSMITTER example above the building block model includes, for it and its standard environment, a control graph description, a data graph description, a PLIP interpretation for each processor and dataset, a socket behavior model and a mapping from GMB to SL1. If space permitted, the data graph interpretations would show how the SE processors P1 and P2 produce the real and complex inputs X0 and Y0 respectively and write them in the named datasets. The initiated multiplication process would be shown to use the input data and be followed by concurrent addition and subtraction. The real and complex results, X1 and Y1 respectively, would be shown to be delivered to the named SE data sets completing the operation. The full model has been executed and checked in the SARA simulator.

Additional behavioral characteristics of the model could be included. A memory requirement model might specify a bound of 1000 bytes. A precision requirement might specify that the outputs have a precision to >5 decimal digits. A timing model might specify a maximum time of one millisecond for each transformation.

COMPOSITION

We shall try now to describe composition of the FFT module using an ensemble of FFT Butterfly building block models to implement the algorithm defined by Cooley and Tukey.[30]

For an n=8 point FFT we have three basic alternatives for arranging the butterflies, in increasing order of parallelism, namely:

(a) one butterfly performing the computation in (n*log(n))/2 (=12) butterfly steps.
(b) n/2 (=4) butterflies performing the computation in 3 butterfly steps.
(c) n/2*log(n) (=12) butterflies performing the computation in one butterfly step.

We chose the third alternative, for it yields the most parallel (and more interesting for our demonstration purposes) algorithm.

At the time of writing this paper the composition procedure for taking building block models out of SARA's library and linking them together automatically had not yet been

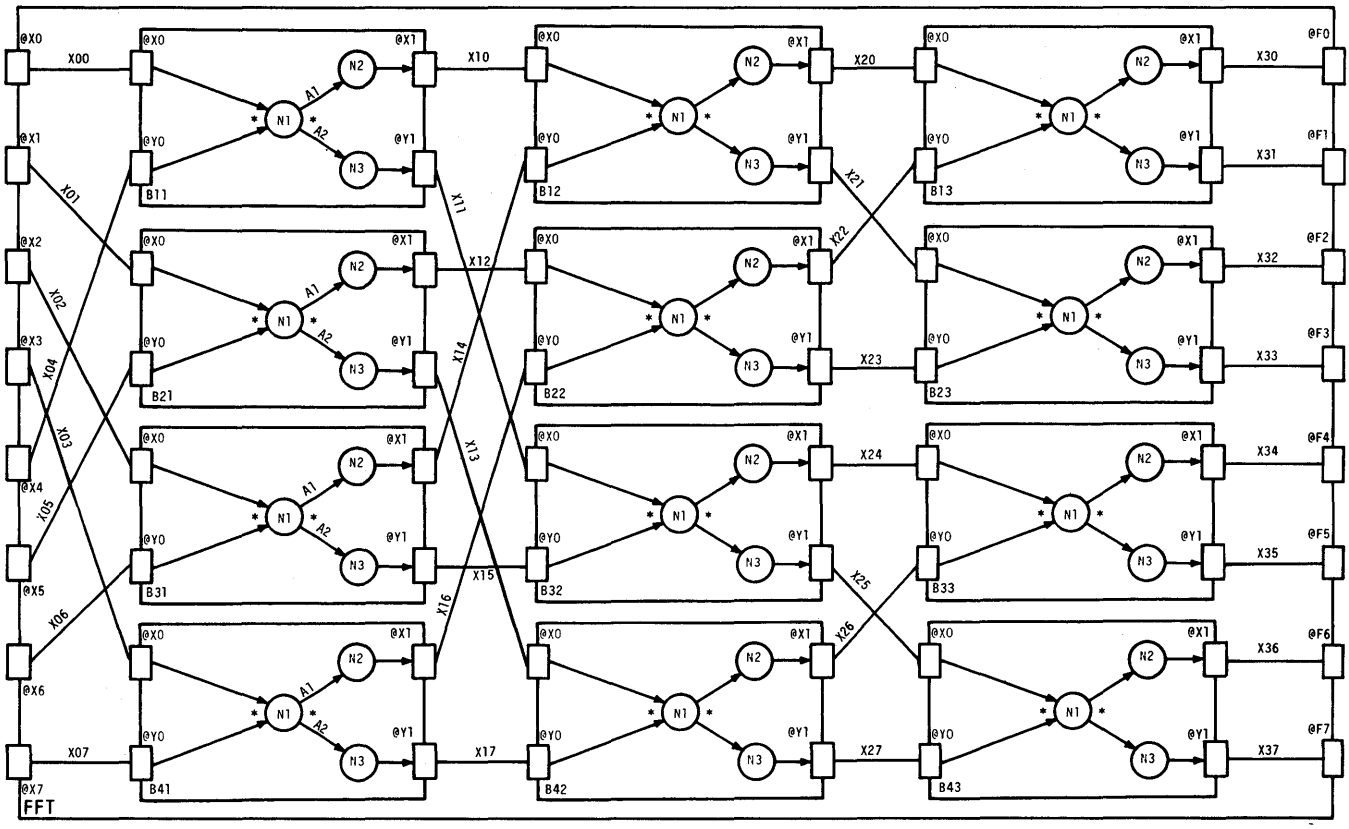

Figure 8—Control graph for 12 butterfly FFT

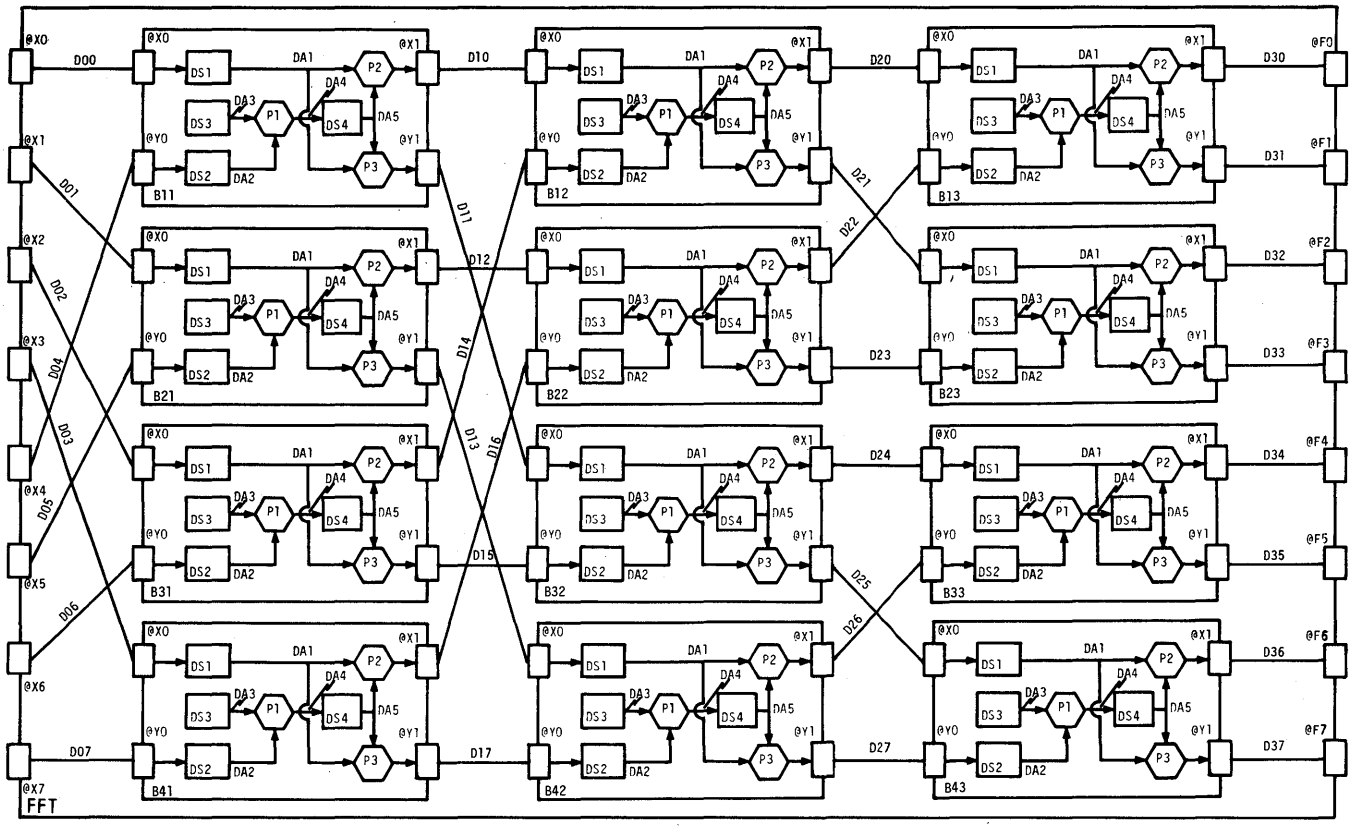

Figure 9—Data graph for 12 butterfly FFT

implemented. Each step was executed independently with existing tools because it uses the same procedure as would be used when creating an original model. The final result for the FFT model is shown in Figures 8 and 9 which display copies of the building block model interconnected to create a concurrent system implementation of FFT. A flow chart of the composition procedure is given in Figure 10.

Let us now consider the evaluation process. The flow-of-control is properly terminating. It can easily be abstracted back into a single control node because it is acyclic and its internal control logic is all "AND."

The data graph interpretation (PLIP) permits us to test and evaluate the FFT system interactively through the GMB simulator. The complete interpreted model was successfully executed. We could enlarge the design to cover a full signal processing system using the FFT as a building block so long as we were consistent with its ENV.

What may be more important is that, in the same manner as we have shown for the MESSAGE TRANSMITTER example, PLIP can be reduced to PL1 code and we have completed a path from programming-in-the-large to programming-in-the-small.

Obviously this is a demonstration problem which will get enriched as SARA matures. We do not presently propose, for each butterfly building block, a machine which can compile and execute PL1 programs. Such a machine may not be available on an LSI chip for a little while. In fact a principal goal of current SARA development is to provide interpretation of the data graph in languages which transform directly to programs that execute on microcomputer building blocks residing in a SARA system architecture environment.

CONCLUSIONS

As a superstructure to be imposed upon the final code or software systems, the structural and behavioral models have the following objectives:

- To show the potential flow of resource names between the structural components of a software system.
- To give a designer complete control over the distribution of information between modules. Sockets are the place where one states one's intent with regards to identifier visibility and access rights among modules at any level. The sharing of resource names is facilitated, without unwanted spread of accessibility, that is, different types of access are distinguishable (read-only, read-write), and access to different subsets of a set of resources can be specified. The idea here is to enforce the specifications over the source code at compile/link time.

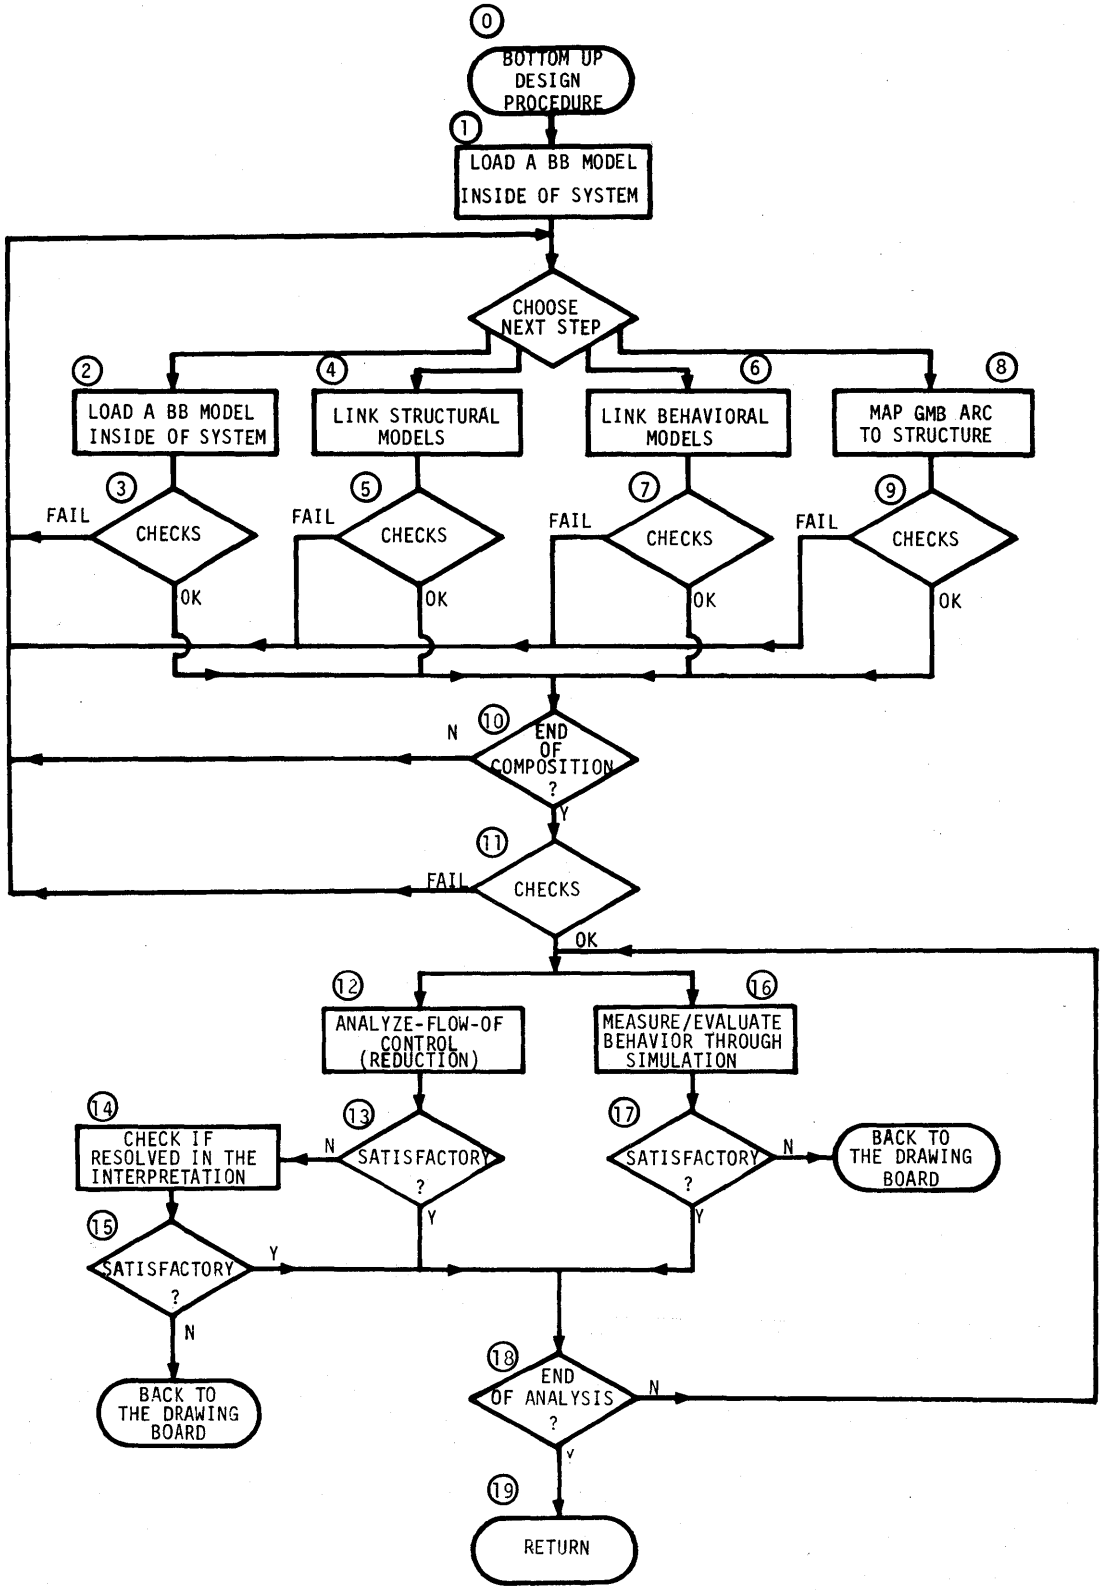

Figure 10—Composition procedure flow chart

- Both top-down and bottom-up design strategies are supported by multilevel modeling facilities.
- Hierarchical organization is enforced, and the structural model, in conjunction with the flow-of-control and flow-of-data models, can keep around conceptual entities that would otherwise vanish in the design process. The whole design tree is kept, not just the leaves, thus making the final product comprehensible both top-down and bottom-up. The SL1 model and the list of attributes associated with each of its sockets encompass what has been proposed in the literature[5,34] as a MIL (Module Interconnection Language). Our approach is more general in that we can define and enforce interface commitments among concurrent software systems.
- To increase the validity of the final product, all mappings and checks for completeness and consistency can be done with machine assistance through SARA.

With respect to flow-of-control, for example, SARA provides analysis facilities to check for proper-termination. A properly terminating flow-of-control model is reentrant, deadlock-free and has determinacy, i.e., regardless of the relative order of execution of the subprocesses involved, the unique output arc is reached and, aside from the vacated entry arc, the state of the control graph is the same as it was initiated to.

The main contribution of the SARA system for software synthesis is the fact that it offers a continuous path from programming-in-the-large all the way down to programming-in-the-small of possibly concurrent systems, while providing a designer with interactive tools and checking procedures to enforce consistency between requirements, structure, function and behavior.

There are a number of issues which require further study:

- The statement of requirements of a design is the cornerstone of the use of the design methodology. So far the English language description of this set is used in SARA. A more formal scheme for describing requirements is needed, as well as the associated criteria to evaluate whether or not a given design satisfies the previously stated set of requirements.
- The structural and behavioral models cited in this paper (SL1 and GMB) are restricted to representing static topologies. We currently handle any dynamic behavior in the interpretation associated with the data graph (i.e., in PLIP). Many interesting design problems, especially in the area of operating systems could be represented in a richer form if we could model and smoothly interface with a modeling scheme in which both the structure and the topology of the behavioral models could change with time, during execution. Other desirable features would be the ability to model recursion, dynamic storage and process allocation (i.e., everything requiring unbounded amounts of a resource) at the level of the GMB control and data graphs.
- Refinement and abstraction rules for GMB primitives are proposed in Reference 27, but they are fairly restrictive. The difficult problem here is to preserve "equivalence" between the two adjacent levels, both during refinement and abstraction.
- Many interesting asynchronous systems, especially in the process-control area are interrupt-driven. The modeling of interrupts in a GMB generates at least two control arcs per interrupt, which tends to overcrowd the control graph. Some extension to the current workings of the token machine should allow for a simpler way of modeling perhaps a restricted class of interrupt handling schemes, such as only allowing one interrupt handler for all interrupts.
- Currently, the only way two GMB processors can transfer information between them is through the use of datasets, which act as external (global) variables for the processors involved. We would like to provide designers with a means of passing parameters between GMB processors (although we might implement them internally in SARA as global variables) in order to make the process of translation from model to code easier.

GM network station—A low cost graphics system for body tooling

by THOMAS J. RENO
General Motors Corporation
Warren, Michigan

INTRODUCTION

Over the years, General Motors has been actively involved in both the development and use of Computer Aided Design/Computer Aided Manufacturing systems to aid in the design, engineering and manufacturing of automobiles. The use of CAD/CAM technology permeates most of our operations, but nowhere is it as important and pervasive as in the body tooling process. The demands for safety, environmental protection and energy conservation have required a responsiveness that only CAD/CAM systems could provide. No longer can we afford the long lead times of 3+ years previously required to go from design concept to steel. Today we must respond quickly and effectively to an ever changing car market—and CAD/CAM is helping us to do so by dramatically shortening the body tooling cycle.

The impact of CAD/CAM on our body tooling process has been demonstrated many times, but never more convincingly than in the years following the 1974 oil embargo. This new technology enabled us to produce the 1976 subcompact Chevette in only two years in response to a then rapid shift of public sentiment to small cars.

CAD/CAM contributed heavily to the design and tooling of our 1977 full size cars. In fact, Mr. Howard Kehrl, GM Executive Vice-President, stated in a Business Week article that only through use of this technology were we able to produce our 1977 'B' and 'C' models *at all,* after a nine month initial delay and a major shift in specifications halfway through the program. Computer graphics was also used to evaluate the structural characteristics of proposed designs and to eliminate much of the trial-and-error process previously involved in making design changes.

CAD/CAM has truly come of age and is now an integral part of our business. It is difficult to imagine how we could design and build a car without it. But CAD/CAM did not just happen in General Motors. Its acceptance today is the culmination of a long process begun in the late 1950's when the possibilities of the newly emerging technologies of Numerical Control and visual man-computer interaction were first recognized.

SYSTEMS ORIGINS

The GM Research Laboratories pioneered man-computer communication through their DAC (Design Augmented by Computer) project. At the same time, GM Manufacturing Development was developing N/C technology for sculptured body tooling. Significant resources of both people and money were devoted to these projects and to related developments in the areas of mathematics and computer science until usable prototype systems were available. These prototype systems included sophisticated new mathematics capable of representing the types of curves and sculptured surfaces found on automobiles; data bases and data structures capable of storing these mathematical models; regional milling capabilities for both ball cutters and end-mill cutters; and user interfaces which permitted the easy addition of other new applications such as structural analysis, vision studies, etc.

In 1967, Manufacturing Development was assigned the responsibility of transforming these prototype systems into usable production tools. The result was two complementary systems, CADANCE (Computer Aided Design and Numerical Control Effort) and INCA (Integrated Numerical Control Approach), which together provided an effective CAD/CAM base for design, engineering and tooling. Additional application and system development was undertaken by Fisher Body and Design Staff to finally bring all of the development efforts into full production use. The systems in use today at GM are the result of all these combined efforts.

COMPUTER AIDED DESIGN BACKGROUND

The CAD systems in General Motors were all developed as outgrowths of the original DAC system and used computer graphics and time sharing as the base upon which they were built. Today approximately 75 graphic consoles served by two large computer installations at the GM Technical Center are employed by our divisions and staffs to do body

design and engineering work. The CAD systems all employ refresh graphic display devices and accept virtually all of their input via light pen selection from the face of the screen. Similarly, all of the output is transmitted to the user via displays on the screen. This combination of time-sharing, graphic input and graphic output provides an unbeatable combination for problem solving. Mistakes are detected instantly and the problem can be re-run at once. Long delays waiting in input and output queues are totally eliminated. The lead time savings achieved using this technology are truly impressive. Very often 6-8 weeks are eliminated from a conventional 12 week job.

COMPUTER AIDED MANUFACTURING BACKGROUND

The CAM systems developed for body tooling exploited the technology of Numerical Control and used the computer facilities available at the time. This was, as mentioned earlier, in the late 1950's and 1960's. At that time, batch mode computer runs using card input and obtaining printed output was the standard bill of fare. Some minor improvements such as Remote Job Entry (RJE) facilities and Time Sharing Option (TSO) were added to the batch systems, but the basic philosophy of our CAM programs remained unchanged. There was no way to avoid the long waits in input queues and output queues, the randomness of courier deliveries, or the large stack of printed output which had to be examined for possible errors.

The CAM programs, such as INCA and APT, used by GM were developed to process the masses of numerical control data required for wood model and die construction. Human decisions were emulated within these programs wherever feasible or possible. Nevertheless, human intervention was required to analyze and evaluate intermediate results produced by these computerized processing aids. These results were in the form of computer listings and usually had to be converted to graphical form via sketches or drafting machine drawings. This process obviously was very time consuming.

For a number of years, this mode of operation was accepted, although the long time delays associated with each step were excessive. The technology of N/C, however, progressed and saved time and money in spite of long processing times. Indeed, instead of working to improve the process, we worked on improving the technology of N/C. Regional milling techniques and flow line cutting were honed to perfection. Sophisticated evaluation techniques and surface linking programs were developed and brought into production use. A data storage and retrieval program which virtually eliminated data cards was perfected and has been operational since the late 1960's. CAM technology indeed grew to where today nearly all full size interior and exterior sheet metal wood models are cut using N/C.

REASONS FOR CHANGE

All the while, however, the operational procedures remained unchanged. The CAM systems became a victim of the computer technology upon which they were based. The batch mode operating systems did not allow any meaningful operational improvements to be made. It still took several weeks to produce a complete set of cutter tapes for a complex wood model. The CAD systems, on the other hand, had benefited from new advances in computer hardware and software and were achieving remarkable results in both processing capability and lead time reduction. The N/C lead times began to be the bottleneck and it soon became apparent that improvement in processing techniques was essential.

Based on the effectiveness that computer graphics had demonstrated in the area of Computer Aided Design, it was obvious that this technology could provide similar processing improvements to our Computer Aided Manufacturing systems. However, it was not obvious exactly how to proceed to implement a graphics CAM system in GM. Since we were attempting to modernize an existing operation—not start a new one—we had to take into account constraints the existing program imposed on us. These were geography, cost, and time.

GEOGRAPHICAL CONSTRAINTS

In GM, the vast majority of design activities occurs within the square mile area of the GM Technical Center. Tool manufacturing, however, encompasses a much larger area and even extends to West Germany where Adam Opel is an active participant in our CAM activities. Any modification of our CAM system for body tooling had to encompass *all* tool manufacturing. Computer graphics—even today—has difficulties economically locating consoles more than one mile from the computer. Consequently, any move of our CAM systems towards computer graphics had to be independent of the large Technical Center computers.

COST CONSIDERATIONS

As to cost, the batch N/C systems had been tuned over the years to the point where processing charges were quite minimal. Also, CAD via graphics had created an excellent data base from which our CAM activities could begin. This meant that very often the full power of the large Technical Center computers was not needed for our CAM work, and if we used them we would be incurring greater processing costs than necessary. This again indicated that a solution independent of the large Technical Center computers was required.

IMPLEMENTATION TIME CONSIDERATIONS

The repertoire of computer programs used in die model construction is very extensive. All of the programs are required in some degree to complete the job. Any modernization of our CAM system would have to take this into account and provide access to similar facilities. Since it would be impractical and very expensive to convert all ex-

isting programs to a graphical format, any new system would have to be compatible with the in-place system.

SYSTEM SPECIFICATION

With these considerations in mind, Manufacturing Development began exploring hardware/software combinations that would meet our objectives. We needed a system that was inexpensive, could operate independently of large computers, and yet could communicate freely with the existing in-place systems. In 1973, we began development of a *Low Cost, Stand-Alone N/C Review System* to bridge the gap between CAD and CAM. This system answered the questions of geography, cost and time and seemed to be a start towards getting the benefits of graphics into our body tooling manufacturing.

HARDWARE COMPONENTS

The system developed consisted of:

Mini-computer with Disk Storage
Interactive Graphic Terminal
Medium Speed Dial Phone Line
N/C Tape Punch

Its total purchase price is approximately $75,000, which equates to less than $10/hour for a one-shift operation. This is well below the cost of large central time-sharing computers and even less than batch system costs. The system is indeed a stand-alone system. It can be placed in any room of any plant and requires no special wiring, floors, or unusual cooling. Its dial-up phone line and N/C tape punch enable remote units to communicate with each other or with the central computers at the Technical Center. These features overcome the geographic and implementation time constraints imposed on our CAM system.

HISTORY AND INITIAL IMPACT

Initially, this system simply provided a graphic input and output facility for our existing batch mode CAM programs. Substantial lead time was gained by simply reviewing data and input commands graphically before submitting them, thereby detecting errors early in the game and correcting them *before* batch runs rather than after. Similarly, graphic review of the output was faster than laboriously scanning pages of printout or waiting for full size drawings to be made on already overloaded drafting machines.

The initial components of the system were few. There was a data base manager to store and retrieve information. Function buttons were available to change views, shift, scale, rotate data, etc.

In addition to these graphic data review features, other computational programs were available to:

Create arcs, circles, straight lines
Modify Data (delete, insert, move points)
Transform Data (Rotate, Translate, etc.)
Create Card Images for Job Submission to Large Computers
Teleprocess
Punch Mylar Tape

This simple review system allowed us to export Computer Aided Manufacturing technology to our plants and was a start towards bringing the benefits of computer graphics to the manufacturing floor.

A CHANGE IN DIRECTION

The use of this low-cost review system never became very pronounced, however, because even while doing our initial development work on the system we realized the potential we had at our fingertips. It became readily apparent that the mini-computer was never really being taxed. The users also posed the question, "Why, since I have all my data here, can't I generate my N/C tapes here?" This, then, marked the turning point of the project and brought about the renaming of the system to the 'Network Station.' This name symbolizes two things. First, the system is still part of our overall CAD/CAM program and depends on access to the central data bases via the telephone network. Second, once the data is received, the system operates as an independent station until the job is complete. The term 'Network Station' seems to fit nicely the function and use of the system.

DEVELOPMENT AND CURRENT CAPABILITIES

User divisions enthusiastically accepted this change of direction and even contributed manpower to assist in the software development. Eight departments representing five divisions and staffs have participated in the Network Station development. Some of the items added to the software repertoire to make possible a full stand-alone operation include:

Additional Curve Generation Functions (Fillets, Sweeps, etc.)
Curve Smoothing
3-D Meshing
Surface Development
Surface Linking and Trimming
N/C Machining
Interactive Cutter Location Verification and Modification

Through the use of this system, it is now possible to completely process our most difficult wood models without using any of our old batch CAM programs. This includes surface definition, cutter location, and N/C tape punching. Divisions with easy access to the Technical Center computers still find it more convenient to use the existing old CAD/CAM

interfaces, but they are all acquiring Network Stations for future use. Someday this new graphic CAM system may make our old batch systems completely obsolete.

NETWORK STATION DATA FLOW

The Network Station offers a range of CAM uses never before available in our body tooling process. The ability to teleprocess information, read in punched tapes, or create data directly on the system provides for a wide variety of different input sources. For example, inputs from all of these sources are a commonplace occurrence today.

Teleprocessed Information from CAD Data Bases
Digitized Information on Punched Tape
3-D Input from Hard Model Scanners
Cutter Location Information on Punched Tape
Experimental Drawings

These input sources cover all of the common ways in which data is now collected. Once entered into the system, the user can proceed to process the model. When finished, a number of choices are available for outputting results. These include:

Punched Tape for Computer Controlled Mills
Punched Tape for Drawing Machines
Data for Teleprocessing
(a) To a Large Computer for Additional Processing
(b) To a Remote Site for Machining, Viewing, etc.
Printed Process Sheets
Printed Checking Information

NETWORK STATION ACCOMPLISHMENTS

As a testament to the productivity and flexibility of the Network Station, Fisher Body, Die Engineering Activity, now uses this system for virtually all of their CAM work related to body tooling. They have six systems which they now use to produce:

All Wood Die Models (Inners & Outers)
All Seat Bun Patterns
All Bend and Sweep Gages
Production Glass Block Tapes
Die Profile Tapes

DIVISIONAL INSTALLATION

Fisher Body is by far the largest single user of our Network Station. They are not, however, the only user. Seven divisions and staffs have equipment either installed or on order. Several others are actively pursuing authorization for equipment. The tally as of now is 18 units installed, 3 awaiting delivery and 3 in the process of approval. The divisions also have tentative plans for 10-12 additional units in the next two years. These units are located as far away as West Germany, thus demonstrating the true stand-alone nature of the system.

GROWTH OF CAD/CAM CENTER

As you can see, the Network Station is rapidly becoming the dominate force in our N/C body tooling system. The growth of this system is well in tune with the expanded use of our Computer Aided Design programs and indeed complements and supplements our design and engineering systems. As the use of CAD grows, it too is spreading out geographically to our outlying divisions and plants. We are even now locating graphic design consoles in Lansing, Pontiac and Flint. The hardware used for both our CAD and CAM systems is interchangeable and thus permits multiple use of the same equipment.

MULTIPLE USES OF EQUIPMENT

For example, a typical remote installation consists of:

Mini-computer and Peripherals
Graphic Console
Drafting Machine

When the mini-computer and the Graphic Console are connected, the result is a Network Station. The Design Console can be connected over high-speed telephone lines to the central CAD computers, thus allowing the mini-computer to be used for teleprocessing, other computing applications, or as an input source for the drafting machine.

The drafting machine, of course, can also operate independently of the mini-computer. This combination of hardware and software allows full use of all equipment, provides access to both CAD and CAM programs, and allows the user to operate either as part of the central design and engineering community or as a stand-alone station. Also, since no specialized hardware is used, it is easily maintained, can be inexpensively upgraded for more power, and a wide range of peripherials such as plotters, digitizers, etc., can be easily added.

ADAPTABILITY OF SOFTWARE

The intent of the Network Station has always been to get some computer power out to the plants where the work is actually done. Realizing that each plant operates somewhat differently, and knowing that one central development activity could never fill all of the needs of all the plants, we designed the Network Station system to be very easy to program. All application programs are written in Fortran. All input, output, and graphic commands are available to the programmer via simple subroutine calls. A simple programmer's manual is available which describes how to write Network Station programs. In addition to our own staff, we have trained twenty-two people representing six divisions

and staffs how to add applications to the system and they have all contributed to some degree. Our experience has been that a programmer knowledgeable in Fortran can be an accomplished Network Station programmer in a period of approximately four weeks.

POTENTIAL FOR COMPUTER AIDED MANUFACTURING

The impact of computer graphics on the GM body tooling cycle has been very substantial. But full lead time and dollar savings will not be achieved until the entire body tooling cycle from design concept to production die is affected. To date the major impact of this new technology has been in the area of product design. Our large graphics systems have been profitably used in body design and body engineering for several years. However, examination of the distribution of work in the body tooling cycle shows that 88 percent of all hours are expended in tool design and construction. Similarly, 70 weeks are consumed in this effort as opposed to only 17 weeks for panel design. Clearly, the greatest potential savings are in these areas, and we have scarcely begun to impact them.

THE BODY TOOLING SCENARIO

What is ultimately required is a general machining-manufacturing system for body tooling. This system would use high performance Numerical Control machines to do the milling and inspection of die models and dies. The processing, communications, and coordination would be done on small computers linked together by telephone lines. The system we envision would consist of at least three major parts.

The first would be Tool Design. Here the die models, dies and fixtures would be designed. The product design data would be used to determine how many and what kinds of dies are needed to produce a part and also the sequence in which the dies would be used. The amount of die tipping would be determined and the runoff conditions developed. Binders and die and checking fixtures would be designed. All the necessary drawings would be output.

The second part of the system would deal with the machining of the die models, dies, and related tools. The product design and tool design data would be used to generate N/C tapes to drive the mills. These tapes would contain all the machining information. They would be verified and used to machine wood die models, gages, and glass blocks. Tapes to cut metal would be produced either from the design data or by tracing the wood die models with computer controlled scanners. All tapes, process sheets, and listings that are necessary for setup and milling would be produced. If the use of computer controlled inspection machines becomes widespread, these tapes would also be generated.

The third part of the system would ensure proper utilization of equipment and metal in the stamping plants. Offal would be scrutinized to see if other parts could be produced from it. The press configurations and material handling equipment would be checked to see if they were available and not overloaded. Once this was assured, layout drawings would be generated and sent to the plants. In addition, material deviation studies would be done to ensure that no plant was using a higher grade metal to produce a part than other plants.

CONCLUSION

We are slowly working towards developing such a system, and the Network Station plays an important role in these future plans. We are already actively working with the divisions to develop programs in the areas of die processing, press planning, clay milling and 5-axis tool center computations. A prototype program for generating N/C inspection tapes is already available on the Network Station. Also, programs to minimize metal waste through optimum blank nesting are now under way. We are convinced that for N/C technology to succeed, it must become the "conventional process." The Network Station is helping this happen by placing the computer in the plant where the work is done and by removing the mystique from Computer Aided Manufacturing.

In summary, we have a tiger by the tail in our Network Station project. He has "devoured" every task given to him and still seems to have a voracious appetite. We are letting go of the tail a little at a time as we assign more and more of the new body tooling applications to him. We feel that it will take quite a while before either his appetite is satisfied, or we "run out of tail."

Computer aided design (CAD)/technical data automation (TDA)

by VERNON R. PEARL
U.S. Army Research and Development Command
Aberdeen Proving Ground, Maryland

INTRODUCTION

The Technical Data Package (TDP) is the terminology used by the U.S. Government to describe the documentation generated during research and development for the procurement of end items.

Spiraling costs in producing TDP's have long been a major concern of the Department of the Army. Thousands of engineering drawings, specifications, standards, and other related technical data that make up a TDP are produced each year. These TDP's are used to document, in detail, the Army materiel end items required to supply troops in the field and to maintain a state of constant military readiness. With industry and Government continuing to change the technological base in both design and manufacture, keeping documentation up to date has become costly and difficult. Because of the continually changing technology, end items may soon become obsolete and many of the repair parts required to maintain fielded items would no longer be manufactured. In either case, it's "back to the drawing board" to start a new design, improve an existing one, or rework items in the field to allow for procurable spare repair parts.

At the CSL-Technical Support Division, ARRADCOM, which services the CSL at Aberdeen Proving Ground, Maryland, there are approximately 50,000 engineering drawings on chemical-related items. There is also a vast number of standards and specifications associated with these chemical items. New chemicals are constantly being developed. Sometimes the specific chemical required to produce a certain munition is not always available. These factors contribute to a high rate of both drawing and specification changes and lead to many contract waivers and deviations. All of these problems result in changes to the technical data and higher documentation costs. It is for these reasons that we begin looking into using the computer in an effort to reduce both time and costs and to streamline the entire technical data generation process.

EXISTING EQUIPMENT AND SOFTWARE

The equipment selected for accomplishing computerized engineering drafting is as follows:

1. A plotting and digitizing system (manufactured by Actron Industries).

This system was purchased in 1972. It consists of a 5- by 12-foot drafting table and a control console containing a digital computer and other electronic equipment related to monitoring and measuring functions. In addition, the console is equipped with a closed-circuit TV monitor providing the operator with a magnified view of the drawing area and enabling him to select individual points for digitizing or to monitor and supervise an automatic drafting operation (Figure 1). A drafting and digitizing head suspended from a gantry and armed with an optical line-following device produces the X-Y coordinate data required for line definition. The system is basically restricted to two-dimensional work but certain perspective, isometric, and three-dimensional views can also be produced. In the digitizing process (the ability to automatically define lines and curves), the measurement system continuously reports line locations to the computer. The computer is programmed to process this data into a tool-path description and output a numerically-controlled tape complete with spindle speeds, feed rates, and other miscellaneous functions. The completed tape can be inputted directly to the machine tool without any further need for processing.*

2. A refresh interactive graphics system (manufactured by Information Displays Incorporated).

This stand-alone system was purchased in 1973. It contains a display console, a display controller, a graphic display processor, a teletype station, a magnetic tape unit, and a disc. The display console consists of a 21-inch cathode-ray tube (CRT), a light pen, and an alphanumeric keyboard. The display controller has vector, character, and circle generators, four types of line structures, and four levels of intensity control. The graphic display processor consists of 32K of core. It has hardware multiply/divide, direct memory access, a priority interrupt module, and an automatic boot

* SME Technical Paper MS73-958, "Application of Automated Drafting and Digitizing at Edgewood Arsenal," by Vernon R. Pearl.

Figure 1—Drawing being digitized

strap loader. The magnetic tape unit uses 7-track, 800-bpi dual-density tape. The disc has a 1.1 million word capacity. The drafting and design software consists of drawing lines, circles, arcs, and rectangles. Texts and symbols can also be generated. Other functions include move, plumb, level, copy, delete, and group. The system also contains library support for storing symbols and procedures for saving, starting, getting, and deleting drawings. The system is a general-purpose operating system programmed in Fortran. In 1975, an additional display console was added to the basic system including a time-share capability which allows for simultaneous and independent utilization of either console (Figure 2). In 1976, a third stand-alone system was purchased and is currently being interfaced with the laboratory's Univac 1108 computer. Other software improvements recently added include three-dimensional modeling/dynamic simulation and printed circuit-board-layout routines.

These three systems in conjunction with the drafting/dig-

Figure 2—Two-station interactive graphics system in operation

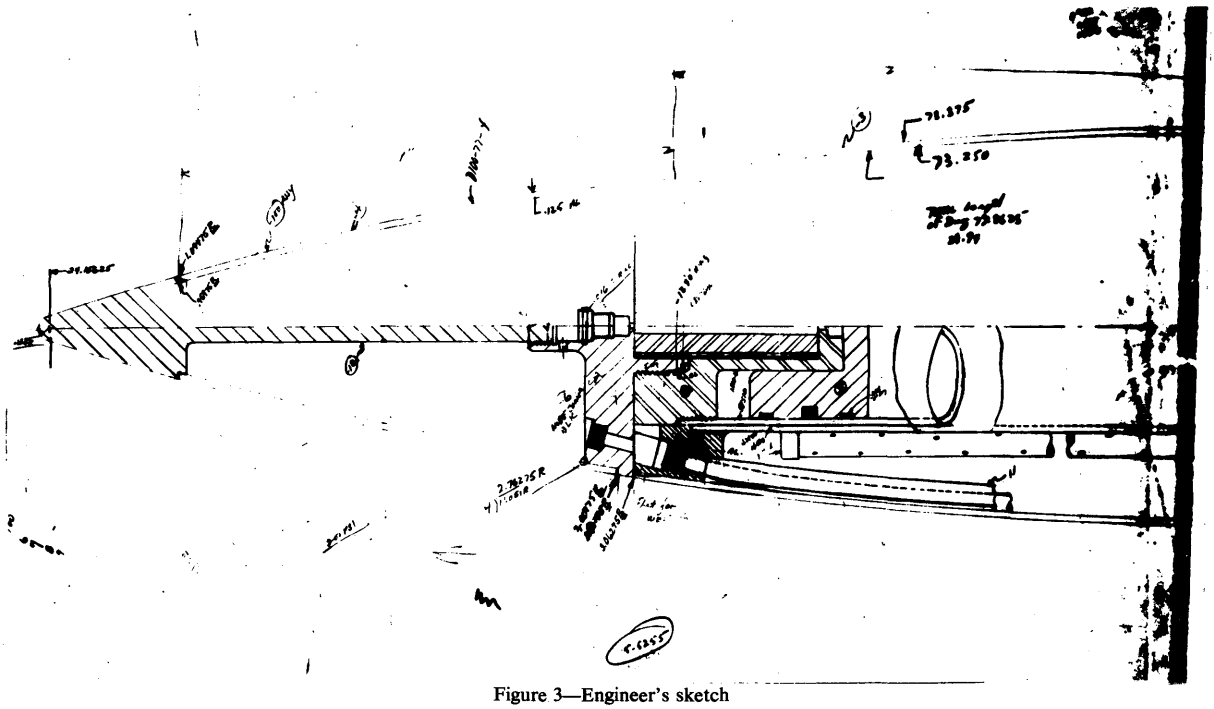

Figure 3—Engineer's sketch

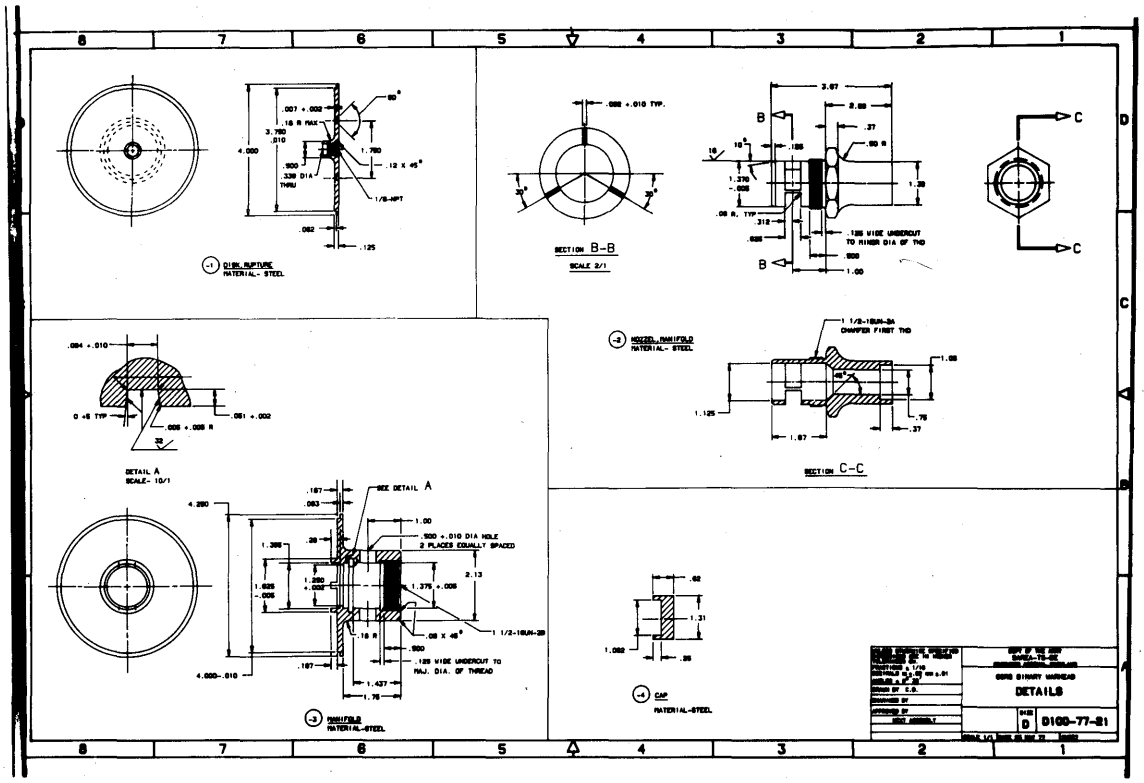

Figure 4—Drawing details

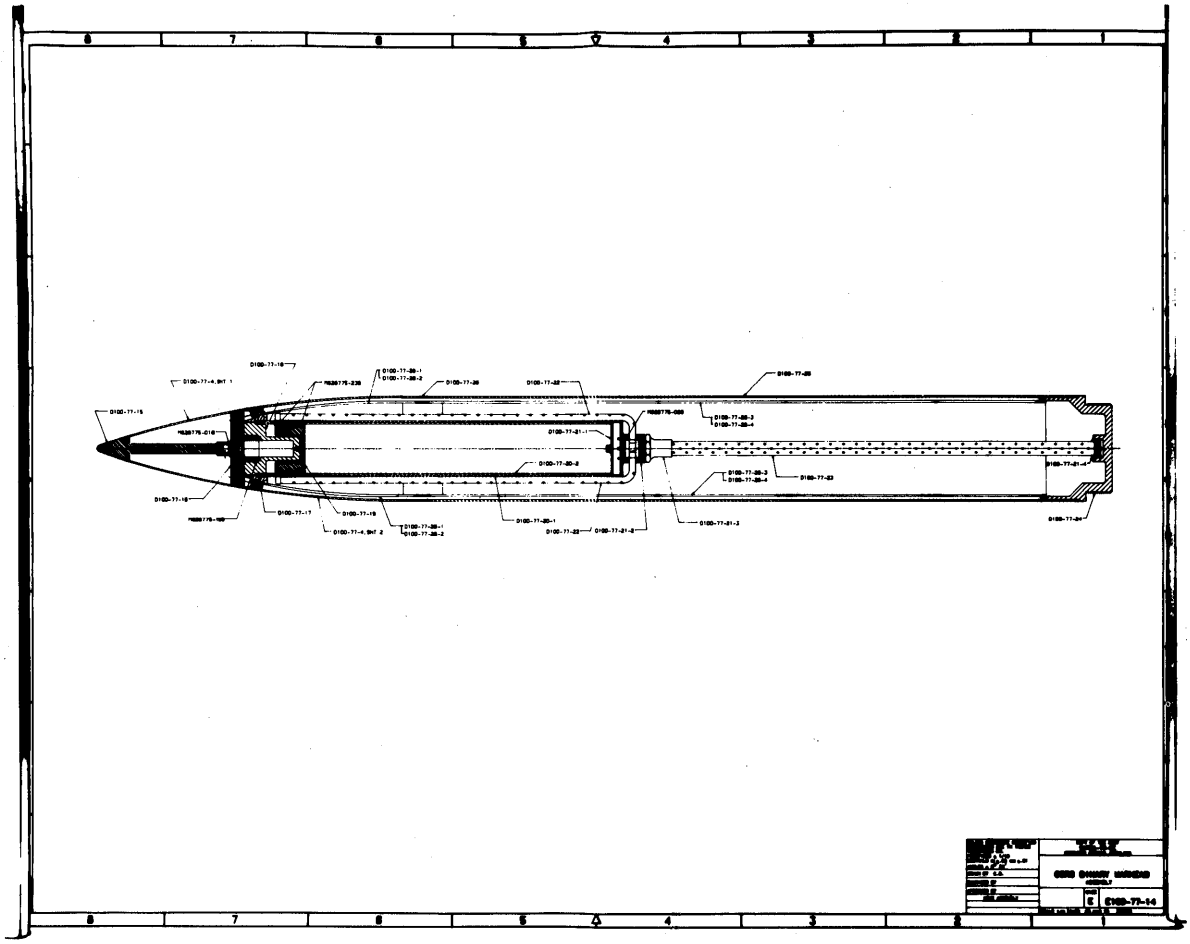

Figure 5—Assembly drawing

itizing system have given us an extremely powerful computer-aided-design system.*

COST-SAVING EXAMPLES

There are many varied cost-saving projects that have been accomplished through the use of this computer-aided-design system. The examples chosen were picked mainly because of their relation to technical data work. Keep in mind, however, that printed circuit boards, numerical control, floor plan layouts, etc., can also be accomplished using CAD.

1st example

This example is one of the more common types performed with the system. An engineer brought in a sketch of a binary munition (Figure 3). He had semi-scaled the sketch to get the proper proportions. With this information we were able to digitize the various proponents using the Actron equipment and ascertain such data as volume, first moment about the Y axis, center of mass along the X axis, second moment about the X-Y axis, radius of gyration, polar moments, and surface areas. The significance of using this program is that while you are designing you can easily determine moments at any time without using any mathematical formula or doing any computer programming. A density factor can be input through the teletype to allow calculations to be made of an object or shape which is constructed of nonhomogeneous material in seconds. The design can be immediately adjusted to achieve the configuration necessary for proper flight stability. Once the engineer is satisfied with the design configuration, the parts are automatically drawn up on the CRT (Figure 4). The parts are then combined to make an assembly drawing (Figure 5). This combining operation checks for both alignment and proper fits, such as does the O-ring engage properly to its mating part. The system also has the ability to automatically dimension any line or circle that has been put on the screen. This method of design allows the operator to make changes rapidly, catch errors, save on fitting calculations, and merge drawings.

Twenty prototype drawings were required to describe the items sufficiently enough for fabrication by the experimental metal shops. By using the computer-aided-design system on

* SME Technical Paper MS77-764, "Cost Effectiveness of Computer-Aided Design (CAD)," by Vernon R. Pearl.

this job, all calculations and drawings were completed within two weeks. It is estimated that approximately two months would have been required if it had been done manually.

2nd example

This area of cost savings comes from the use of a three-dimensional software package with dynamic rotation that resides within the graphic system. The Research Division of the Chemical Systems Laboratory uses this software routine to visualize and verify molecular binding. Before this routine can be used, certain coordinate data describing the molecule must be fed into a molecular coordinate calculation program that resides within the Laboratory's Univac 1108 computer. This program gives the scientist an idea of the shape of the molecule and produces a printout yielding the X, Y, Z coordinates of the various elements associated with it. This data is then fed into a molecular orbital calculation program which produces X, Y, Z coordinates for a minimum energy configuration of the molecule. The scientist has no way to visualize these several sets of data in space. Incorrect data fed to the computer would go undetected. Erroneous data used in further research proved costly in both time and manpower.

To eliminate this problem, the initial molecular coordinate data is now displayed on the graphics system after the initial Univac 1108 data is received (Figure 6). Here it is possible to rotate the entire molecule at any atomic point and at any angle to check the bonding for errors. This verified data is then fed back into the Univac 1108's molecular orbital calculation program. The new data is again displayed on the screen. This becomes quite significant, since the scientist can now see the minimum energy configuration which may bear little resemblance to the original configuration. This visual display allows for a more direct and rational evalua-

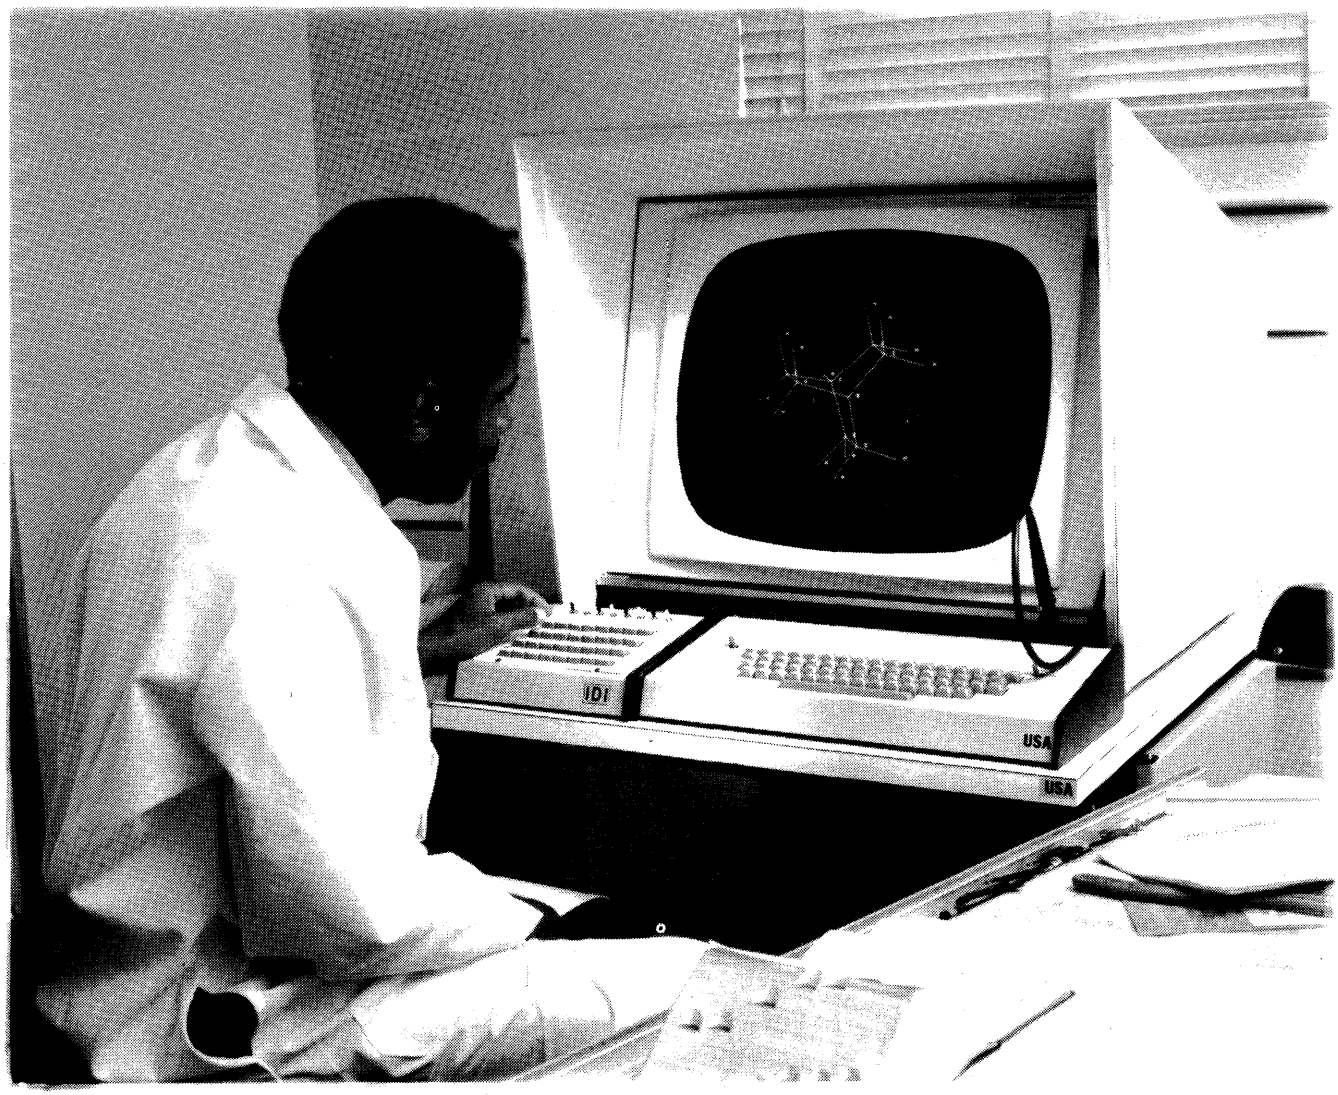

Figure 6—Molecular rotation displayed on the cathode-ray tube

tion and replaces expensive manual simulation methods. We also have the most probable molecular configuration which will subsequently be used in various biological and physical studies. Though the savings are somewhat intangible, one can easily see that by using the computer-aided-design for just one hour per molecular validation many man-hours of the researchers labor are continually being saved.

3rd example

This example is a mechanical schematic, which was accomplished with ease by using the graphic system. A freehand sketch giving an idea of the flow was the only requirement needed to get started. Symbols generated months ago and stored were pulled from the library and displayed on the screen. New symbols were generated as required. The plumb and level functions were used to line up these symbols. A line connecting function was used to tie the symbols together. The alphanumeric keyboard was used for labeling. Once again changes were completed rapidly. Sections could be grouped and relocated anywhere in the drawing in seconds (Figure 7).

Including changes, the drawing was completed in one day, and it is estimated that three days would have been required if it had been done manually. Electrical schematics and wiring diagrams are also easily handled using the same techniques.

4th example

The final example depicts a set of production drawings used in a TDP for manufacture by contract. To prepare drawings for a TDP was the primary reason the equipment was purchased. The development of a TDP can take anywhere from two to six years and requires many man-hours of labor and various prototype hardware building and testing methods. Engineering drawings, and changes to them, are involved in nearly every step of the development phase. The cost of producing drawings while going through this cycle,

Figure 7—Mechanical schematic

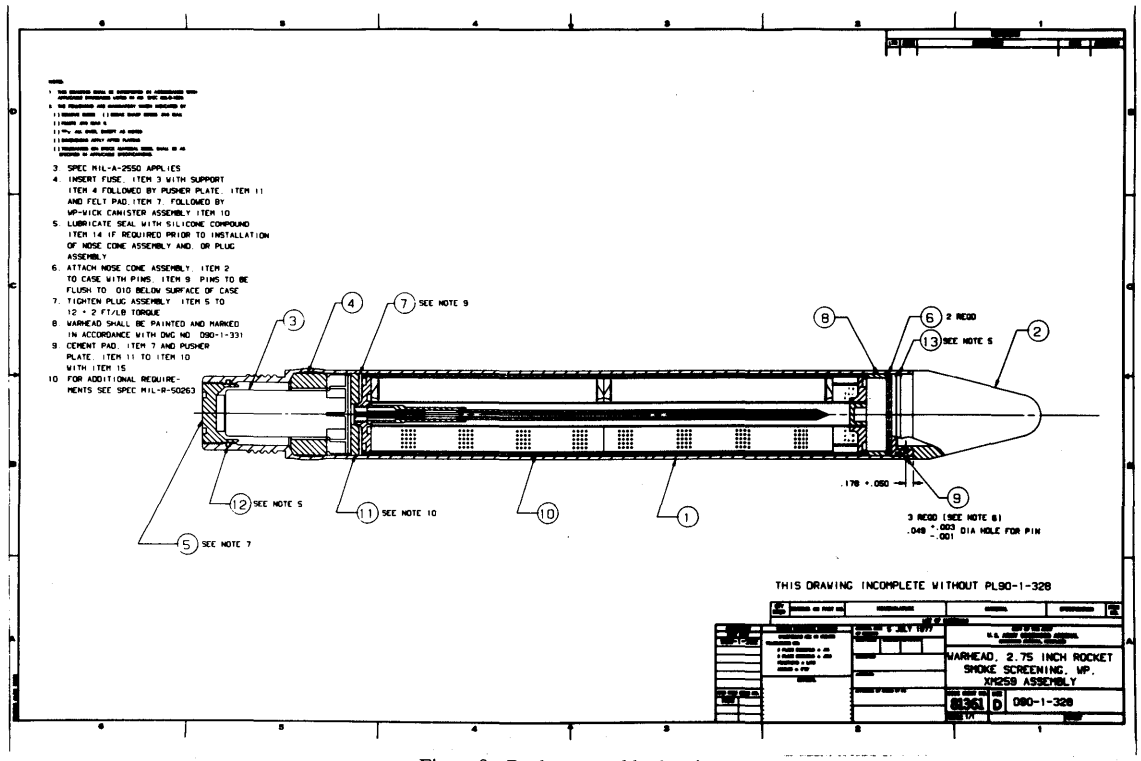

Figure 8—Rocket assembly drawing

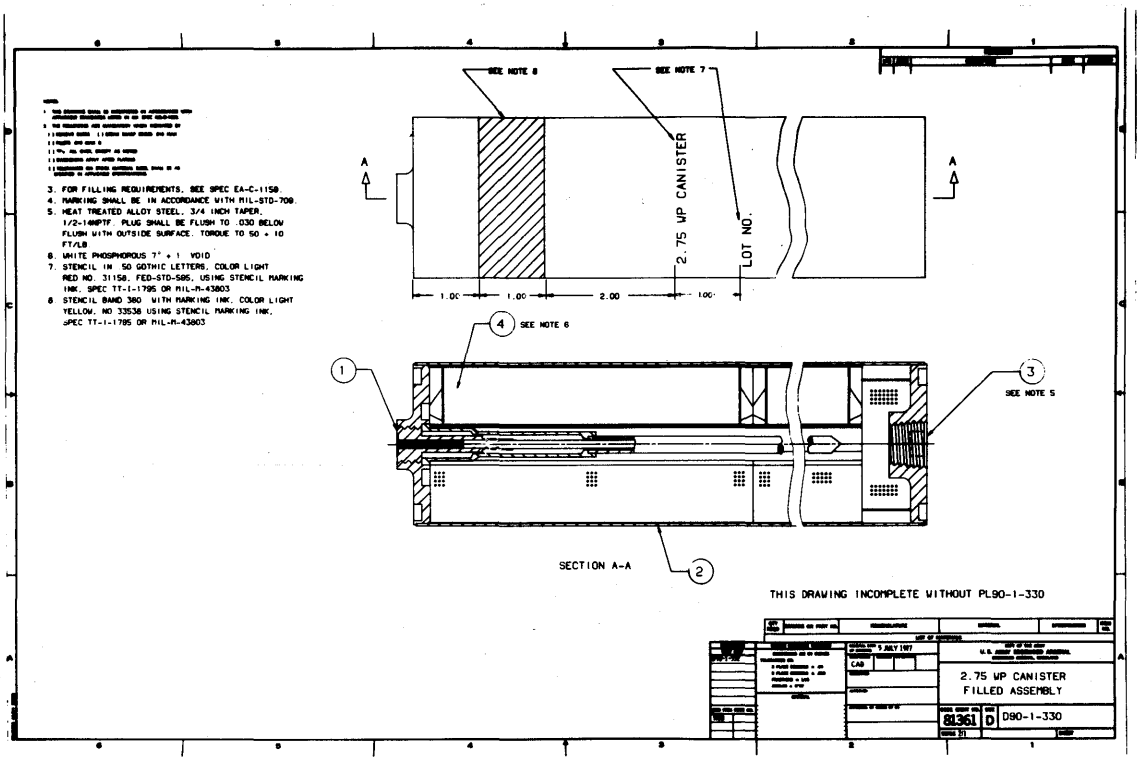

Figure 9—Rocket sub-assembly drawing

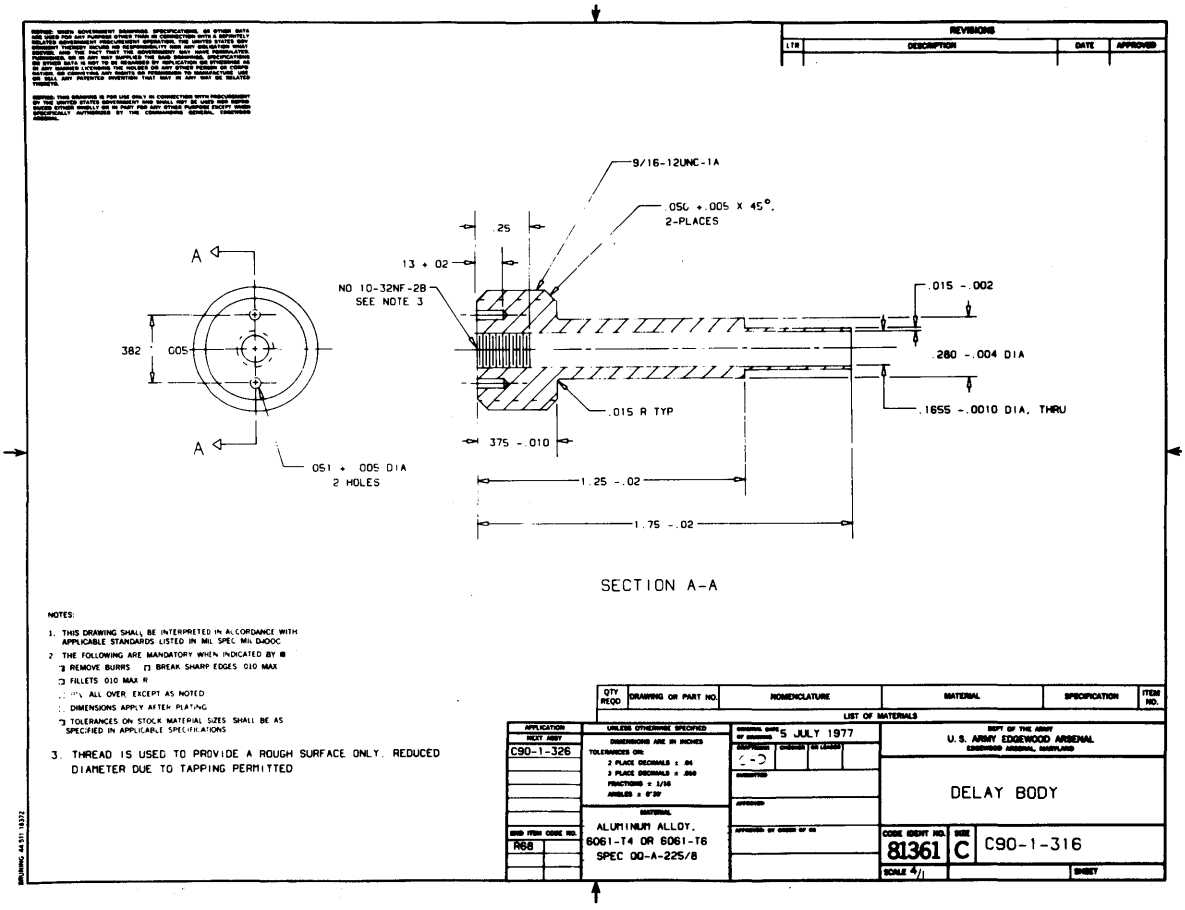

Figure 10—Rocket detail drawing

has continually increased. When the prototype phase is completed, the drawings must be redrawn according to DOD-D-1000 in a level 3 format. This format is required for all engineering production drawings associated with a TDP. The final drawings that become a part of a TDP must be complete and clear so that the manufacturer has no doubt about what he is to produce. Eight prototype drawings originally done on the graphics system were required to be converted to production drawings. The number of drawings was expanded from eight prototype drawings to 22 production drawings to meet the military specification. Drawings had to include subassembly, packing, marking, and individual details on each part (Figures 8, 9, and 10). Careful inspection of the drawings illustrated in the first example with the examples shown above will show the difference between prototype and production drawings. By using the computer-aided-design system, the job was completed in three days. If this work had been accomplished manually, at least three to four weeks would have been required. After the initial drawings were made, an engineering review was conducted which resulted in many additional changes. Using computer-aided-design, all the drawings were made in one day. One week would have been required if done manually.

These examples are only a few of a large variety of engineering applications that can be accomplished through computer-aided design. These examples show simple uses in computer-aided design illustrate that it can be an excellent investment. The average manpower savings generated is about a 4 to 1 ratio. The equipment purchased were both turn-key systems. The drafting and digitizing system cost $250,000 and was amortized in less than 2½ years. The first interactive graphics system costing $150,000 was amortized in 1½ years and the second system, worth $75,000, showed a return on investment in less than one year. With these results in equipment and software amortization, there is little doubt that computer-aided design has become an economic necessity.

TECHNICAL DATA AUTOMATION

The automation of Technical Data is concerned with a means of creating, storing, and retrieving technical data using computer technology. Within the Department of the

Army, there is a requirement to develop and maintain various types of data. This data is in the form of engineering drawings, specifications, standards, packaging sheets, and Quality Assurance provisions. All of this data is currently manually reduced from original drawings or type-written pages to 35mm film and mounted in 80-column aperture cards containing the document's identification. These aperture cards are manually gathered and form the technical documentation required for government procurement.

Computer-aided design and drafting techniques have made it possible to create an engineering drawing on a Cathode-ray tube (CRT). This method has proven to be extremely fast and highly cost effective. It also permits the user to create, store, and retrieve engineering drawings electronically in digital form.

This initial step has formed the basis for the automation of technical data. Data stored in this fashion allows us to go directly to a computer output microfilm unit to obtain the 35mm film which is then mounted on the aperture card. Funds are currently available for such a unit and it is anticipated the system will be purchased and in operation by the end of 1978.

A major problem, however, develops in trying to get existing drawings and various data into the computer system. Manual digitizing is too costly. To eliminate this problem, a method is required to scan the drawing or card, vectorize the data and put it into computer memory. Negotiations have recently been completed between ARRADCOM and Altman Associates, Incorporated for an aperture card scanner. The major problem is to extract the data without destroying the inherent vectorization. This is to be accomplished by the use of a high speed random access combination scanner and laser line follower operating with a dedicating computer (Figure 11). The system is expected to be in operation early in 1979.

A mass memory storage unit will also be procured in the near future to handle all the data requirements involved with the technical data package. It will provide on-line storage

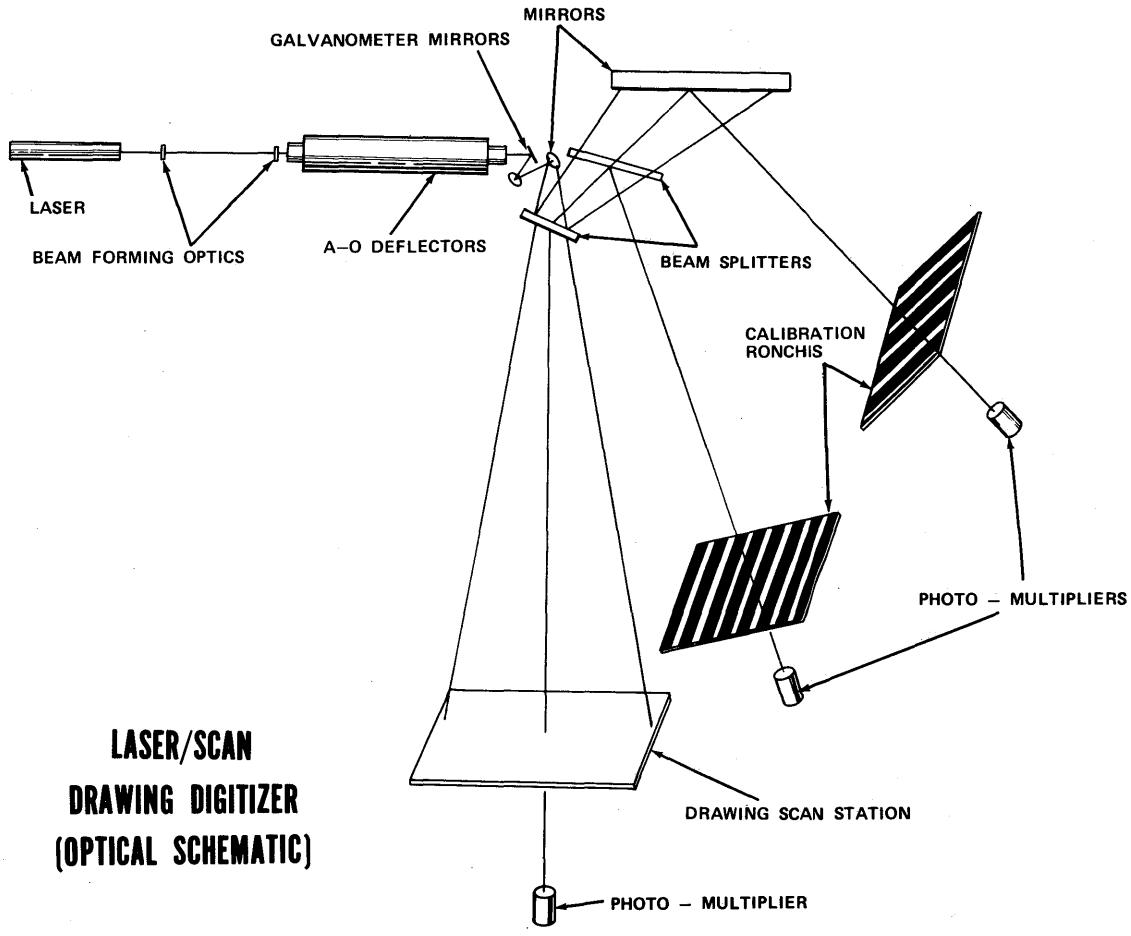

Figure 11—Optical schematic for scanner

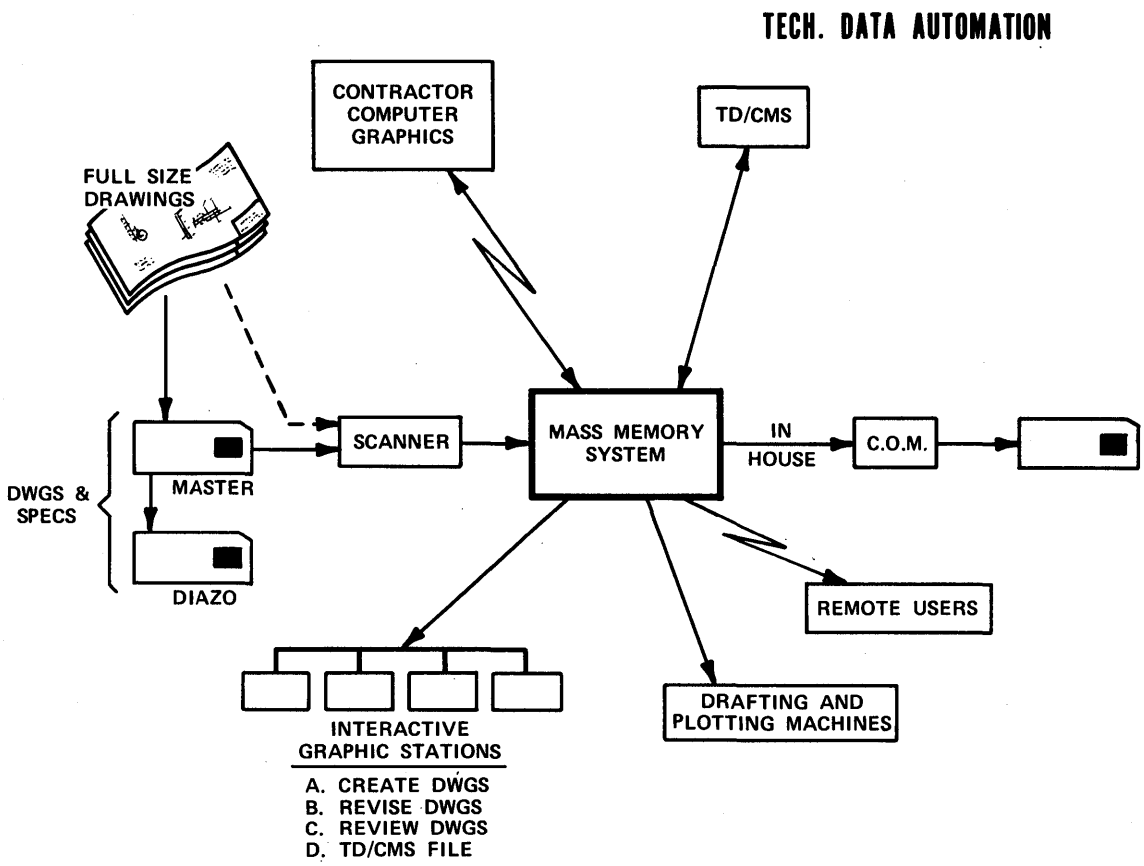

Figure 12—Technical data automation flow diagram

and retrieval capabilities of digital data in archival, non-erasable form and permit random access to any identifiable record.

The combination of this equipment will enable us to change existing drawings or specifications, etc., through Interactive Graphics and go directly to aperture cards without the need of hard copy. The target date for the total system completion is set for 1980. When completed, this technical data automation system will save the government thousands of dollars and greatly reduce the engineering lead time now required in the development of Army materiel (Figure 12).

The Boeing electronic computer aided design system

by BRUCE H. INMAN
Boeing Aerospace Company
Seattle, Washington

PROBLEM

A large percentage of the cost of most DOD-contracted programs is concerned with the concept development, circuit design, packaging, test and fabrication of electronic systems and subsystems. The application of Computer Aided Design (CAD) concepts to facilitate these operations can significantly reduce cost and minimize flow time in the design, fabrication and test of end item hardware.

OBJECTIVE

The fundamental objectives of CAD are to reduce cost and minimize flow times in the design and factory production of electrical hardware. This calls for identification of areas in the equipment design, packaging, test and fabrication processes that are operationally and economically adaptable to computerized techniques and the specification and development of those techniques.

SYSTEM DESCRIPTION

The following is a brief description of the Electronic Computer Aided Design (E/CAD) system in use at The Boeing Company.

E/CAD system description

Some of the factors making the development of electronics systems a lengthy and time-consuming process relate to the sheer mass of detail work that must be performed. Examples are: the drafting and checking of logic diagrams, the tabulation of electrical parametric data (time delays, logic states, voltages, etc.), evaluation to verify electronics designs and functional test sequences, the assignment of logic elements to integrated circuit packages (allocation) and of integrated circuit packages to printed circuit boards (partitioning), placement of circuit packages on the boards, boards in card cages or drawers, and the production of documentation to convey fabrication details to the shop. This accumulation of data during development of a product is an essential procedure, from preliminary design analysis through manufacturing.

To facilitate efficient transfer of data, the E/CAD system was designed to ensure that the programs do not communicate directly with each other but through common groups of data residing in the design data base. This facilitates the addition of new software programs to the system. A separate Data Base Utility program is provided to allow the user to add user-prepared data to the data base and to store and control data.

The Boeing E/CAD System is schematically represented in Figure 1. The rectangular boxes represent programs that are operational on Company computers, while the oval-ended boxes represent manual design functions and are entry points into the system. The programs are divided into two categories: design validation (including analysis, simulation and functional test) and packaging. Analog analysis, digital analysis, Computer Simulator, logic simulator, and digital functional test comprise the design validation programs. They assist the user in converting the data represented by a schematic or logic diagram into a format that can be used by the E/CAD System and provide aids to detect and correct logic errors in the system design. The Logic Simulator program assists the engineer in performing detailed logic simulation (design verification) of digital assemblies, including automatic worst case timing analysis. The Digital Functional Test program aids in the efficient development of high quality functional tests. Also included are post-processing programs which translate the test output data to releasable documentation and format the data for use on automatic test equipment. In addition, numerous analog circuit analysis programs (e.g., ISPICE, CIRCUS, SCEPTRE) and thermal analysis programs (e.g., BETA) are utilized but are not currently integrated into the E/CAD system.

The Packaging Interface program is the interface between design validation and packaging design. User-supplied packaging information (the assignment of logic devices to parts and parts to assemblies) is combined with the design description from the analysis programs. The Packaging Inter-

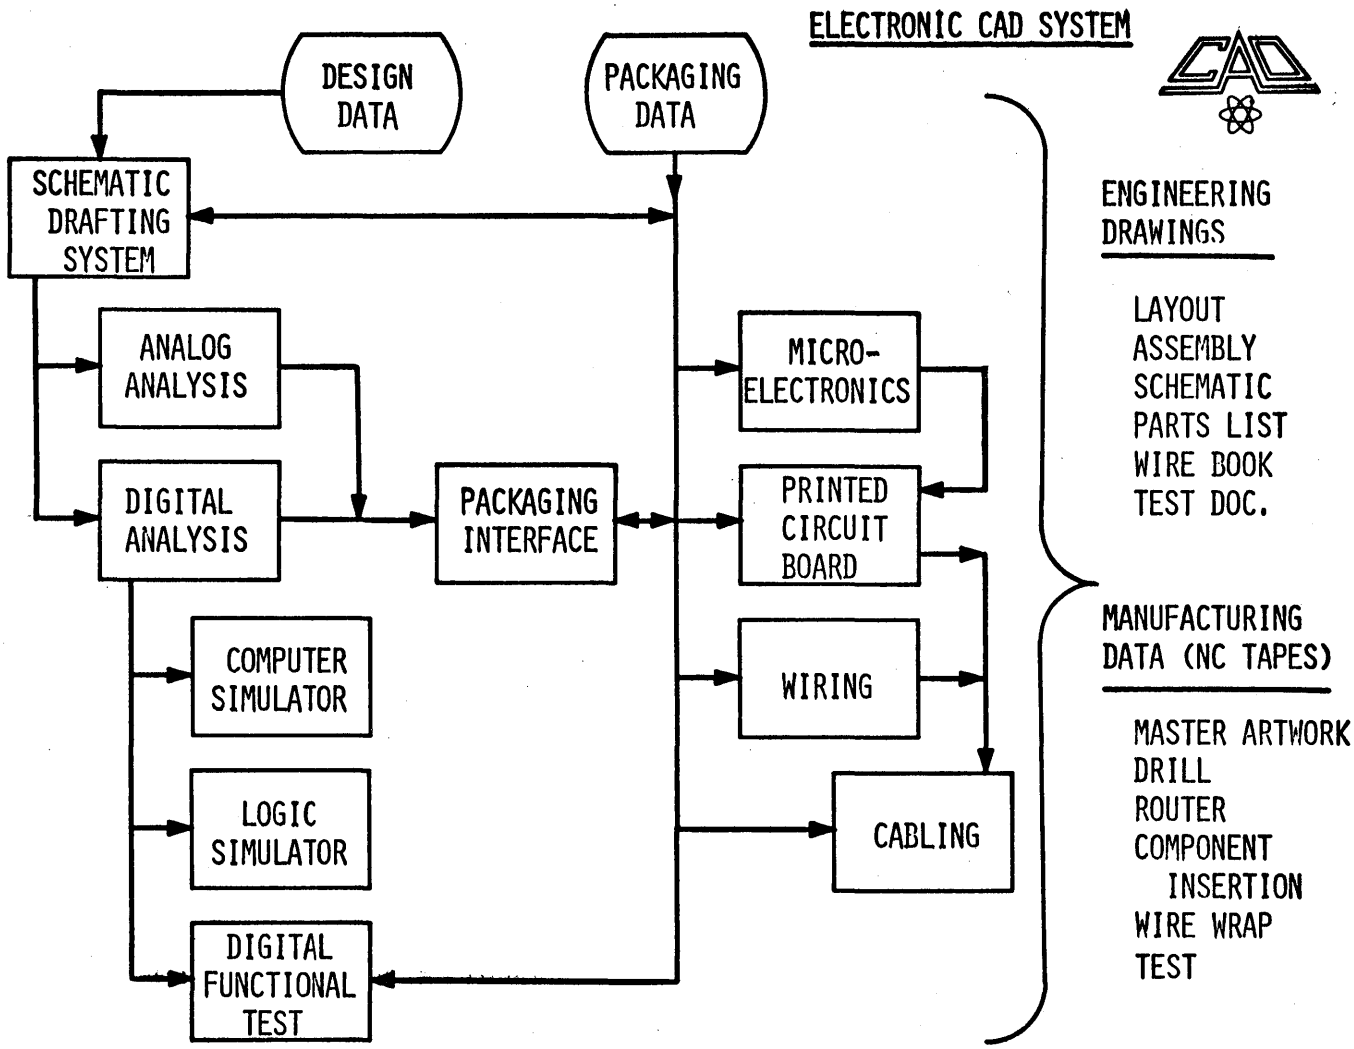

Figure 1—E/CAD system diagram

face program ensures against incompatibilities between logic design and packaging design information, determines all signals that must be brought to the connectors on the assembly, automatically assigns pin numbers for all logic devices, and generates pin-node data for use by the packaging programs and the functional test patterns for producing the final test program package.

The packaging programs are divided into two major categories: printed circuit board design and backplane design. Design of a printed circuit board (PCB) is accomplished with a combination of large-scale computer and small midicomputer with interactive graphics. The PCB editor utilizes packaging design information in addition to the data from the Packaging Interface program. Packaging design information (design rules, pad sizes, spacing, optional part placement, etc) is entered into the system, processed, and edited to correct errors. The resulting information is used for interactive placement of components and automatic routing of conductors. Once automatic routing is completed, options are provided for manual intervention and modification of conductor routes by means of the interactive graphics console (Figure 2). Automatic checking for connection and dimensional spacing violations is a part of the software system. Once board layout is completed, necessary information is generated to drive plotters to produce assembly drawing and photo master artwork and a control tape for numerically controlled drilling is produced. The assembly drawing, photo master artwork, and drill tape, when combined with other manually prepared instructions, are used to produce the finished printed circuit board.

The second major category of packaging programs is backplane design, which involves point-to-point wiring predominantly by wire wrap. This packaging technique is used for two general categories of assembly design: digital logic assemblies and PCB connector backplanes. Wire wrap assembly of digital logic assemblies usually proves to be more cost effective than PCB's in applications such as breadboards and small-quantity production runs. The shop aids

Figure 2—Interactive PCB design

necessary to wire the assembly are produced from the wiring program in the form of a punched tape and a computer listing. This tape and listing are used by the shop for fabrication. The wiring program also places data on the data base for use by a documentation program to produce a complete wire book. The wire book contains necessary information to identify the wiring on an assembly and maintain unit configuration control. The documentation program, in turn, places data on the data base for use by the DITMCO Test-Postprocessor program, which generates a test tape for the DITMCO test equipment to check for open or shorted circuits in the completed wiring assembly.

Utilization within boeing

The E/CAD system has been in development since late 1970. An overall system approach was selected and capabilities added on a modular basis. The E/CAD system is used on all major electronic design and development activities within The Boeing Company. To date, approximately 2,000 PCB's and 700 wired assemblies have been designed using these capabilities. The average PCB is four to six layers and the average wired assembly has in excess of 1,000 wires. Cost savings/avoidance to date are in excess of 10 million dollars.

Home & hobbying computing

OVERVIEW

Computers became consumer products around the beginning of 1975. In less than three and one half years, a considerable array of companies have come into existence to address the new marketplace of "personal computing." This portion of the Conference Program addresses the topic of home and hobby computing from several aspects.

A survey is provided of the brief "history," the current situation, and the foreseeable futures of personal computing. Following this overview, a discussion will address the variety of usual and unusual hardware, software, and systems that have appeared in the personal computing application areas. This will include comments regarding the problems and promise of home computing hardware, software, and applications.

To date, personal computing has been limited to the fifty to one hundred thousand computer enthusiasts who currently own home computers. This is not a mass consumer market, however it is evident that such a market is about to open up, in some ways comparable to the market for stereos, television, and CB radio. The final session in this Technical Area of the Conference Program will address this topic—providing computer power for the average lay person; the mass consumer who will use computers only to the extent that they may be used without expertise, and only to the extent that they can solve problems that the average person may be interested in solving.

THEMES

SESSION 1: Computers became consumer products around the beginning of 1975. Since then, a multitude of companies have been created to address the new

marketplace of "personal computing." There are 50,000-90,000 computers in people's homes, today. The speaker will briefly survey the "history" of this movement, detail the present situation, and hypothesize concerning the foreseeable future. Panelists will address various aspects of the alternative foreseeable futures.

SESSION 2: A variety of usual and unusual hardware, software, and applications are appearing in the world of computers as computers become personal devices. These new facilities provide a wide range of problems and promise. The speaker will provide an overview of the positive and negative aspects of personal computing equipment, programs, and uses. Panelists will present a variety of views regarding the hard and soft facilities that are unique to consumer computing.

SESSION 3: The microcomputer emerged from a laboratory curiosity to a hobbyist toy and from there to a usable business and industrial tool. What of its potential as a mass merchandised electronics device (like radios and televisions) which can be used by persons technically disinterested and incompetent to do other than turn a knob or two?

Representatives from companies which are near the leading edge of this market will present their views and insights in this session.

Personal Computing—A little past and a lot of future

by PORTIA ISAACSON
The Micro Store
Richardson, Texas

INTRODUCTION

We are incredibly lucky! When I look back in time, I see no time more exciting than now! When I look forward in time, I see no time more exciting than now! For now, we are privileged to witness the dawn of the era of personal information processing. Few people have ever lived at such a time of technological change. Perhaps only those who were present when the first book was printed have, before us, had a similar opportunity to observe the birth of a technology-derived tool having the power of the personal computer to improve our quality of life. We are presently witnessing what is probably the most significant of all technology-based revolutions surpassing in importance the printing press, the automobile and the assembly line.

Low-cost abundant computing brings us to the dawn of a new era. A new era in which information processing power will no longer be the exclusive tool of government and large business. Rather we will have computers for people to use in a near limitless variety of ways in our work, our play, and all aspects of our daily lives.

THE COMPUTER HOBBY

Five years ago, and even before, those of us involved with microprocessors were making rather accurate predictions as to the declining cost of computing resources based on our knowledge of the new microprocessor technology. We did not predict, however, the absolutely incredible growth of hobby computing.

Although there had been some activity previously by really enterprising do-it-yourselfers, the computer hobby really took off in January, 1975, when the MITS Altair Computer appeared on the cover of *Popular Electronics* magazine.[1] The computer was available in kit form for about $400. A new hobby and a new industry were born.

In July, 1975, Dick Heiser opened the first retail computer store. Many others were to follow. The computer store started making its place in the computer industry as a new way to market and service low-cost computers and related equipment.

In the summer of '75, MITS was driving its van all over the country demonstrating the Altair computer. In city after city computer hobby clubs were born at the MITS van, which brought the computer hobbyists in each geographic area together for the first time. Now computer hobby clubs number more than 300, with several in other countries. One of these clubs has membership numbering in the thousands and hundreds is very common. Soon these clubs will join together to form an international amateur computer society.

What sort of person is this computer hobbyist? He or she is a hardware or software tinkerer—an experimenter. The computer hobbyist comes complete with clubs, conventions, magazines, T-shirts, and bumper stickers. Hobby computing will surely become the elite of the technological hobbies. Who is this computer hobbyist? He or she is an engineer, a programmer, an electronics buff, an amateur radio enthusiast, a lawyer, a small business person. Most actually have surprisingly serious intended uses for their computers. In fact, a surprising number are depreciating their computers on their income tax returns.

Personal computing is not only hobby computing. The fact that hobby computing has received so much publicity is really misleading. The graph in Figure 1 illustrates this point. Discussions with several computer stores indicate that the personal computing equipment sold over the past year has gone, for the most part, to business, industry and educational institutions. Only about 20 percent of the personal computers sold this past year have been sold to hobbyists. To further illustrate this point, customers of my computer store include: oil companies, universities, hospitals, trucking companies, security companies, public schools, personnel agencies, power and light companies, manufacturing companies, and electronics companies.

Personal computers are replacing time-sharing services in businesses large and small. Personal computers are replacing mini computers in process control applications. Additionally, personal computers are finding their way into new applications where the new low cost of computing makes possible the use of computing where before it was too expensive. One way to view personal computing is that it is simply low-cost computing. And this new low-cost computing will compete with all other traditional forms of computing resources.

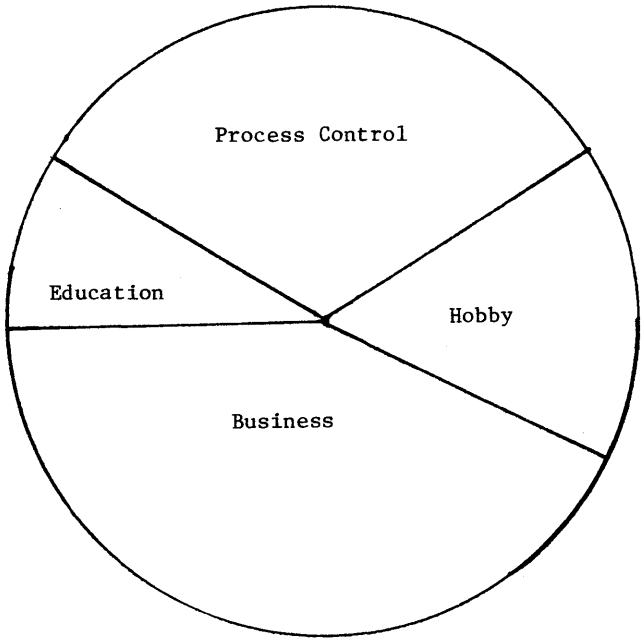

Figure 1—Personal computing sales.

A NEW INDUSTRY

A new industry has emerged to support the personal computing market. There are more than 100 companies manufacturing personal computing products. There are more than 500 computer stores selling and servicing these products. There are 10 major magazines dedicated to personal computing.

The new computer industry differs in several important respects from the computer industry that preceded it. These differences include fierce competition around a standard internal bus and a new way of marketing and servicing computers.

The standard bus

Fundamental to this difference and to the development of the personal computing industry itself has been the S-100 bus standard. The S-100 bus is a set of electrical and logical specifications for the connections between the various printed circuit cards that may share the bus. These printed circuit cards can include: a CPU card, memory cards, keyboard and video-display interface cards, audio cassette interface cards, floppy disk interface cards, music synthesis cards, voice recognition cards, joy stick control cards, and so on. The S-100 bus was originally the MITS Altair bus. Now there are at least twenty companies manufacturing S-100 bus computers. There are more than 150 different products including computers, memories, disks, printers, graphics displays, joy sticks, music synthesis equipment, voice recognition boxes, voice generation boxes, and home electrical system controls presently being manufactured for the S-100 bus. The broad range of available S-100 bus equipment greatly exceeds the offerings of any one manufacturer.

The most important aspect of the S-100 bus standard has been its impact on the evolution of the personal computing industry. Up to this time most of the companies manufacturing personal computing products have been small companies, including many garage-type operations. Few of these companies could afford to manufacture and market an entire computer system and most of them offer only one or two types of boards. The S-100 bus standard has created a marketplace large enough to enable a small company to be successful in the market on a low budget offering only a single board that provides some nice option for a S-100 bus computer.

The small entry cost to the S-100 bus market has made the competition fierce. If a product can be manufactured and marketed for less, it will be. Products are priced very close to the manufacturing cost. This is quite unlike the traditional computer industry which is well-known for prices that have little relation to the manufacturing cost but rather have been priced by looking at what the market will bear.

The computer store would not have been nearly so viable a concept without the standard bus. Virtually all the personal computing manufacturers have been under capitalized, resulting in long waits for products. In many cases stores have been forced to buy essentially the same product from several different manufacturers in order to be assured of an adequate and timely supply. Additionally, since many of the products in a computer store are interchangeable, inventories of particular brands can be reduced. A store can choose a product such as an S-100 bus memory board from among a large number of possible suppliers, using consideration such as delivery time and margin as primary parameters rather than being forced to take whatever the CPU manufacturer cares to offer. This kind of competition has enabled stores to get nearer the kind of margin and service they need.

The retail computer store

The new low-cost computer products require a new way of marketing and servicing these products. It no longer makes sense for a salesperson or field engineer to call on the individual customer when his computing system costs only a few thousand dollars. The retail computer store fills this need. Computer stores offer a place to test drive several computing systems before buying one. Stores try to offer off-the-shelf delivery of computers and associated equipment and software. Computer stores offer advice on configuring a system for a particular application from the wide variety of personal computing products available. Most stores repair the equipment that they sell. Some stores offer hardware and software consulting. Most offer a wide assortment of computer books and magazines. Some stores hold classes in using and programming personal computers. The computer store plays a new and essential role in the new computer industry.

THE HOME COMPUTER REVOLUTION

In late 1977 we saw the first signs of the real home computer revolution. The fully assembled complete computer was offered by two different companies, Radio Shack and Commodore, for under $600. These computers include the CPU, memory, a keyboard, video display, and read-only-memory Basic language interpreter. So now we have the hardware in the right price range for the massive home market, but still missing are the huge libraries of programs that will make these computers really useful. This software will come. Eventually we'll buy programs like we buy stereo records—from a wide selection—where some program can be found to satisfy nearly any taste or requirement. When these program libraries are available, millions of home computers will be sold.

Now what would motivate millions of people to buy home computers? The two primary reasons are entertainment and education.

Do not underestimate the sales appeal of the computer game as an entertainment form. Look carefully at the computer as a new form of personally available, intellectually challenging, interactive entertainment. Of course, the computer offers simple games like pong, target, and guess-the-number. Much more importantly, the computer offers the opportunity for simulated experiences without risk. For example, the well-known Star Trek game provides the player the experience of being a star ship captain—the opportunity to make monumental decisions on which rests the fate of the universe. Other games let us pretend to be a ruler of a country or the president of a company. The simulated experience-type of computer game is a powerful new entertainment form. A $600 price tag seems very small for just this one function of the home computer.

Education is the other major reason computers will be sold to millions. The home computer coupled with well-known computer assisted instruction techniques will offer an interactive personalized form of instruction for the home. CAI programs will be available for instruction in subjects as far ranging as arithmetic drills, French grammar, and driver education. This new home educational medium may eventually have a dramatic impact on our educational systems. When the computer-assisted home education center has evolved to its full potential using such technologies as video disks and two-way electronic communication links to schools, the home could very well become the center for educational acitvity. The school's function would be to prepare instructional materials and certify levels of achievement.

Entertainment and education will surely be reasons enough for many people to buy home computers. Of course, the home computer will have many other uses including: personal financial management, astrological forecasting, keeping inventories of collections such as stamp or beer can collections, centralized control of home physical systems, maintaining address lists, and use as an artistic medium in graphics and music. In fact, the uses of computers are as varied as the individuals who apply them. Applications of the home computer have little limit other than the imagination.

COMPUTER INDUSTRY CHANGES

The new low-cost computing will cause many changes in the traditional computer industry. Some of the changes are starting now. Some will not reach their full impact for years to come. The very structure of the data processing organization will be impacted. Additionally, the individual data processing professional may find his or her role changing significantly.

Personal computers are replacing and are competing with mini computers in low-end applications including process control and small business. In order to understand why personal computers are able to successfully compete with minis in many applications, it must be understood that personal computers are not small—they are just inexpensive. A recent article compared the performance of an IBM S/360 Mod 30, the work-horse business data processing computer of the late 1960's, to the personal computer.[2] According to some parameters the personal computer actually exceeds the S/360 Mod 30 in computing capability.

As personal computers move into the mini computer low-end market, minis will be forced to look upward for more applications. They have already started eyeing the strongholds of the large mainframes.

Personal computers are replacing time-sharing services. Time-sharing was devised as a means of bringing computing resources to the individual. Now that the individual can own an entire computer, there is simply little need to time-share a large computer. The advantages of a 16-user personal computer laboratory over a 16-user time-sharing system were recently documented.[3] They include the fact that the personal computers are half the price of the time-sharing system, the personal computing laboratory can be built incrementally with a very low entry cost, personal computers offer the latest in technology, the personal computing laboratory is more reliable and available more of the time, and the individual can typically have more disk storage space. Disadvantages of the personal computing laboratory include the lack of large software libraries and the fact that very large programs that might use the entire time-sharing computer during non-time-sharing hours cannot be run. In many cases the personal computer offers a better way than time-sharing of bringing computing resources to the individual.

The data processing center will soon find itself loosing control of the corporate data processing function. This has already happened to a certain extent as mini computers first meant for process control applications were found useful as general purpose data processing machines. Departments within corporations found that by buying their own small computer they could spend significantly less on data processing than if they bought computing services from the data processing center. This trend will be greatly accelerated by the still much lower cost of the personal computer. The eventual result of this type of pressure on the centralized

data processing facility will be pressure on the large mainframe manufacturer to lower prices to compete with the low-cost computers. Ultimately personal computers will force lowering of prices by the large mainframe manufacturers.

A major change for the computer professional will be the fact that the public will be computer literate. The public will have a much better understanding of computers and software. No longer will they be awestricken and unquestioning about a computerized process. They will understand the role of the programmer and demand that programs interfacing with the public offer reasonable human interfaces and consideration.

Today society's view of the computer programmer is with considerable awe and respect. Other departments in a corporation view the data processing person as the practitioner of the black art of computer magic. Most of us in computing have at one time or another used our technological jargon to our advantage in cutting short a discussion. All this will change when computing and programming become household activities. The computing profession will not be viewed with quite the splendor it once was. This author occasionally reflects on the fact that a Ph.D. in Computer Science will have the same social prestige as a Ph.D. in refrigerator science when the computer becomes just another household appliance.

It is well-known that one of the biggest problems in the computer industry today is the high cost of software. Low-cost computing may eventually help solve that problem in an indirect way. Low-cost computing will lead to widely available computer education at all levels. Now that the cost of a computer is not much different than the cost of a typewriter, the major block to widely available computer education is gone. With computer education abundant there will be a flood of qualified entry level programmers. The effect may ultimately be more competition for data processing positions and ultimately lower salaries for programmers. The result: a decline in software costs. A possible weakness in this scenario is that at the same time the number of computer trained people is increasing, the amount of software needed by new low-cost computing applications is also increasing. Perhaps the need for programmers will be adequate to absorb the higher production.

CHANGES IN OUR WAY OF LIFE

Predicting the future is always a risky venture at best. However, we can take a few peeks at what the effects of abundant low-cost computing may be. We have already discussed the fact that to our homes the computer will bring powerful and exciting new forms of entertainment and education.

For those skeptical about the magnitude of the potential impacts of the home computer a simple scenario usually removes any doubts. What if a million people, or a thousand, or even just a hundred all owned the same type of computer; all used the same stock market analysis program, and—based on predictions of the program—all made the same moves in the market? Chaos!

Probably the largest contributing factor to change is that now computer-inventiveness is in the public domain. No longer can only large business and well-endowed universities invent devices having computers in them, computers themselves or computer-related equipment. Now because of the new low cost of computing, the average person can use computers as components in inventions giving them a new dimension—intelligence. History tells us that many of our most personally useful inventions were not invented by large corporations or universities, but rather by an individual with a problem to solve. Now that same kind of motivation and inventiveness will be applied to computer products. In fact, from the present computer hobby movement will come gizmos too numerous to mention. We are now on the threshold of a gizmo age in which we will be surrounded by intelligent devices supplying services that would be impossible to imagine at this time.

All is not good, however. For example, it is now possible to build a computer-based device that will place telephone calls, play a recorded message, record the verbal response, and even accept the touch-tone input of a credit card number. This device can be very persistent and devious in placing calls. For example, it can either place calls against a provided list of numbers or it can generate the numbers within a given prefix which, of course, corresponds to a geographic area. Notice your unlisted telephone number is of no help. The call-placing device can remember that you didn't answer and place the call periodically until you do. It could even remember that you hung up! The devastating truth is that a device can be built to place junk telephone calls for about $2\frac{1}{2}¢$ per call compared to $7\frac{1}{2}¢$ per letter in postage alone for junk mail. The only answer is probably legislation. In the meantime a low-cost device can be built that will answer your telephone and require entry of a touch-tone password before the household is notified of the call.

Over the long range the abundant computer will add a new and rewarding dimension to our lives. We have a new fundamental tool, a new medium for expression and experience. We are indeed incredibly lucky to be present at the dawn of the era of personal information processing.

Personal computers—Hardware, software and documentation

by JEF RASKIN
Brisbane, California

INTRODUCTION

What is a personal computer? Possible candidates for personal computers range from programmable calculators and games on one end to an antique IBM 7094 in a hobbyist's basement on the other. There is no doubt that the pocket sized programmable HP-65 and its successors *are* computers in the classical sense. They can be programmed to execute any algorithms that fit within their memory limitations. This is all that can be said of *any* computer. For this discussion, a useful dividing line between calculators and computers is that calculators do not provide for the input and output of natural language text.

It is more difficult to draw a line between *personal computers* and other devices that are correctly called computers. In fact, there is no special term for those computers not intended to be personal computers. The term "impersonal computers" is tempting. For this discussion (and at this point in history) personal computers will be defined as those computers that are *marketed* as personal computers. This correctly reflects the fact that there is nothing special about personal computers except that they are inexpensive enough to be reasonably sold to large numbers of individuals.

Excluded from this discussion are truly home-brewed computers, designed and built by a rugged individual for his or her own edification and amusement. Also excluded from this discussion are computers, however small, marketed as small business systems. They may, in fact, be identical to the systems that are being discussed, but very different considerations apply to their software and documentation—they are also directed toward a different audience. Business users will apply different criteria than home users to the selection of a system. During business hours, at least, they are not personal computer systems. It is less than reckless to predict that they will have their own publications and conferences in the near future.

The systems considered here are those that are being programmed and used by thousands of people, each of whom can point to the computer and say, "It's mine."

HARDWARE

A personal computer is based on one of the commercially available microprocessors. Most begin with an 8080 or a 6800, or their successors (such as the 8085, 280 or the 6500 series). The hardware achieved commercial quality very quickly, except for a few design errors, some of which have become almost legendary. By and large, personal computers are reliable. They use the same quality components, boards connectors, enclosures, and manufacturing processes as commercial computer products—with only a few brands cutting corners.

PERPHERALS

Anybody familiar with minicomputers might expect that paper tape readers and punches would be major peripherals in micros. It is not so. Cassette tape machines and ordinary commercial audio recorders dominate the field. Simple but clever interfaces make them moderately reliable off-line storage devices. There used to be a certain fascination in buying your computer peripherals on special at a discount store. Since you will soon be able to buy the whole computer system there, the novelty will quickly wear off.

One of ten best personal computer peripherals is the memory-mapped video display. The speed and capabilities of these displays—which drive an ordinary TV monitor—rival and often best even the more expensive "intelligent" terminals. Their main limitation is their small (typically 16 line by 64 character) display. Many TV drivers display fewer characters than that. Nonetheless, most *mini*-manufacturers have far poorer console displays. Most of the personal computer displays provide some form of graphics as a standard feature; a few brands even offer color graphics.

Floppy disk drives and controllers do not differ significantly from the rest of the industry. Hard disks for personal computers are not yet available, and may never be; it all depends on the price of various new forms of memory. Again, the personal computers are in the same position as the rest of the industry. Keyboards are mostly encoded, with a few more advanced systems going to polled operation. Keyboards are rapidly being integrated into products.

Paper tape is used. The only popular punch is the ASR33. Some clever tape readers have appeared, including at least two that can go as fast as you can pull the tape through. Since they work asynchronously, all one needs is a simple electric motor and a spool to have a cheap and remarkably fast tape reader.

Punched cards have no hold in the personal computer industry at all.

The number and variety of peripherals and interfaces for personal computers are incredible. Just one system the popular "S-100" bus, has over 300 different devices that are mechanically and electrically (more or less) compatible. Never has one bus been available on so many different computer brands. Never have so many *hundreds* of companies made accessories for the same bus.

MEMORY

It took the personal computers to show the industry how cheaply memory could be sold. The personal computer designers have not been shy at using the latest memory chips as they have become available. In hardware, the personal computer user has the latest, the best, and the cheapest.

SOFTWARE

Personal computer software, for the most part, does not attain the state-of-the-commercial-art level that the hardware does. There is a unique problem in the hobbyist industry: almost everybody has a choice of only a few processors. In the mini and maxi computer world, manufacturers could afford to develop software, since it could only be used on their brand of computer. This problem has only begun to creep into the mini and maxi computer world. At present, it is not clear that a substantial investment in software development can return a profit. Selling packages to individuals at $5.00 to $50.00 a shot is working for some small, low-overhead organizations and individual free-lance programmers. Writing the obligatory BASIC interpreter for various companies is keeping more than one firm alive.

Very few owners of personal computers are aware of the benefits of the more advanced computer languages, and therefore, are content with an endless stream of ad hoc additions to BASIC. Since the structure of BASIC makes writing long and complex programs lugubrious, programs tend to be short. Since the overhead for remarks is high, they tend to be poorly documented at best.

One of the most widely used assemblers for the 8080—you may not believe this—is missing a few instructions! Assemblers that offer macros and relocatable code are only beginning to be available. Noise about APL is often heard, but the product lags far behind. FORTRAN is beginning to be used, and there is some interest, for some reason, in COBOL. FORTH is available but overpriced for most of the market.

An amazing software development has been the versions of Tiny BASIC. They use interpreters whose object code can easily be displayed on a single quarto-sized page. The cheap personal computer has forced such development on one hand, and made it usable on the other. The disk-operating systems are rapidly gaining in sophistication. Personal computer software is a funny mixture of cleverness and conservative copying of outmoded programming techniques.

DOCUMENTATION

Personal computers are being marketed mainly at first-time users. That is not the current user population—that is the *anticipated* user population. With few, if any, exceptions there aren't any computers systems that you can hand a beginner, then come back a week later and find the person happy and the computer up and running. The fault is partly with the software and mostly with the documentation. This will have to change radically for the better in the next few years, or personal computers will continue to be the exclusive toys of the electronics engineers and programmers who now buy them.

Area Director:
John McLeod
SIMULATION
La Jolla, California

SIMULATION

An increasingly important application of computers is their use for simulation. Simulation involves performing experiments on models instead of the real-world system—the simuland—for obvious reasons. Simulation is cost-effective whereas experimenting with real systems is usually more expensive, may be dangerous, and is often impossible because the simuland is not available, or is intractible to experimental manipulation.

In recognition of the current and exponentially increasing importance of the use of computers for modeling and simulation the NCC Program Committee has dedicated a Program Area to the subject.

There are three sessions in this Simulation Area. One is a panel discussion during which panelists will address the question "Can Large-Scale Models Alleviate World Resource Problems?" The written Position Statements of each panelist has been distributed to all other panelists with the expectation that each will thus be prepared better to discuss points raised by the others. However, besides setting the stage for a more enlightening discussion, this was done because panelists were selected to some extent because of their differing points of view and it was thought "forewarned would be forearmed" with pertinent material.

An effort was made to keep the number of panelists relatively small so that each could have a reasonable time in which to present his views, then defend them if they are challenged either by other panelists or by members of the audience. On the other hand the panel organizer and moderator has invited knowledgeable (and sometimes opinionated) simulationists of his acquaintance to join in the discussion from the audience.

In addition to the panel session there are two simulation sessions for the presentation of technical papers. The subject of one of these is:

MICROPROGRAMMING AND SIMULATION

This session was arranged by Dr. Lance A. Leventhal, Society for Computer Simulation, in cooperation with Dr. Gary Nutt, Department of Computer Science, University of Colorado, Boulder, Colorado, the Session Chairman.

The concept for this session was developed because new technical developments have extended the range and power of simulation. One long-standing problem however, has been the development of software and systems for computers which are unavailable for use, unsuited for development, or not yet even built. Simulation has long been used to alleviate this problem while allowing experimentation with new architectures. Recent hardware developments have made it possible to create special computer facilities for these purposes. Such facilities can serve as universal hosts, capable of simulating (or emulating at the microprogram level) a wide variety of computers. One paper in the session on "Microprogamming and Simulation" presents an overview of the uses and advantages of emulation. A second paper describes an emulation facility while a third paper discusses an example application.

These papers are:

"Emulation: Tool for Software Development," by N. F. Schneidewind, Department of Computer Science, Naval Postgraduate School, Monterey, CA. 93940;

"PRIM System: a Framework for Emulation-based Debugging Tools," by J. Goldberg, A. Cooperband, and L. Gallenson, University of Southern California Information Sciences Institute, Marina Del Rey, CA. 90291, and

"A Microprogrammed AN/UYK-20 (V) Emulation," by D. A. Deel and W. A. Burkhard, Computer Science Division, Department of Applied Physics and Information Science, University of California, San Diego, La Jolla, CA. 92093.

The subject of another session is:

PERIPHERAL AND MULTI-PROCESSORS IN SIMULATION

Also arranged by Dr. Lance Leventhal, Society for Computer Simulation, this one with the cooperation of Dr. Walter J. Karplus, Computer Science Department, University of California, Los Angeles, Session Chairman.

The fact that hardware can now be inexpensively produced in configuration specifically suited to simulation applications inspired this session. This is important because most simulation problems involve a large number of concurrent activities and hardware elements can be connected in parallel to handle such problems. Several different approaches are possible; the parallel system may be an add-on to a general-purpose computer, a general parallel multiprocessor may be built, or a parallel system may be specifically configured for a particular class of problems. One paper in the session on "Peripheral and Multi-processors in Simulation" describes a system that can be used with many large computers. Two other papers describe the use of multiple processors working in parallel to solve plasma and fluid flow simulation problems.

The papers in this session are:

"A Multiprocessor Digital Computer for Dynamic Systems Simulation" by R. M. Howe, Dept. of Aerospace Engineering, University of Michigan, Ann Arbor, Mich. and E. Gilbert, Applied Dynamics International, Ann Arbor, Mich. 48104;

"Plasma Simulation on the UCLA CHI Computer System" by R. W. Huff and C. C. Wu, Dept. of Physics, University of California, Los Angeles, Los Angeles, CA. 90024; and

"A Multiple Microcomputer Approach to Fluid Flow Problems" by J. Steinhoff, Research Department, Grumman Aerospace Corporation, Bethpage, N.Y. 11714.

Emulation—Tool for software development

by N. F. SCHNEIDEWIND
Naval Postgraduate School
Monterey, California

INTRODUCTION

A major computer operations problem is the conversion of programs from one language to another when a replacement computer is acquired. Emulation was developed as one solution to the conversion problem. Emulation allows the machine instructions of the emulated (target) machine to be executed on the emulating (host) machine. Thus permanent program conversion is avoided. Frequently, emulated programs execute several times faster than their non-emulated counterparts. This occurs because the host is faster than the target or its microinstructions are more efficient than the target's machine instructions, or for both reasons. Other methods of program conversion which compete with emulation are: recompilation, reassembly, translation and simulation (interpretation).

Although "translate" is frequently used as a general term to denote all types of language conversion, including assemblers and compilers, here it will be used more specifically to mean a conversion from language A to language B where A and B are not machine languages. It should be noted that recompilation, reassembly and translation effect a permanent conversion, i.e., the result of the process is a program in another language, whereas emulation and simulation employ another language, microinstructions and interpretive routines, respectively, only during the period of program execution. Another way of viewing this difference is that execution of a converted program using recompilation, reassembly or translation is a two step process-conversion followed by execution—whereas emulation and simulation are one step processes; as far as the user can discern, conversion and execution take place simultaneously in a single computer process.

Another application of program conversion techniques is in a software development organization, where a multiplicity of hardware and software systems are produced. This occurs, for example, in organizations which are developers of tactical software systems for ships and aircraft. Typically, many computers comprise a single system. The variety of computers is even greater across the many systems with which the software development organization could become involved. It would be quite expensive for the software organization to acquire all the required computers and programming languages, particularly in view of the transient nature of the development process. In addition, the computers and languages which are needed for testing purposes are frequently unavailable at test time. If the organization were to wait until all hardware and software is designed and implemented, system integration would be delayed to the point of causing delivery slippage. Thus a procedure is necessary for executing and testing programs prior to the availability of the hardware which will be used in the delivered system. In addition to the hardware being unavailable, it is possible that compilers to be used with the hardware are also unavailable at test time. This situation would require a method for producing programs which are not dependent on the use of machine language generated by the operational compiler. Here and subsequently, "operational" will refer to the software and hardware which will be used in the field after the system is delivered to the customer.

This paper will describe and evaluate different alternatives for providing a software development organization with the capability of writing and testing programs prior to the availability of the operational hardware and compilers. In this context we will describe the concept of a software production and test facility which could be used for the development and implementation of a variety of software and hardware systems in the absence of full operational capability. We will also address some of the problems which arise in the execution of this concept, such as the difficulty of faithfully representing I/O operations.

PROGRAM CONVERSION ALTERNATIVES FOR A SOFTWARE DEVELOPMENT ORGANIZATION

We now explore various alternatives for achieving a multihardware, multilingual capability for a software development organization. First, some terminology and notation are in order for the purpose of identifying the various types of languages and machines which may be involved in the operation of the software facility. The terms "target" and "host" are frequently used to refer to the "executed on" and "executed by" machines, respectively. In order to describe the software development environment referred to above, it is necessary to expand the terminology to include two types of languages and two types of machines as shown below. It should be noted that the case described below differs from the situation where an organization converts

from system A to system B. In this case A and B represent the target language/machine and host language/machine, respectively. In the software development organization case, the target language/machine is the operational system and the host language/machine is the system used in the software development facility for testing and integration.

- Source language: Language used for coding the program initially.
- Host language: Language used for executing the source language program at the software development facility.
- Host machine: Machine on which the source program is executed in the software development facility.
- Target machine: Operational computer.

These relationships are shown in Figures 1 and 2. Figure 1 shows the general concept of the software development facility wherein two major choices exist for producing software for test and integration purposes. One method in Figure 1 involves producing host machine language which is executed on the host machine. This method tests problem logic in terms of host machine language. This method could be implemented by selecting one of the following paths in Figure 2:

- 1, 2 Interpretation
- 1, 3, 9, 10 Translation
- 1, 9, 10 Compilation
- 5, 9, 10 Assembly

The second method shown in Figure 1 involves producing target machine language which is executed in the host. This method tests problem logic in terms of target machine language. This method could be implemented by selecting one of the following paths in Figure 2:

- 1, 4, 7 or 1, 6, 7 Compilation followed by Simulation
- 4, 7 Simulation with Assembly Language Input
- 6, 7 Simulation with Machine Language Input
- 4, 6, 8 Assembly followed by Emulation
- 1, 6, 8 Compilation followed by Emulation
- 6, 8 Emulation with Machine Language Input

For tactical system development, the use of either method would be limited to testing the logic of individual programs and the logic of integrated programs. Tests of system timing, storage utilization and hardware dependent tests—performance testing—would be deferred until the target system is available. However, a substantial portion of the testing of most systems involves the checking of sequence of operations and the correct production of outputs for given inputs. The correct functioning of many of these operations is not speed or hardware dependent. This approach is also compatible with the top-down method of system design which emphasizes the early development of the system framework—calling sequences and communication paths. Thus logic testing performed in advance of performance testing will facilitate the entire test process.

In Figure 2, many alternatives are listed for the sake of completeness; some of the alternatives would be impractical for a software development organization to implement. Although many alternatives are shown in Figure 2, only one or two would actually be used in a single organization. We now examine each of the alternatives shown in Figure 2; before doing this, the languages indicated in Figure 2 will be identified.

Item 1. HLL1: A host compiler exists for this high level language.
Item 3. HLL2: A host compiler and translator exist for this high level language. A host compiler does not exist for HLL1.
Item 4. AL1: Target assembly language.
Item 5. AL2: Host assembly language.
Item 6. ML1: Target machine language.
Item 9. ML2: Host machine language.

Interpretation

- One step process.
- Slow because of software approach used in interpretation.
- Does not execute target machine language.

Translation

- Two step process.
- One hundred percent translation is not feasible.
- Does not execute target machine language which is necessary for testing equipment oriented operations.

Compilation and Assembly

- Two step process.
- Does not execute target machine language. (see Translation above)

Simulation

- One step process.
- Slow because of software approach used in simulation. About one-half the speed of the target system.[1]
- Executes target functions but by using host machine instructions to simulate target machine instructions: modified target execution.

Compilation followed by Emulation

- Two step process.
- Relatively easy to program.
- Execute microinstructions in host which carries out target machine instructions.
- Fast execution relative to simulation (at least as fast as target systems).[1]

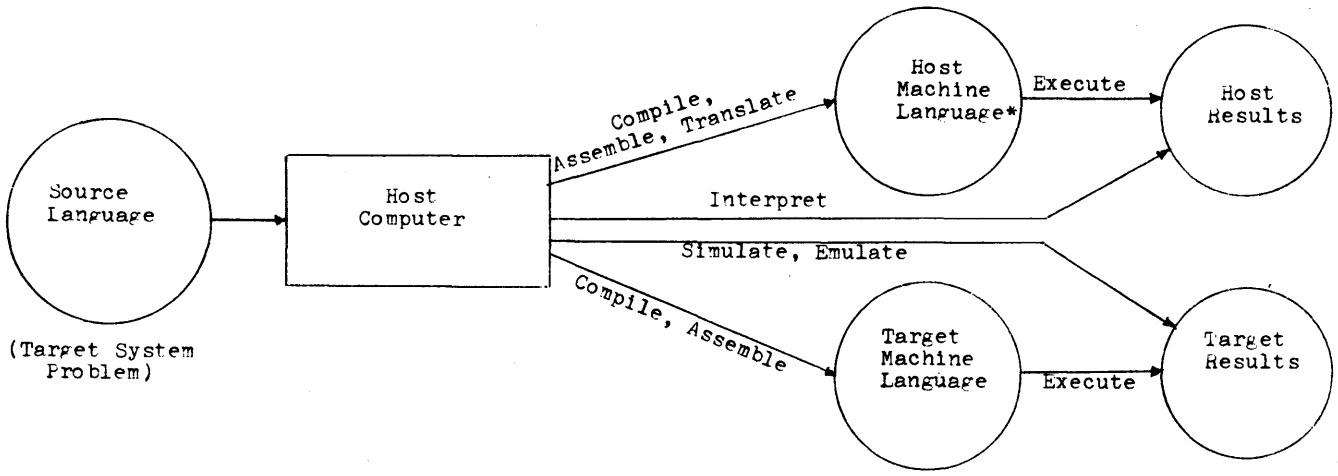

Figure 1—Software development concept

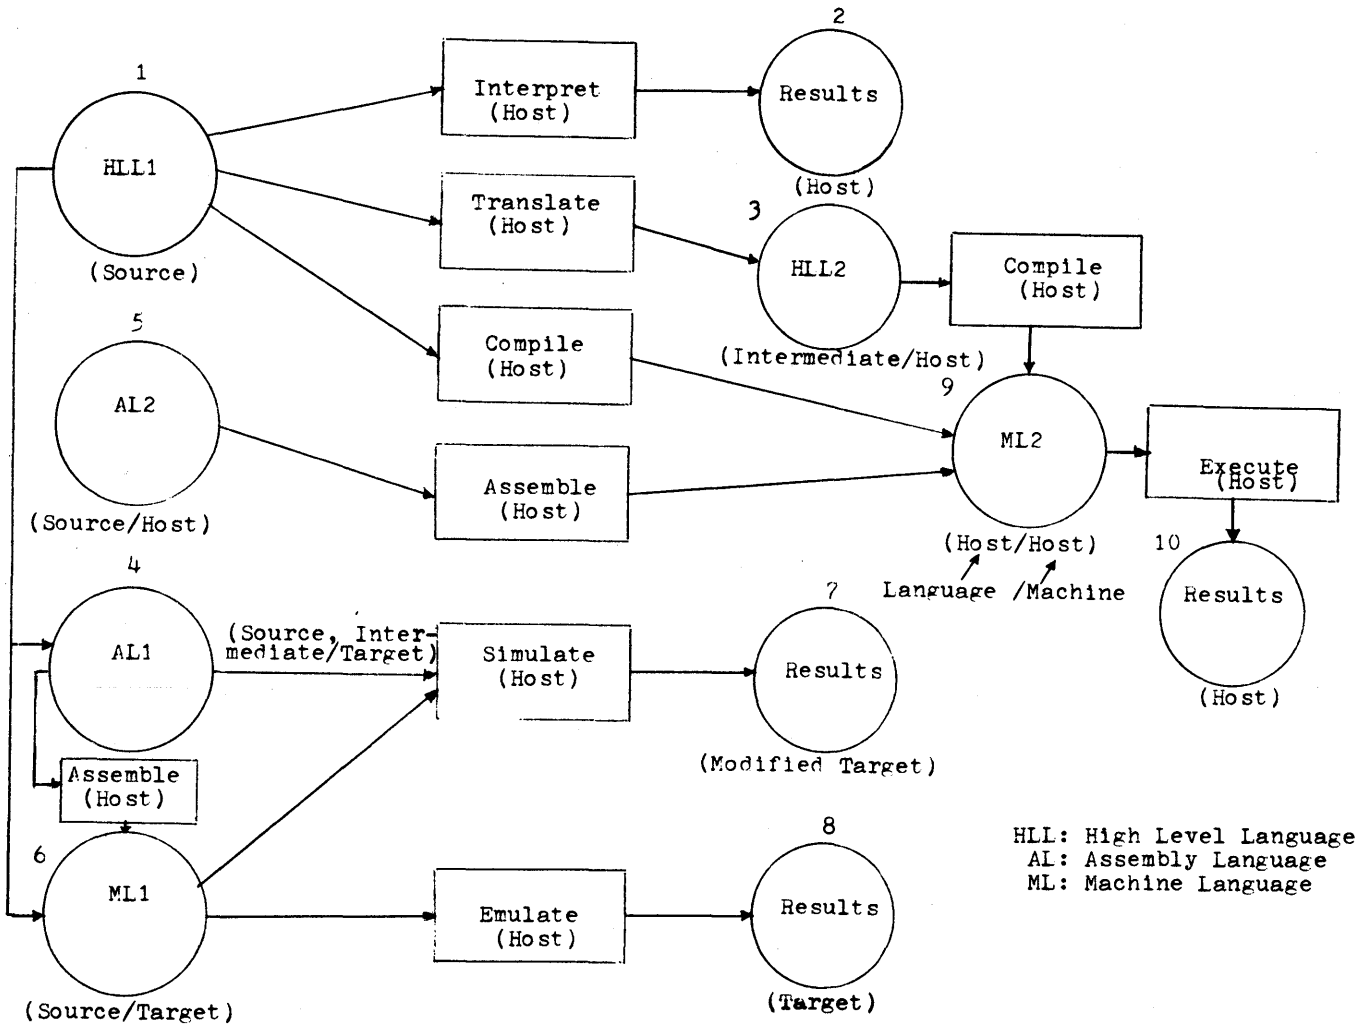

Figure 2—Alternatives for testing target machine programs

Emulation with Machine Language Input

- One step process.
- Difficult to program.
- Execute microinstructions in host which carries out target machine instructions.
- Fast execution relative to simulation (at least as fast as target system).

EVALUATION OF EMULATION FOR A SOFTWARE DEVELOPMENT FACILITY

Some of the considerations involved in deciding whether to employ microprogramming (emulation) for software development are the following:

Word Length

Is the host machine microinstruction length an integral multiple or divisor of the target machine instruction?

Program Size

Is the program so large that target assembly or machine language programming would be prohibited—necessitating the use of a HLL and its compiler for producing machine language which can be emulated?

Control Store Speed

How fast is the control store of the host relative to its main memory speed? Unless the control store is several times the speed of the host's native mode, the speed penalty will be excessive and the target machine's timing characteristics become distorted.

Type of Control Store

Will the emulator be stored in Read Only Memory (ROM) or Writable Control Store (WCS)? The latter is clearly preferable for a software development organization. One computer could suffice for emulating a variety of target machines by changing the contents of WCS. An on-line library of target machine emulation programs, accessible to the WCS, can be envisioned.[2] Another advantage of WCS is that it provides a user microprogramming capability.

Internal Data Code

Does the internal data code in the host differ from that used in the target (byte versus word orientation)? Does one machine use variable and the other fixed word length?

Arithmetic Operations

Do the arithmetic operations differ (decimal versus binary instructions)?

Instruction Length and Format

What are the differences in instruction length and format (size of operation code, number and length of addresses)?

Nature of I/O Operations

Are the I/O operations of target and host vastly different, such as the use of programmed I/O in one and DMA in the other? Even a common device like a card reader may cause problems if the number of columns read, data code or error processing differ between machines.[3] Another example of the complexity of the microprogram which can ensue from attempting to emulate another common device are the control signals of a typewriter terminal—carriage return, margin release, backspace, paper advance, etc.[4]

Microprogram Preparation Tools

How easy will it be to prepare emulation programs? Since microprogramming by conventional means requires a high degree of programming skill, lacks good self-documentation procedures and is difficult to debug, research has been under way to develop high level languages for producing microcode.[5]

Despite some of the problems of using emulation cited above, it can provide a powerful capability for the representation of a variety of systems in a software development organization because of its fundamental property which allows the host architecture to be changed in accordance with different target machine requirements.[6] Rather than provide n sets of hardware in a software development organization, n ROMS can be provided or, better, n emulators can be recorded in a library for loading into WCS. Another alternative is to use a combination of ROM and WCS, where the former is used as a backing store to hold emulator programs and the latter is the working storage where the current emulator program is stored; programs are swapped between ROMS and WCS. This capability would allow testing of a multiple computer target system.

Examples can be cited of the successful employment of emulation in software development.[7] However, in order for emulation to be considered a general solution to the software development problem, its limitations must be assessed and circumvented. Suggestions for dealing with the limitations are discussed in the next section.

LIMITATIONS OF EMULATION

The following discussion addresses certain limitations and issues which are crucial to the success of an emulator oriented software development facility.

Input/output operations

As stated previously the objective of advanced testing in the software development facility is limited to checking for correct operation and sequence of various functions; testing of timing relationships would be deferred until the target hardware, including I/O, is available. In other words, advanced testing checks for correctness of logic; later testing checks for correctness of performance. Using this approach, the following emulation control of I/O could be employed during advanced testing: Upon decoding an I/O command in the emulator program, control would be transferred to the host operating system where a timer would be set to simulate the duration of the I/O operation. Control would then be returned to the emulator. At the expiration of the timer interval, a timer interrupt would occur. For a read, the operating system would load the input buffer from the test data area in memory after the interrupt and prior to returning control to the emulator. For a write, the emulator would transfer data from the test data area to the output buffer; when the write command is decoded, control is passed to the operating system as described previously. In neither case is data transferred to or from a peripheral unit. Only the movement of data in memory, to or from the I/O buffers, is simulated. The time interval which is set in the timer would be drawn from a probability distribution which is representative of the characteristics of the target I/O device.

Speed relationship between host and target machines

It is important to be able to predict the speed of the target machine based on the speed of the host emulator. The speed analysis would be separated into two parts: CPU and I/O. In the case of the CPU operations a time ratio would be established based on sample measurements of time taken in the host to emulate specified target commands and the known time required for executing the target commands. This ratio would be applied to the number of commands to be executed by the target machine in order to estimate its CPU time. Several ratios might be needed, one for each type of command. The I/O timing analysis would be treated differently. Measurement of emulator time would not apply, since the emulator is not involved in I/O operations. Input/output time would be estimated from target I/O equipment specifications and problem specifications: numbers of file accesses, records read/written; blocking factor, etc.

Validation of emulator program

There is no way to guarantee total correctness of emulator operation during advanced testing because all target equipment is not available and performance characteristics involving timing dependencies and storage utilization cannot be totally tested during this period. The best that one can do, as with any test, is to compare the observed operation with system and program specifications. In the case of advanced testing, the comparison is limited to checking of: expected outputs for given inputs and expected sequence of function execution. The time of these events and efficiency of resource utilization cannot be evaluated.

Figure of merit for fidelity of emulation

It is desirable to have a simple-to-compute figure of merit which provides an overall measure of the closeness between emulator and target machine operations. A single comprehensive measure may not be possible. If closeness is to be the criterion, speed ratio is not a good measure, because we desire the host to operate several times faster than the target machine. This would be advantageous for advanced testing because the time and cost of testing would be reduced. A more appropriate measure would account for host deviations from target operations. Examples would be the frequency of simulating I/O. A ratio could be computed of software simulated commands to total number of target commands processed in the host. This would provide a measure of lack of fidelity between emulator and target machine.

Simulation versus emulation

A natural competitor to emulation is simulation. Simulation has an advantage of being less limited in the types of target operations which can be performed. This is because, in general, software provides a flexibility for performing complex operations which is unattainable with microinstructions. An example is the operating system task management and resource allocation operations which are necessary for executing the microprogrammed application functions. However, if all target functions were performed by simulation, there would be a lack of validity in target program testing because the simulator executes host machine instructions. This amounts to executing in pseudo target machine language. In contrast, although emulated CPU instructions are not pure target machine language, the use of microinstructions for representing target machine control and execution sequences comes closer to imitating operational conditions. In addition, emulators are reported to have a performance of five to 10 times more than simulators.[8] The best approach is to blend emulation and simulation so that the characteristics of each are used to advantage.

CONCLUSIONS

Alternatives for providing an advanced testing capability in a software development organization have been discussed. The need arises because some organizations are responsible for developing a series of systems each of which may be comprised of several software and hardware systems. It would be too expensive for the organization to acquire all the hardware and software systems necessary for test and integration. In addition many of the systems would not be available at test time. Emulation, combined with simulation, has been discussed as one solution to this problem. Its

advantages relative to compilation/assembly and translation have been examined. Although emulation is an attractive alternative, it should not be pursued unless the following conditions are satisfied:

- An easy way of producing microprograms is needed. This requires a high level language. Research has demonstrated that it is practical to use high level languages for producing efficient microcode.[9]
- The host should have a writable control storage for allowing multiple emulator programs, representing a variety of target machines, to be utilized.
- Related to the preceding items is the need for a user microprogramming capability. In a study of user microprogrammable systems it was concluded that this capability can improve both the space utilization and execution time performance of a computer system.[10]
- The host should not differ greatly from the target machine in terms of CPU and memory characteristics: word length, number of registers and memory size. Where differences do exist, the host should have the greater capability.

PRIM system—A framework for emulation-based debugging tools*

by JOEL GOLDBERG, ALVIN COOPERBAND, and LOUIS GALLENSON
University of Southern California Information Sciences Institute
Marina del Rey, California

INTRODUCTION

For some applications the native machine is not the system of choice in which to develop software, as when the target machine is unavailable (because it is still being developed, is obsolete, or is inaccessible) or inconvenient (as when there is minimal target-system support for debugging). In such cases, simulation or emulation may be preferred. Simulation has the advantage of giving the user intimate access to the target machine, usually through a rich debugging package. Typically this richness is achieved at a high development cost for the simulator and at a target-system performance degradation of four or more orders of magnitude. Emulation can offer processing speeds comparable to the target system (even faster, for slow target machines), but typically does not support a rich debugging environment. In designing the PRIM system, we have attempted to retain the best features of both the simulation and emulation approaches while at the same time minimizing their disadvantages. PRIM provides a sharable, uniform framework for running emulations of target machines; within that framework is a rich user interface that supports interactive target-system and emulator debugging. When the user is not engaged in debugging, the target system runs at emulator speeds, but a sophisticated debugging package is available immediately when needed. PRIM was developed within a modern timesharing system so as to provide convenient access, a file system, resource management, and a large set of utilities without the cost of developing yet another operating system.

THE PRIM SYSTEM ARCHITECTURE

The emulation of a target machine under PRIM involves three different system levels: a timesharing system, which runs on a DEC PDP-10; the PRIM framework, which runs at user level on the PDP-10; and target-machine emulation tools controlled by that framework, which run on a sharable MLP-900 microprogrammable processor. (The MLP-900—Multi Lingual Processor—is the prototype of a microprogrammable processor designed by Standard Computer Corporation[1] to follow their IC-7000.) This architecture is shown schematically in Figure 1. A more complete description of the PRIM architecture was presented by the authors at the Tenth Annual Workshop on Microprogramming.[2] The timesharing system hardware and software provide shared access to the MLP-900. The PRIM framework supports interactive users at terminals and provides access to the file system for the emulator. And the emulator maintains a complete target-system environment. The PRIM framework can be used for both emulator development and target program debugging.

The PDP-10 is a large, general purpose computer to which new devices can be connected fairly easily, since the I/O bus is extensible and the multiported memory is external to the processor. At USC Information Sciences Institute (ISI), it runs the TENEX timesharing operating system developed at Bolt, Beranek, and Newman.[3] TENEX is strongly oriented toward the support of interactive computing, serving both local users and remote users connected via the ARPANET. The operating system does not interact directly with the user; rather, it allocates resources, manages the file system, and supports the execution of TENEX processes, each process running in its own paged virtual memory and interacting as appropriate with its own user via a terminal of some kind. To support PRIM, TENEX was extended with software to provide access to the MLP-900 by TENEX processes; the MLP-900 was extended with hardware and software to guarantee the integrity of TENEX even against errant microcode.

The MLP-900 is a large, fast, vertical-word, microprogrammable processor with a writable control memory. The processor consists of an operating engine and a control engine. The operating engine is a 36-bit arithmetic/shift unit with 32 general registers, 16 mask registers, and a 1K internal memory. The control engine is a control unit with interrupt and branch logic, a subroutine-call stack, 128 programmable flip/flops, and 4K of writable control memory. Cycle time is 250 nanoseconds, during which either one or both engines can execute a 32-bit instruction. The MLP-900

* This research was supported by the Defense Advanced Research Projects Agency under Contract No. DAHC15 72 C0308, ARPA Order No. 2223, Program Code No. 3D30 and 3P10. Views and conclusions contained in this paper are those of the authors.

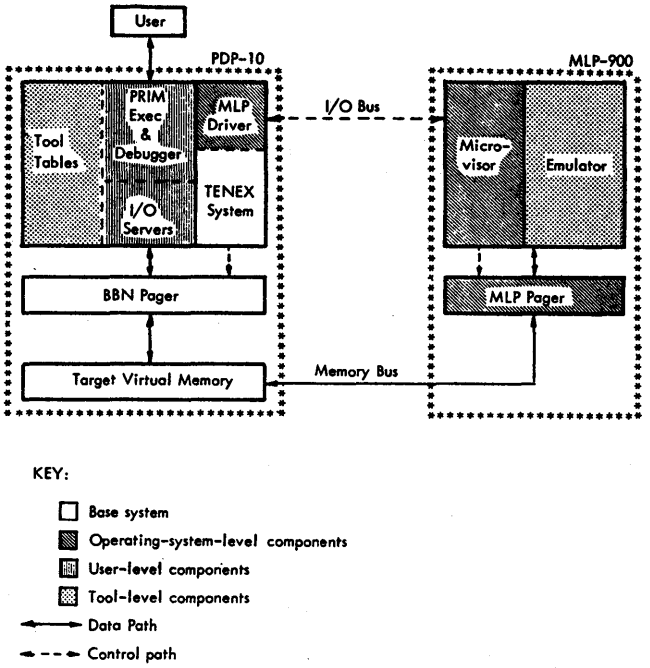

Figure 1—Architecture of PRIM

is interfaced as a peripheral device on the PDP-10 I/O bus with direct access to the PDP-10 memory via one of the four existing memory ports; it has no peripheral devices of its own. The I/O bus interface allows the exchange of control information between the MLP-900 and the PDP-10; via this interface, either processor can interrupt the other. Hardware modifications were required only in the MLP-900; they consisted of the interfaces to the PDP-10 and a supervisor/user state to protect the I/O bus interface, the MLP pager (an address translator in the memory interface that mimics the TENEX pager), most of the MLP-900 interrupt system, and the MLP-900 control memory itself against user microcode.

The software at the system level consists of a small operating system resident in the MLP-900, known as the microvisor, and a new TENEX device driver to shake hands with the microvisor and govern access to the MLP-900 by TENEX processes. The MLP device driver is the sole TENEX operating system module added. It allows a TENEX process to create, run, and control a subordinate MLP process in much the same way it can a subordinate TENEX process. It schedules use of the MLP-900 among contending users and supervises the microvisor. Most of the microvisor is devoted to swapping emulator contexts (control memory and MLP registers) as the driver passes control of the MLP-900 from one user to another. The process of swapping an emulator's context into and back out of the MLP-900 requires about ten milliseconds of microvisor execution and introduces no perceptible delays beyond those ordinarily encountered in a timesharing system. The rest of the microvisor responds to emulator requests for service, manages the MLP pager, and performs other tasks required by the driver in TENEX. The microvisor runs in the privileged supervisor state that allows access to all resources; emulator microcode runs in the user state that protects all the critical resources from modification. PDP-10 memory is not directly addressed by microcode; instead, memory references are to addresses in a virtual memory identical to that of a TENEX process. These virtual addresses are translated to real addresses by the MLP pager, which is controlled (via the microvisor) by the driver in TENEX. A reference to a page not in memory results in a page-fault interrupt into the microvisor, which passes the fault on to the driver and retries the memory operation after the page is fetched by TENEX.

The net effect of the design is a sharable emulation facility in which each emulator runs independent of all others in its own context, accessing its own virtual target memory under control of the PRIM framework that created it. The framework has potential access to all of its emulator's context and target memory and may inspect and/or modify them.

The PRIM system development started in 1972. The initial hardware and software were operational in May 1974 with the ability for multiple (local and remote) users to develop and debug emulator microcode. The complete system became available in March 1976. All software and hardware were developed at ISI. System software took about one man-year. The TENEX MLP-900 device driver represents about 2000 machine instructions; the MLP-900 microvisor occupies about 500 words of control memory.*

THE PRIM FRAMEWORK

The PRIM framework consists of TENEX processes that define and implement the PRIM user command language, create an MLP-900 emulation process and control its execution at the user's behest, and provide I/O service for that emulation process. The I/O service implements a set of primitives that allow the emulator to transfer data to or from the TENEX file system. The emulator invokes these primitives to perform target I/O operations on installed devices after the user has associated them with TENEX files.

An emulator is required to cooperate in the debugging process, although the demands are minimal. Essentially, an emulator is expected to stop cleanly when interrupted by the framework or on the occurrence of a small number of predefined events that it monitors and to report its reason(s)

* It is worth noting that the operating-system level of PRIM was designed, developed, and tested using a TENEX system that, except for maintenance, was in production use continuously. The hardware interfaces were checked out using a dedicated 16K-word memory module and a specially built I/O bus simulator that connected the MLP-900 to the PDP-10 via a high-speed EIA terminal line. A private MLP-900 driver controlled this "smart terminal." After the microvisor was developed and the swapping and paging algorithms validated, the memory module was shared among concurrent MLP-900 users. After validation of the hardware and software interfaces between the MLP-900 and the PDP-10, the I/O bus simulator was removed and the MLP-900 was connected to the PDP-10 I/O bus. An MLP-900 device driver was then added to TENEX and the MLP-900 connected to the full TENEX memory; since most of the driver logic had already been checked out, only a short extension of maintenance periods was required for stand-alone checkout of the new device driver. The change-over to this driver had no effect on the microvisor.

for stopping. When the emulator halts or is interrupted by user intervention, control returns to the user at command level via the framework. Specific commands are available to start (or resume) execution.

The emulator writer must supply the PRIM framework with tables that define the target system architecture and symbols and drive a target system assembler and disassembler. Except for machine and user symbols and target assembly language, the same command interactions apply to every use of an emulator and framework. The framework contains two separate command-processors, known as the exec and the debugger. The exec has a large number of commands of fixed form that are used infrequently. The debugger has a smaller number of commands, but they are of variable form and are used much more frequently. Although both command processors offer automatic command completion and help facilities, each uses a language tailored to its functions. Typically, a user interacts with the exec only briefly when starting and ending a session; during the session he interacts primarily with a target program or the debugger. The exec commands are based on easily remembered keywords that often require several characters to establish uniqueness; the debugger commands are uniquely identified with only a single keystroke.

The PRIM debugger is a target-system-independent interactive program for debugging a PRIM emulator or a target program running on such an emulator. Basically, it permits a user to examine, search, and modify target system locations and to set and clear breakpoints. Target system assembly language and symbols are recognized and generated, expressions of arbitrary complexity are accepted, and arithmetic is performed according to the conventions of the target machine. The debugger commands are listed in Table I.

Representation commands allow the user to designate the form and notation of the debugger's representation of data (FORMAT, MODE, and the three SYMBOL commands). Target system data may be represented as text or instructions or as formatted or unformatted numeric values; numbers may be represented as symbols or as signed or unsigned integers. The user may define multi-field data formats, select user symbol tables loaded earlier via an exec command, and add new symbols to a symbol table or delete existing ones.

Control commands allow the user to execute debugger commands conditionally or indirectly (IF and USE), to continue execution of a target system, either at the system's program counter or at a supplied address (GO), to single-step a target program (SINGLE STEP), to set and clear breakpoints in the target system and enter or edit debugger command "programs" to be executed at break time (BREAK, DEBREAK, and PROGRAM EDIT), and to return control to the PRIM exec (RETURN); privileged commands permit an emulator writer to single-step or set or clear a break in the MLP-900 (MLP STEP and MLP BREAK). Conditional and indirect execution are particularly important when a command is to be executed at a later time in an indeterminate context, such as in a command file or a break-time program. Breakpoints can be set on references (read, write, or execute) to target machine locations or on events that have been predefined by the emulator writer. The most powerful features of breakpointing is the ability for a user to associate with each breakpoint a sequence of debugger commands (the break-time program) to be executed when the break condition is detected and control is passed to the debugger. Coupled with conditional and indirect execution of debugger commands and the ability to continue target system execution, break-time programs offer the user a very powerful facility to trace execution, monitor events, and perform other complex exploratory functions automatically and repeatedly.

TABLE I.—PRIM Debugger Commands

Representation	Control	Display	Miscellaneous
FORMAT	MLP BREAK*	MLP TYPE*	MLP CHANGE*
KILL SYMBOL	MLP STEP*	EQUALS	CLEAR
MODE	BREAK	EVALUATE	COMMENT
NEW SYMBOL	DEBREAK	JUMP HISTORY	SET
OPEN SYMBOL	GO	LOCATE	
	IF	NEXT	
	PROGRAM EDIT	PRIOR	
	RETURN	SAME	
	SINGLE STEP	TYPE	
	USE		

* Commands for emulator developers only.

Display commands allow the user to examine the contents of designated target locations (TYPE, PRIOR, NEXT, SAME, and EQUALS), to search extended areas within the target system according to content (LOCATE), to evaluate arbitrary expressions (EVALUATE), and to review a record of recent target-system control transfers (JUMP HISTORY); a privileged command permits an emulator writer to display MLP-900 control memory symbolically (MLP TYPE). Any displayed location may be modified.

The miscellaneous commands offer convenience features that do not fit in the other categories. They allow the user to change the contents of target system locations without having to display them first (SET and CLEAR) and to annotate transcripts or break-time output (COMMENT); a privileged command permits an emulator writer to compile code changes directly into MLP-900 control memory (MLP CHANGE).

The PRIM exec comprises a diverse collection of commands that are not directly involved in the intimate control of debugging. The exec commands are listed in Table II. One major group of commands is concerned with the establishment of a target machine configuration (INSTALL, SET, and UNINSTALL) and with the mounting of TENEX files on the configured I/O devices (CANCEL, MOUNT, REASSIGN, REWIND, and UNMOUNT). Another group of commands involves the loading of various classes of state information from files (LOAD, TABLES, RESTORE, and SYMBOLS) and with the saving of all or part of the target context on a file for subsequent restoration (SAVE). There are commands that transfer control from the exec to some other state (QUIT, DEBUG, and GO), and commands that alter the state of the PRIM framework (NO, CHANGE, COMMANDS, and ENABLE). PRIM will, on request, maintain a transcript of all or a part of a PRIM session (TRANSCRIPT and CLOSE); such transcripts have been

TABLE II.—PRIM Exec Commands

Configuration	Save/Restore	Miscellaneous
CANCEL	LOAD*	NO*
FILESTATUS	TABLES*	CHANGE
INSTALL	RESTORE	CLOSE
MOUNT	SAVE	COMMANDS
PERIPHERALS	SYMBOLS	DEBUGGER
REASSIGN		ENABLE
REWIND		GO
SET		NEWS
SHOW		QUIT
UNINSTALL		TIME
UNMOUNT		TRANSCRIPT

* Commands for emulator developers only.

found invaluable by users with CRT terminals—and therefore no written record of their work. The remaining commands (FILESTATUS, PERIPHERALS, SHOW, NEWS, and TIME) are information-displaying commands.

The PRIM framework was written in BLISS.[4,5] It occupies about 35K words of PDP-10 memory, including fixed work space, and took somewhat over three man-years to produce.

EMULATOR MODEL

A prototypical PRIM emulator has been developed based on the constraints of the MLP-900 environment, the objectives of the PRIM system, the requirements of the PRIM framework, and the specific interface conventions that framework defines.[6] The environment consists of execute-only microcode residing in control memory, the MLP-900 registers, and a 256K 36-bit (virtual) main memory; the registers and virtual memory together comprise the context into which are mapped the registers and memory of the target machine plus various other regions devoted to required PRIM functions. The mapping is arranged at the convenience of the emulator writer, with accompanying tables describing this mapping to the PRIM framework. The emulator can modify its context in the course of emulation, stop (thereby returning control to the framework), and request I/O services from the framework.

The most fundamental PRIM requirement is for a bit-compatible emulation of the target machine with accurate timing. Beyond that, an emulator must have a control structure that allows it to stop after any cycle and subsequently resume emulation in a manner totally transparent to the target machine. While a single target instruction constitutes the typical cycle, other events, such as interrupts or I/O data transfers, must also be treated as emulator cycles. Changes to the context made by the user during an emulator stop must appropriately affect the target machine on resumption of emulation. In particular, this requires that the emulator have no hidden copies of target state information when it stops.

Target timing in PRIM is virtual. The emulator is required to increment an internal, high-resolution (typically, 50 nanosecond) clock to reflect the passage of target-machine time; there is no fixed relationship among target time, MLP-900 time, PRIM framework time, and real time. Emulated cycles that consume target time (e.g., instruction execution) advance the clock; emulated cycles that nominally occur in parallel with the former (e.g., I/O controller activity) are scheduled for service relative to that internal clock. The result is a small, event-driven, discrete simulation system with target instruction execution being treated as a background task. Figure 2 is a top-level outline of a typical PRIM emulation tool.

Target peripheral devices are included in an emulation. Device control logic, timing, and interaction with the target machine are contained entirely within the emulator. An I/O transfer is performed by the I/O server in the PRIM framework in response to a call by the emulator, which must then monitor the transfer for completion. The transfer is carried on in parallel with emulator execution, and the emulator may have several I/O operations outstanding simultaneously. The freedom given the user to define target system configurations and the protocols for use of the I/O server primitives, together constitute a generalized framework for device emulation.

User commands to inspect and modify the target machine environment are implemented by the PRIM framework via tables associated with each emulator, requiring no direct intervention by the emulator itself. But user commands involving the breakpoint facility do require the cooperation of the emulator. Each breakpoint a user sets is marked by a flag in a portion of the shared context outside the address space of the target machine; these flags are called "metabits." The emulator must monitor the target machine con-

```
initialize emulator ;
FOREVER DO
BEGIN
  IF reason to stop
  THEN BEGIN
    stop ;
    respond to switches and buttons ;
    END;
  IF time to serve next scheduled event
  THEN BEGIN
    remove event from list ;
    execute event routine ;
    END
  ELSE
    IF interrupt pending
    THEN execute interrupt cycle
    ELSE execute instruction cycle ;
END ;
```

Figure 2—PRIM emulator outline

tinually for the occurrence of any breakpoints flagged by these meta bits and, when one occurs, log it and prepare to stop at the end of the current emulation cycle. Interrupting execution at the end of the cycle is consistent with the requirement for stopping cleanly and also avoids a problem that would arise if execution were interrupted in mid-cycle on the occurence of the break condition—that of responding to possible changes made in the context during the break while not reporting the same breakpoint repeatedly.

PRIM defines two classes of breakpoints, known as reference breaks and event breaks. A reference break occurs on a read (data fetch), write, or execute reference to specified target locations. The meta bits for reference breaks are the four high-order bits of each 36-bit context word. As every target location can have its own meta bits, there is no practical limit on the number of simultaneous breakpoints the user may set. An event break occurs whenever a specified target-machine event arises. Each emulator supports its own set of event breaks, but at a minimum includes instruction execution (target machine single-step), jumps or branches, memory stores, interrupts, and I/O transfers. One meta bit is used for each type of event break an emulator monitors. The event breaks are particularly useful for close monitoring of target machine behavior.

To date, there are three supported PRIM emulations: the AN/UYK-20 (a modern 16-bit computer),[7] the Univac U1050 (an ancient byte-addressed decimal machine with a 30-bit instruction word),[8] and the Intel 8080 chip. Both the AN/UYK-20 and the U1050 emulations include a comprehensive set of peripherals. These two emulators each require about 3K words of control memory; the 8080 emulator, which supports only a simple terminal-like device, requires about 1K words of control memory. For the AN/UYK-20, which is a well-documented system of moderate complexity, the emulation of the CPU and the peripherals each required about six man-months. Although the U1050 is of comparable complexity, development of the emulator took somewhat longer because of the unavailability of accurate and up-to-date documentation. The 8080 emulation took only one man-month. All of these emulators require on the order of five microseconds to emulate one target memory cycle. For the AN/UYK-20, the ratio of emulated-to-real time is about 10/1; for the U1050 and the 8080, the ratio is about 1/1. For all emulations, as the I/O traffic increases, the performance ratio increases.

DISCUSSION

Since it became operational, PRIM has been used extensively by the System Design Laboratory (SDL) at the Naval Ocean Systems Center in San Diego, by the Logistics group at Gunter Air Force Station, and by a "smart terminal" project at ISI. SDL is using PRIM to support the design and development of naval systems employing the AN/UYK-20 minicomputer. The Logistics group at Gunter has used PRIM to examine the consequences of replacing existing peripherals with higher-performance ones on a Univac U1050 system. In the process, they discovered an unexpected design limitation in a communications interrupt routine and also uncovered several system bugs for which patches were developed on the spot. An Intel 8080 emulation was used at ISI to debug terminal software that would otherwise have been impossible to observe. The MLP-900 has been used an average 20 hours per month (representing an average of about 40 hours of connect time) by as many as six concurrent users. During this time an average of ten hours of TENEX time per month was used by the PRIM framework. The maximum level of use to date has been 90 hours of MLP-900 time in one month. Ordinarily, a PRIM user is unaware that he is sharing the MLP-900 with other users.

By cleanly and sharply separating the debugging and target-machine emulation tasks, PRIM has been able to avoid most of the disadvantages of simulation and emulation while at the same time combining their advantages. In achieving this sharp separation of function, PRIM established a uniform and systematic structure for the development of emulators. This structure not only minimizes the involvement of the emulator in the debugging process, but also greatly simplifies the task of emulator development as it utilizes a standard package of I/O service routines and provides a convenient control structure suitable for a large family of target-machine emulations. As most of PRIM consists of sharable system-level and user-level code that is common to this potentially large family of target system emulations, a more extensive development effort (with its consequently more sophisticated design) could be justified than would have been appropriate for a single-machine emulation or simulation.

A microprogrammed AN/UYK-20(V) emulation*

by DONALD A. DEEL and WALTER A. BURKHARD
University of California
La Jolla, California

INTRODUCTION

In this paper an emulation of the Sperry Univac AN/UYK-20 computer on the Nanodata QM-1[2] is described; the paper is divided into four sections. Short descriptions of both the target machine and the host machine are presented in the first section, each emphasizing those characteristics which most affected the emulation. The second section consists of a description of the basic structure of the emulation. This includes brief explanations of the flow of control through the various parts of the emulation, the principal routines, and the allocations of storage within the QM-1. Also, inaccuracies in the emulation are noted, with an indication of their effect and how they might be remedied. The third section gives a sampling of emulation performance characteristics and in the final section future plans are presented.

The AN/UYK-20 target machine

The AN/UYK-20 is a militarized 16 bit minicomputer. It possesses a large instruction set and good I/O provisions. The following paragraphs form a brief description of the machine.

Memory

Main memory consists of up to 64K words of 16 bits each. Several memory locations are dedicated to specific purposes: locations 110-137 (octal) are for processing interrupts; locations 140-141 (octal) are the I/O command cells, which are used to start up I/O transfers; and locations 200-217 are for external interrupt word storage.

Registers

There are two banks of general purpose registers, with sixteen 16 bit registers in each bank. Only one bank can be in use at one time; which bank is currently in use is determined by a bit in the Status Register #1. This register also indicates which interrupt classes are locked out, what the current condition code is, and what the carry and overflow bits are. The Status Register #2 controls the type of addressing that will occur for certain kinds of memory references. It also holds I/O instruction fault and memory resume interrupt data.

Other registers include a Real Time Clock, a Monitor Clock, and 64 Page Registers. The Real Time Clock is a 32 bit register which counts up, and the Monitor Clock is a 16 bit register which counts down to zero. The Page Registers are used to affect all memory accesses. The upper 6 bits of each 16 bit address coming from the CPU is used to access one of the 64 Page Registers; the six-bit contents of the selected page register is then substituted for the original upper 6 bits of the memory address.

Instruction formats

The AN/UYK-20 has both single and double word instructions. Figure 1 presents the various formats.

I/O provisions

There are sixteen I/O channels; each with dedicated control memories. Figure 2 displays the data formats within each I/O channel control memory.

A Control Memory holds all the information required by the I/O channel to perform data transfers. I/O instructions that control the input and output activity on all peripheral channels are executed under an active chain that is associated with each input and each output channel. I/O activity is initiated in the channels by placing the "initiate chain" instruction in the command cells in main memory (locations 140-141) and executing the "I/O command" CPU instruction.

The I/O Channels are capable of performing 8 bit or 16 bit parallel data transfers. 32 bit transfers can be affected by using two channels wired together. Serial I/O channels are available which meet the characteristics specified in EIA standard RS-232C, MIL-STD-188C, or NTDS serial specification.

Interrupts

There are three classes of AN/UYK-20 interrupts. From highest to lowest priority, these are: hardware error interrupts; software interrupts; and I/O interrupts. Within each

class, there is a priority structure to handle simultaneous interrupts.

Each interrupt class has associated with it several dedicated locations in main memory. These locations are similar to the OLD PSW/NEW PSW memory allocations in the IBM 360. Interrupts are responded to by first storing the program counter, status registers, and Real-Time Clock in several of the dedicated locations, and then re-loading these registers from the remaining dedicated locations.

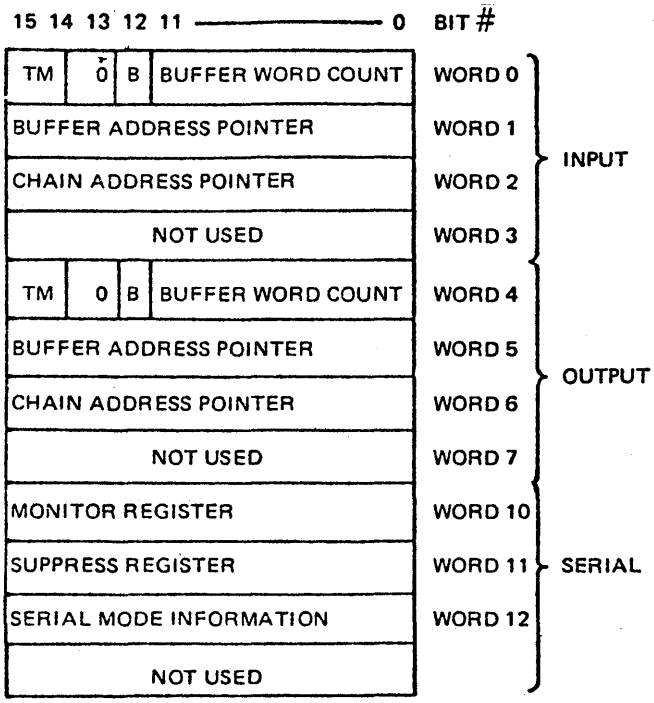

Figure 2—I/O channel control memory

The QM-1 host machine

The Nanodata QM-1 is a machine possessing two levels of microprogrammed control. This is accomplished using three different memories: Nanostore, Control Store, and Main Store. Target Machine (AN/UYK-20) instructions in Main Store are executed by (and defined by) microprograms in Control Store, under vertical control. Microinstructions in Control Store are in turn executed (and defined by) Nanoprograms in Nanostore, under horizontal control. This Control Hierarchy is illustrated in Figure 3.

With appropriate software, including both a micro language definition and systems support functions for the QM-1, the micro-level user can utilize the machine without being concerned with the nano-level. The micro language definition consists of a complete set of nano programs collectively called MULTI,[3] which is well-adapted to writing emulations. The systems support is given by two programs written in the MULTI micro language called TASK[4] and PROD.[5] TASK supports multiple co-resident Control Store tasks in a hierarchical manner. TASK also manages all QM-1 I/O functions for the micro-programmer. PROD (Programmable Run-time Operator's Display) allows the QM-1 operator to use the console to control the emulated target machine. PROD also provides trace/debug capabilities for the emulated hardware system and trace-debug capabilities for the microprogrammer. Since MULTI, TASK, and PROD were used for the AN/UYK-20 emulation, the Nanoprogramming level of the QM-1 will not be discussed in this paper.

The following paragraphs are a brief overview of the QM-1 resources available to the microprogrammer using MULTI.

Control store

Control Store is a fully readable/writable general-purpose 18 bit wide store implemented in 75 ns semiconductor memory. A maximum control store configuration consists of 16K words.

Main store

Main Store is a general-purpose 18 bit core storage consisting of up to 256K words; full cycle time is 800 ns.

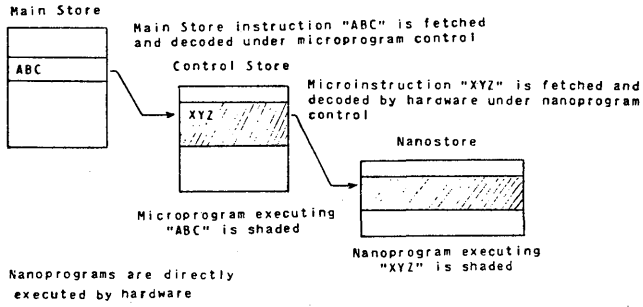

Figure 3—QM control hierarchy

Local store

Local Store is a bank of 32 18 bit registers. Some of these registers have special uses; for instance, the micro program counter and the micro instruction register are kept in Local Store.

Arithmetic-logic unit

The Arithmetic-Logic Unit can be controlled to perform all of the 16 logical (Boolean) operations, as well as common arithmetic operations, upon two 18 bit operands. A 16 bit mode permits the two input operands to be sign-extended from 16 to 18 bits so that the operation of the ALU need not be changed when dealing with 16 bit data values. Also, a decimal control facilitates decimal arithmetic.

Shifter

The 18 bit combinational logic shifter is capable of performing both left and right logical and circular shifts, as well as right arithmetic shifts. Also, double precision (36 bit) left and right logical, arithmetic, and circular shifts can be specified.

THE EMULATION OF THE AN/UYK-20 ON THE QM-1

The emulation of a machine on the QM-1 is very straightforward. It consists of an assembly language program running at the Control Store level of the QM-1. This micro-program explicitly performs all the operations and data manipulations expected of the emulated computer. Thus, object code (for the emulated machine) residing in the Main Store of the QM-1 can be executed in the same manner as it would be in the emulated (target) machine. This micro-program should be considered to be an "action translater;" it converts each of the emulated machine's action requests (the object code instructions) into an equivalent set of QM-1 actions.

In the case of the AN/UYK-20, the micro-program that runs in Control Store has several I/O channels to emulate as well as the Central Processor itself. The micro-program performs the following four operations repeatedly: execute one AN/UYK-20 micro-instruction; service each emulated I/O channel as necessary; update the emulated real-time clocks; emulate any interrupts that might have been caused by the previous three items in this list. Figure 4 illustrates this structure.

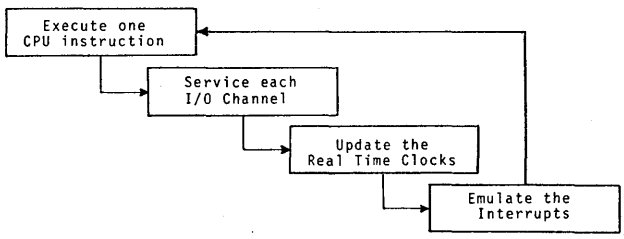

Figure 4—AN/UYK-20 emulation cycle

The following paragraphs are a brief description of the control flow through the various sections of the main emulator loop.

The CPU emulation

The part of the emulation that executes one AN/UYK-20 micro-instruction begins by reading the instruction out of Main Store. The number in the emulated program counter is used as the address. Once the instruction has been obtained, the six-bit opcode field is inspected to determine whether it is a Central Processor command, or an I/O instruction. If it is an I/O instruction, then an error flag is immediately set that tells the interrupts emulation to generate the equivalent of the AN/UYK-20 Central Processor instruction fault interrupt; the flow of control then passes to the interrupts emulation.

For Central Processor commands, it is normal to decode the opcode of the instruction at this point and then execute some micro-routine that is equivalent to the instruction. In the AN/UYK-20, however, it is possible to pre-fetch at least one of the instruction's operands before decoding the opcode. This is done by a micro-routine which first determines the type of the instruction from the two-bit f field. Then, based upon this information, an operand register kept in the Local Store of the QM-1 is loaded with the appropriate data item which always comes either from the currently active AN/UYK-20 general-purpose register bank or from the AN/UYK-20 memory. All of the various memory reference modes are handled in this pre-fetch routine; these modes include direct, indexed, indirect, and cascaded indirect memory references. Besides the operand, the routine also returns the four-bit A and M fields of the instruction in QM-1 Local Store registers; these parameters are used very frequently in processing an instruction after it has been decoded. Also, the address of the operand is put into Local Store if the operand is from memory. This address is used by the "store" instructions.

After the operand is pre-fetched, the instruction is decoded. This is accomplished by using the six-bit opcode and the two-bit modifier field (the f field) together as an index into a table of 256 Control Store locations. Each entry in this table is the Control Store address of a micro-routine which will execute an AN/UYK-20 micro-instruction. Opcode-modifier combinations which are undefined in the AN/UYK-20 all reference the address of a routine that immediately generates an emulated Central Processor instruction fault interrupt.

Immediately before entering a micro-routine, the QM-1 is switched to the 16 bit mode; consequently, the QM-1 ALU conditions can be used directly to set the AN/UYK-20 conditions code. All other portions of the emulation utilize the full 18 bit width of the QM-1 system.

The micro-routines which actually "execute" the instruction generally only consist of a few micro-instructions that

manipulate the QM-1's resources to implement the instruction. Routines that do not affect the AN/UYK-20 conditions code switch the QM-1 back to 18 bit mode and then exit to the next portion of the emulation. Routines that set the conditions code exit to one of two conditions-setting routines (single and double precision) before setting 18 bit mode and going to the next emulation section.

The I/O emulation

Two of the possible sixteen I/O channels of an AN/UYK-20 are presently emulated. This is because two channels are sufficient to handle the peripheral devices available to the emulation: a card reader, a lineprinter, and a CRT console. Additional channels can easily be added for more devices.

The emulation maintains a special flag which indicates whether any I/O activity is taking place. If this flag is not on, then the I/O emulation is exited immediately. This mechanism allows the CPU emulation to run as rapidly as is possible. Otherwise, the channels are emulated serially from highest to lowest priority.

Each emulated channel has a Control Store word of flag bits associated with it that reflect the current status of the channel. AN/UYK-20 channels have both input and output parts that are capable of executing I/O instructions or performing data transfers at the same time. When a channel is being emulated, the micro-program checks both parts to see if they are executing some I/O chaining program that is either active or waiting. Active chaining programs, or chains, are serviced by executing one I/O chaining command from memory. Waiting chains are waiting for some I/O transfer to complete, and are serviced by setting the chain "Active" when the transfer is finished. When an input or output portion of a channel is neither active nor waiting, it is dormant and requires no servicing.

AN/UYK-20 Channels have Control Memories; in the emulation, these are kept in Control Store. The Control Memory of a channel holds information needed for both the input and output portions such as: a buffer address, a word count, and a chain address pointer, which holds the address of the next I/O command to be executed if that portion of the channel is active. The entire I/O interpreter is structured as a subroutine so that each channel with an active chaining program could easily be serviced. This routine begins by fetching an I/O command from memory. The chain address pointer in the channel's control memory is used as the address. After the fetch, the chain address pointer is incremented to point at the next instruction. The opcode is then inspected; if it is not a valid I/O Command, control immediately passes to a micro-routine that generates an emulated I/O Instruction fault interrupt. Otherwise, the instruction's operand is pre-fetched. The major difference between the I/O pre-fetch routine and the Central Processor pre-fetch routine is that there are no indirect references in I/O Commands. After the pre-fetch is done, the instruction is decoded via a table of micro-routine addresses. As in the Central Processor emulation, undefined opcodes result in entries in the table that all point to one routine that generates an emulated I/O Instruction fault interrupt. Each micro-routine that actually executes the I/O command ends by returning to the routine that called the I/O command interpreter subroutine.

Emulation of the real-time clocks

The emulated Real-Time Clocks do not run in true real time; they are run at the same speed as the rest of the emulation. The actual execution times of Central processor instructions and I/O commands are well-known; these times make up the entries in a Control Store table. Just after an construction has been executed, this table is referenced, and the entry corresponding to the last instruction is added to the emulated Real-Time Clock whenever it is enabled. Similarly, the emulated Monitor Clock is decremented by the entry if the Monitor Clock is enabled. When the 16 bit Monitor Clock goes to zero, the emulated Monitor Clock interrupt is generated. When the lower 16 bits of the 32 bit Real-Time Clock overflows, the emulated Real Time Clock interrupt is generated. Running the Real-Time Clocks in this "relative" time keeps events occurring in the emulation in the same relative order that they would have had in the AN/UYK-20 itself.

Emulation of the interrupts

All interrupts are emulated in a single routine so that the proper priority scheme can be maintained. The Central Processor, I/O, and Real-Time Clock emulations generate interrupts by setting the appropriate bits in a QM-1 Local Store register.

The interrupts emulation proceeds by checking each of the enabled AN/UYK-20 interrupt classes from lowest to highest priority. Within each enabled class, each of the applicable emulation interrupt flags are checked, from highest to lowest priority; when an interrupt flag is found on, it is reset and the interrupt is immediately emulated. No further checking of interrupt flags is done for that class. This process of checking for interrupt flags is then repeated for the next higher priority enabled class of interrupt.

Interrupts are emulated by implementing the Old PSW/New PSW interrupt structure of the AN/UYK-20. When an interrupt must be honored, the emulation stores the AN/UYK-20 program counter, status register #1, status register #2, and the Real-Time Clock in Main Store locations dedicated for that purpose. These registers are then loaded from an adjacent set of Main Store locations that contain what is commonly called the "New PSW"; this causes the desired interrupt response, since the Program Counter has been changed. The emulation also calculates an interrupt entrance address index for the class and type of interrupt being honored and adds it to the new program counter.

Simultaneous interrupts of different AN/UYK-20 classes result in Old PSW/New PSW switching in order from lowest to highest priority; then the individual interrupts are serviced in order from highest to lowest priority by AN/UYK-20 programs in Main Store.

Inaccuracies in the emulation

The emulation of the AN/UYK-20 has the following inaccuracies:

The mapping of the upper 6 bits of AN/UYK-20 memory addresses through the 64 Page Registers does not occur. The Page Registers themselves exist and can be loaded and read up normally. No real difficulty is foreseen in correcting this; the nanoprograms have been written but not implemented or tested.

The nondestructive read-out (NDRO) memory is not emulated. There are no plans to correct this, since the AN/UYK-20 Bootstrap programs can reside in Control Store. Thus, the NDRO Mode Designator bit in Status Register #1 has no effect whatsoever.

These are the only known discrepancies in the emulation of the basic AN/UYK-20 at this time. The I/O emulation is complete where the following peripherals are concerned: the card reader, lineprinter, and CRT console.

PERFORMANCE

The AN/UYK-20 emulation is not large; it occupies less than 2.5K words of 18 bit Control Store. Additionally, TASK and PROD occupy approximately 2K words of 18 bit Control Store and 4K words of 18 bit main store.

One of the primary concerns with an emulator is its runtime efficiency. With no I/O activity in progress, the AN/UYK-20 emulation executes CPU instructions with an average slowdown factor of approximately 25. This number was determined by first finding the total time required by the QM-1 to execute an entire emulator cycle for several AN/UYK-20 instructions. These times were then compared to the AN/UYK-20 execution times for the same instructions.

Representative times for typical AN/UYK-20 instructions under different instruction formats are presented in Appendix A. It is assumed that no I/O activity is taking place and that no interrupts are pending. Each instruction time is broken down into the times taken to go through each section of the emulation; each time represents the worst case time for that section. The time units are QM-1 T-periods, which are 80 nanoseconds each.

From these examples, it should be clear that there is an emulation overhead of at least 269 T-periods for every AN/UYK-20 CPU instruction executed. This is incurred by the code sections that fetch instructions, decode instructions, check for I/O activity, check for interrupts and check for emulator single-step mode. The only sections that vary in execution time are those which pre-fetch operands, execute instructions, and set conditions (some instructions do not set conditions). It is this emulation overhead which gives rise to the rather severe slowdown factor of 50.5 in the case of the RR format Load instruction. The overhead time of 269 T-periods constitutes more than half of the execution cycle time of 474 T-periods. This is not true in the case of RX format instructions and instructions which take longer to execute on the AN/UYK-20. This can be seen in the RX format Load and the two Load PSW instructions, which have slowdown factors of 19.3, 13.3 and 11.6, respectively. The last instruction timing breakdown is given as an example of an instruction where the emulation overhead is not a dominate factor.

The overhead incurred by checking for I/O Activity, Interrupts, and Single-Step Mode can be reduced by an order of magnitude. This will result in a 15 percent reduction in the time required to execute an AN/UYK-20 instruction.

FUTURE PLANS

Currently, the AN/UYK-20 emulation on the QM-1 correctly executes the entire Univac AN/UYK-20 Processor 1 Diagnostic test program.[6] This thoroughly tests the CPU functions. Also, several I/O tests have been run in which the emulation has had all the connected peripherals busy while simultaneously executing normal CPU instructions.

Currently, the emulation can write and read Main Store images to and from the QM-1 tape drives; the Processor 1 Diagnostic is loaded into memory for execution in this manner. Adding true bootstrap ability will allow other large programs to be easily loaded. This will entail emulating another AN/UYK-20 I/O Channel for the tape drive and putting the appropriate AN/UYK-20 bootstrap code in Control Store.

One of the first "larger" programs to be run on the emulation will be the AN/UYK-20 Level II Operating System. This will allow the QM-1 to be used as a complete, standalone AN/UYK-20 system. It will also require the addition of an AN/UYK-20 disk I/O Channel to the emulation.

The completed emulation can be used for software development. It is well suited to this task, since an operator can exercise much greater control over the emulation than over a hardware AN/UYK-20.

APPENDIX A—TYPICAL AN/UYK-20 EMULATION TIMINGS

AN/UYK-20 opcode 01: LOAD (RR format)

T-periods	
108	Instruction Fetch
86	Operand Pre-fetch (RR format)
63	Instruction Decode and Update RTC

15	Instruction Execution
104	Set Conditions Code
28	Check for I/O Activity
55	Check for Interrupts
15	Check for Emulator Single-Step Mode

Total = 474 T=periods=37.9μs
Actual AN/UYK-20 execution time=0.75μs
Slowdown factor=50.5

AN/UYK-20 opcode 01: LOAD (RX format)

T-periods	
108	Instruction Fetch
155	Operand Pre-fetch (RX format with no indexing)
63	Instruction Decode and Update RTC
15	Instruction Execution
104	Set Conditions Code
28	Check for I/O Activity
55	Check for Interrupts
15	Check for Emulator Single-Step Mode

Total = 543 T-periods=43.4μs
Actual AN/UYK-20 execution time=2.25μs
Slowdown factor=19.3

Note: If indexing is done in the Operand Pre-fetch, the total time goes up by 92 T-periods; this makes the total time=635 T-periods=50.8μs and the slowdown factor becomes 22.6.

AN/UYK-20 opcode 07: Load OSW (RI format)

T-periods	
108	Instruction Fetch
110	Operand Pre-fetch (RI format)
63	Instruction Decode and Update RTC
120	Instruction Execution
0	No conditions are set
28	Check for I/O Activity
55	Check for Interrupts
15	Check for Emulator Single-Step Mode

Total = 499 T-periods=39.9μs
Actual AN/UYK-20 execution time=3.0μs
Slowdown factor=13.3

AN/UYK-20 opcode 07: Load PSW (RX format)

T-periods	
108	Instruction Fetch
155	Operand Pre-fetch (RX format with no indexing)
63	Instruction Decode and Update RTC
120	Instruction Execution
0	No conditions are set
28	Check for I/O Activity
55	Check for Interrupts
15	Check for Emulator Single-Step Mode

Total = 544 T-periods=43.5μs
Actual AN/UYK-20 execution time=3.75μs
Slowdown factor=11.6

Note: If indexing is done in the Operand Pre-fetch, the Slowdown factor becomes 13.6.

AN/UYK-20 opcode 17: Circular Left Double Shift (RK format)

T-periods	
108	Instruction Fetch
123	Operand Pre-fetch (RK format with no indexing)
63	Instruction Decode and Update RTC
748	Instruction Execution
104	Set Conditions Code
28	Check for I/O Activity
55	Check for Interrupts
15	Check for Emulator Single-Step Mode

Total = 1244 T-periods=99.5μs
Actual AN/UYK-20 execution time=3.0μs
Slowdown factor=33.2

Design considerations in a multiprocessor computer for continuous system simulation

INTRODUCTION

The current importance of computer simulation of dynamic systems is well-known. Such simulation is useful in system analysis, design, and testing, as well as in the training of human operators. Whenever a computer simulation involves interaction with actual system hardware (including humans) the computation must by definition take place in real-time; i.e., the computer must solve the simulation equations at the same speed with which the actual dynamic system operates. Real-time simulation of dynamic systems plays an important role in many areas of technology, including aerospace, process control, automotive, and other applications. In the simulation of flight vehicles such as aircraft, helicopters, and missiles the computational requirements associated with real-time simulation can become especially severe due to the complexity of the equations to be solved and the high frequencies present in the dynamic behavior of the solutions.

In the early 1950's, when real-time simulation of flight vehicles began to be achieved on a widespread basis, only analog computers possessed the necessary dynamic capability to accomplish the simulation. Over the ensuing two decades, as digital computers have increased dramatically in speed and computing power, more and more of the real-time simulation of flight vehicles (and other dynamic systems) has been taken over by digital computers. For example, today even general purpose digital minicomputers have the capability of real-time simulation of many aircraft.

However, there continue to be many flight-vehicle systems which currently are impossible or uneconomical to simulate adequately in real-time with existing general-purpose digital computers, e.g., small high-performance missiles, high performance aircraft which include flight-control system dynamics, helicopters, and jet engines. In many of these cases the simulation is being performed successfully with hybrid (i.e., combined analog/digital) computing systems. However, because of the potential advantages which all-digital simulation can have over hybrid simulation, e.g., better reliability, easier programming, lower cost and operation from a stored program, there is ever increasing pressure in favor of all-digital simulation. The purpose of this paper is to describe a multiprocessor digital computer with architecture and hardware designed specifically for efficient high-speed simulation of continuous dynamic systems.

REQUIREMENTS FOR REAL-TIME SIMULATION

There are a number of requirements associated with real-time simulation of continuous dynamic systems which should be understood to appreciate the problems peculiar to such simulation. First of all, because of the basic origin of the requirement, a real-time simulation will involve interaction with the real world external to the computer, usually on a more or less continual basis. For example, a computer used for simulation in flight training or for man-in-the-loop engineering studies will receive continuous inputs from the cockpit controls being activated by the pilot and will need continuously to furnish outputs to drive the various cockpit displays. When portions of a large simulation are implemented by using the actual system hardware with the remaining simulation accomplished on the computer, again the hardware furnishes continuous inputs to and requires continuous outputs from the computer. Of course, in the case of digital simulation continuous data will be approximated by discrete time series, but in any case the data-word rate for each input and output variable must be fast enough to avoid compromising the fidelity of the simulation. Thus real-time simulation often involves high input/output data rates. In typical aerospace simulations these rates may exceed several hundred data words per second for each of 100 channels or more.

In cases where the speed of a digital computer used for real-time simulation is being pushed in order to achieve satisfactory dynamic accuracy, it almost certainly follows that a fixed time step for numerical integration must be used.

This also simplifies greatly the A to D (analog-to-digital) and D to A (digital-to-analog) conversion problem when the computer is interfaced to external analog channels.

Many simulations of continuous dynamic systems involve evaluation during each integration step of numerous functions of many variables. For example, the aerodynamic coefficients used for flight simulation can involve several dozen functions of two, three, four, or more variables with a correspondingly large data base required for function storage. Such simulations also require numerous coordinate transformations during each integration frame, i.e., the transformation of vector components from one spacial coordinate system to another.

Another characteristic of many continuous system simulations is the existence of a wide range of dynamic frequencies inherent in the system. For example, a typical air frame simulation might exhibit a phugoid longitudinal mode at 0.01 hertz and at the same time have a short period pitching mode of 1 hertz, a structural vibration mode of 10 hertz, and a control-surface actuator mode of 25 hertz. The integration frame rate must be high enough to handle the highest mode frequency with adequate accuracy. This means that the integration frame rate is extremely high (i.e., step size is extremely small) with respect to the mode corresponding to the lowest frequency. This can lead to errors caused by roundoff if care is not taken. Multiple integration frame rates can also be employed, but most users prefer to avoid that complexity.

Finally, typical continuous system simulations often involve nonlinear functions with discontinuities, especially in the modeling of control systems. Typical examples include linear functions with limiting, relay (on-off) controls, deadzone, hysterisis, etc. Digital simulation of such functions, especially when employing fixed integration frame rates as normally used for real-time simulation, can result in very sizable dynamic errors unless very small integration steps are utilized.

To summarize, real-time digital simulation of continuous dynamic systems, especially flight vehicles, is characterized by many input-output channels with high data rates, numerous multivariable functions requiring large data bases and many high-speed repetitive-type calculations, coordinate transformations which also tend to be repetitive in nature, a very large spread in dynamic frequency, and many nonlinearities with discontinuities. The computer described in this paper has been designed for efficient processing of simulations having these characteristics.

NUMERICAL CONSIDERATIONS

An important parameter affecting both cost and performance in the design of any digital processor is the word size used for arithmetic operations and memory. As stated in the previous section, much of the computational load in dynamic simulation of continuous systems, especially flight vehicles, involves evaluation of multivariable functions. Usually the data involved in the function tables is known with only limited precision, so that 16 bits is more than an adequate word size to represent the data points. Furthermore, with careful scaling techniques the evaluation of functions using table lookup and linear interpolation can be performed with a 16 bit arithmetic processor without any deterioration from 16 bit precision.[1] Under these circumstances it would in fact be inefficient to use a word size significantly larger than 16 bits.

In the case of coordinate transformations the scaling of the required trigonometric functions is such that 16 bit precision can be maintained. Additional algebraic computations are also required in general to compute the time derivatives of the state variables in typical simulations, but in most cases these do not include small differences of large quantities which might reduce the computational precision. Division can be accomplished by generation of a reciprocal function followed by a multiplication. Simple scaling algorithms insure that precision is maintained even when the divisor varies over a large range. Expanded use of function generation instead of algebraic computation in many other formulas further improves the scaling.[2]

Thus for an accuracy range considered more than adequate for continuous system simulation, e.g., 0.01 percent to 0.1 percent, a convincing case can be made for using a fixed point 16 bit computation for the state-variable derivatives. Not only is the 16 bit precision adequate, but also the maximum range of state-variables is either known or can itself be computed, so that efficient scaling to take full advantage of the 16 bit precision is straightforward. The use of true roundoff as opposed to roundup or rounddown in the arithmetic processor prevents bias which might cause error buildup.

However, in the arithmetic involved in the mechanization of numerical integration formulas it is easily seen that 16 bits can represent quite inadequate precision. In particular this is true when a simulation exhibits a very wide range in dynamic frequencies, which can often occur in flight simulation and other examples as noted in the previous section. The problem can be understood by considering a simple integration formula. Assume we wish to solve the equation

$$\frac{dx}{dt} = Kf(x,y,\ldots) \tag{3.1}$$

where $x,y,\ldots$ are state variables in the simulation. The constant K is chosen so that the function f ranges up to unity in magnitude. For simple Euler integration we use the following formula:

$$x_{n+1} = x_n + hKf(x_n, y_n, \ldots) \tag{3.2}$$

where h is the numerical integration step size and $x_n = x(nh)$, $y_n = y(nh)$, etc. Equations similar to (3.2) will be repeated for each of the problem state variables. As a result there will be a maximum scaling constant, K_{max}, associated with one of the equations and a minimum scaling constant, K_{min}, associated with another of the equations. In the flight-equation example of the previous section, $K_{max}/K_{min} = 25/.01 = 2500$. To be conservative, assume

$$\frac{K_{max}}{K_{min}} = 10^4. \tag{3.3}$$

Now the maximum allowable numerical integration step size, h, will depend on K_{max}. In particular, the modal time constant associated with the equation $\dot{x}=K_{max}\, f \cong K_{max}\, x$, assuming $f(x,y,\ldots)$ can be represented quasilinearly by the simple function x, will be $1/K_{max}$. Let's further assume that we take 10^3 integration steps per time constant, $1/K_{max}$. This would yield good dynamic accuracy (~0.1 percent) using Euler integration. To be sure, higher order integration formulas would allow much larger step sizes for comparable accuracy. However, even in that case one would like to preserve the option of using the smaller step size without getting into roundoff problems. Thus we assume that

$$h=\frac{1}{K_{max}}\times 10^{-3}. \tag{3.4}$$

Now let us examine Eq. (3.2) for the case where $K=K_{min}$. Then we can write

$$x_{n+1}=x_n+hK_{min}\, f \tag{3.5}$$

or from Eqs. (3.3) and (3.4)

$$x_{n+1}=x_n+\frac{K_{min}}{K_{max}}\times 10^{-3} f \tag{3.6}$$

$$=x_n+10^{-7} f \approx x_n+f\times 2^{-23}. \tag{3.7}$$

If the function f is computed to 16 bit precision, and we wish the increment $f\times 2^{-23}$ to be added to x_n with 16 bit precision, then clearly x_n must be represented to at least 23+16=39 bits of precision. Certainly 32 bits would be inadequate and 48 bits contains a conservative safety factor. This is the rationale behind using 48 bits for the numerical integration processor even though only 16 bits is used in the computation of the derivative function f. The above argument also explains why many 32 bit floating-point computations which effectively realize only 21 to 24 bits of mantissa precision must actually be mechanized in double precision for simulations involving "stiff" systems (large ratios for K_{max}/K_{min}).

In order to confirm the effectiveness of 16 bits for the computation of state variable derivatives and 48 bits for numerical integration, a number of typical systems have been simulated on a general purpose computer with a program using the word lengths as proposed above, along with true roundoff. These simulations, including nonlinear airframe dynamic equations, have demonstrated the validity of the approach.

TECHNOLOGY CONSIDERATIONS

As we have seen, many continuous system simulation applications impose severe requirements in speed, real-time operation and economics. We also have observed that 16 bit fixed point computation is adequate in many important simulation applications. A significant exception is implementation of integration algorithms, where a 48 bit word length is desirable to accumulate small increments accurately. Reflecting this application insight, a specialized digital computer for continuous system simulation should maximize, in some reasonable sense, its performance to cost ratio by matching real-time speed and numerical requirements to the currently available technology. This kind of optimization is reflected in the choice of memory, the logic family, the system architecture and a software approach.

Factors in this kind of optimization include the following:

(1) large data memory for function data and solution storage (up to 256K words or more),
(2) high data rates to and from data memory,
(3) fast 16 bit addition and multiplication rates for irregularly structured computations,
(4) flexible and fast accumulation of 48 bit operands,
(5) functional parallelism and pipelining of different aspects of the computational tasks,
(6) architectural flexibility to grow capability with minimal interaction on existing hardware and software, and
(7) very high speed analog to digital, digital to analog and digital to digital data transfers.

Requirements (1) and (2), at first glance, are incompatible in a cost to performance optimization, since low cost memory technology (cost per bit) emphasizes moderate speeds. Thus the currently available 4K×1 and 16K×1 MOS RAMS provide the lowest cost memory but with cycle times from 200 to 500 nanoseconds. This compares with the much faster 1K bipolar RAMS which offer 50 nanosecond cycle time but have much higher cost, increased power requirements and less packaging density. This dilemma is avoided by using the slower MOS RAMS in a highly interleaved configuration. This strategy requires data organization that allows overlapped accesses. Since the continuous system simulation application[1] permits this kind of data organization, the architecture to be described uses an inter-leaved memory to realize both economic and speed objectives.

Requirements (3) and (4) can be realized by parallelism or by very fast addition and multiplication hardware. One extreme approach to parallelism would be to use hundreds of inherently slow microprocessors, each implementing addition and multiplication routines. This scheme imposes serious architectural constraints on data management and hardware interconnection. An alternative is to employ the very high speed-to-cost performance of emitter coupled logic (ECL). With ECL technology, a 17 bit by 17 bit product can be obtained in less than 50 nanoseconds. Also, the ECL family permits very high speed data rates between registers and between blocks of processing hardware. For these reasons, ECL was selected.

Requirement (5) just emphasizes the fact that memory and arithmetic speeds have practical limits and, at some point, additional speed improvements must come from parallelism and pipelining. These techniques can give striking performance improvements, but with penalties in increased cost, increased hardware complexity, difficulty in data transmission, and severe programming and software constraints. These penalties become overbearing in the design of a general purpose digital computer. However, for an application-centered digital computer, which limits scope, the penalties

are more easily controlled and parallelism and pipelining offer intriguing possibilities.

In particular, we can realize significant performance advantages by designing each processor for a given function. Each processor of the multiprocessor computer is then different and suited to a class of operations. An important fringe benefit of this approach is ease in meeting the architectural flexibility of Requirement (6). In fact, the numerical integration processor, which will be described, is being added to existing systems with no difficulty.

Requirement (7) is faced in interfacing the simulation computer to real-time hardware. To be compatible with a high speed digital architecture, both the analog to digital and digital to analog converters must be parallel. Fortunately, fully parallel analog to digital conversion is now feasible because of the improved performance and decreased cost of modular analog to digital converters. Digital to digital transfer is now encountered frequently as digital computers become an integral part of real-time hardware. The net effect of these real-time data conversion and transfer requirements is a special interfacing approach to the digital computer hardware. This implies simple, fast, burst-oriented transfer of data blocks to and from the data conversion equipment.

COMPUTER ARCHITECTURE OF THE AD-10

Figure 1 is a block diagram showing the architectural features of the special digital computer suited to the continuous system simulation task. This system, designated the AD-10 and manufactured by Applied Dynamics International, will be described in the context of the major system elements shown in Figure 1. The purpose is to show how an application-architecture viewpoint can lead to truly significant performance improvements.

Data, address, control and status multibus

The data, address, control and status multibus is a parallel ECL bus composed of 16 data lines, 20 address lines and 12 control and status lines. This high speed multibus supports 20 data/address bus transactions per microsecond. These bus transactions pass data to and from data memory, five functional processors, the real-time input-output channel and the host digital computer.

The transactions, as well as all memory and processor functions, are synchronously controlled from a master 40 MHz clock. This synchronous approach maximizes speed by avoiding handshaking delays characteristic of asynchronous control.

Host interface control

All functions of the system are under control of a host computer interfaced to the multibus through the host interface control (HIC). Through the HIC, the host computer loads the program memory resident in each functional processor, loads data into the interleaved data memory, supervises run/halt control of the system, and performs other control, status interrupt and diagnostic functions. The host may be a relatively large or a moderately sized Digital Equipment PDP-11 system. In addition to control functions, the host provides software support for program generation, translators, file management and debugging and diagnostic aids.

Except for these set up and control functions, real-time continuous system simulation is achieved through coordinated programs stored in the five functional processors. These programs access required data from data memory and control the input-output channel. The data, address, control and status multibus, under control of these processors, serve as the data communication path between the processors and data memory.

Interleaved data memory

The interleaved data memory (DM) holds the large data tables for multivariate function generation, solution storage and general data storage. Data is organized in DM so that data bandwidth is at rates up to the 20 MHz bus transaction limit. With up to 64 interleaved 4K pages of 16 bit words (plus parity), full memory bandwidth can be realized in many applications. Addresses for data are generated by the memory address processor (MAP). Memory size is expandable to 1024K words by using 16K RAMS instead of 4K RAMS.

Functional processors

The functional processors, COP (control processor), MAP (memory address processor), DEP (decision processor), ARP (arithmetic processor) and NIP (numerical integration processor), work in an overlapped and coordinated manner on different aspects of the simulation task. All these processors have certain common features, which will be discussed.

The functional processors synchronously execute instructions at a 10 MHz rate. Each processor contains its own program counter and program memory. These program memories, which are loaded through the HIC, are 50 nanosecond, 1 K word, bipolar writable control stores. The word length in each processor is matched to the needs of that processor. In total, these word lengths add to 272 bits. These processor instruction words, fetched with look ahead, execute in 100 nanoseconds and are responsible for the parallel computing power and speed of the system.

The advantages of this distributed processor architecture are significant. First, the relatively independent character of each processor minimizes design and construction problems implicit in 100 nanosecond execution times. Second, the structure of each processor is determined by a few functional requirements. This is a great simplification over the complex job of designing one processor to do all things. Third, the flexible parallel structure allows the system to be tailored to different application without important impact on other ele-

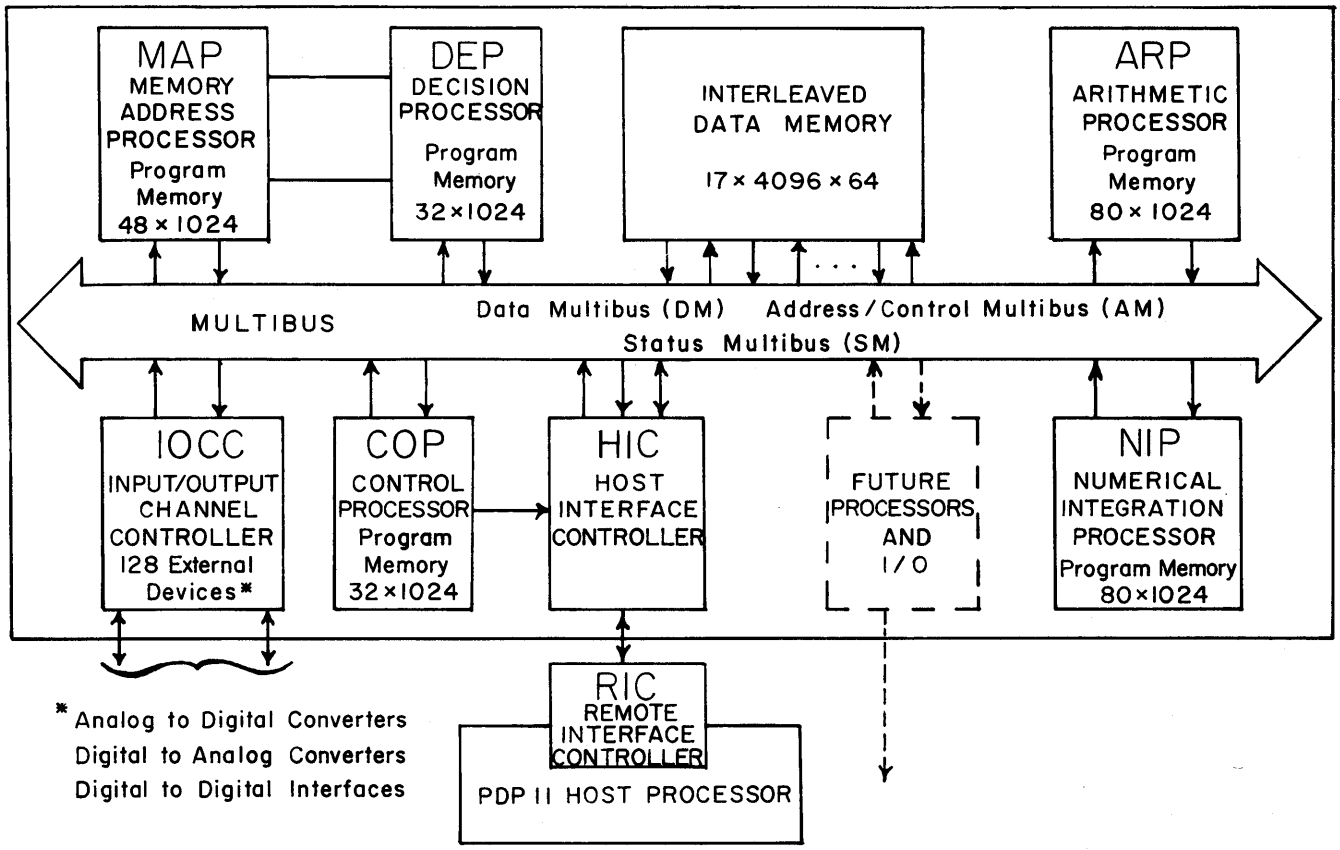

Figure 1—AD-10 block diagram

ments of the system. Fourth, the sequentially coordinated operation of the different processors minimizes programming difficulties inherent in parallel processing. This sequential orientation is consistent with usual programming concepts and avoids the very difficult task assignment and data communication problems which characterize other parallel architectures.

The different functional processors and their roles in continuous system simulation will be considered now in more detail.

Control processor (COP)

The COP coordinates the activities of the other functional processors and provides the means to request service from the host computer. In particular, COP instructions

(1) provide halt and conditional halt control,
(2) control the active/wait status of all processors,
(3) load processor program counters and status words,
(4) read status and data bits for conditional halts and jumps, and
(5) control the real-time input-output channel.

Programmed halts from the COP allow the host computer to control both single frame and periodic operation. Conditional halts permit error conditions or program conditions to halt the program and request host service.

Each processor has an active and wait state. In the active state the program counter is counting and executing instructions; in the wait state a processor is not executing instructions. Through the active/wait instruction, the COP can conserve program memory in a temporarily unneeded processor.

Through load program counter, jump and conditional jump instructions, the COP provides a minimal looping and subroutine capability. Because of the pipelined character of the interleaved memory and, to a degree, the processors, loops should be relatively large for speed effectiveness. Philosophically, the architecture is most capable in executing blocks of branch-free code. Thus, as an example, a linearly coded binary search is used to determine input location between function breakpoints. This technique fully controls the search time and avoids looping.

Memory address processor (MAP)

The MAP generates physical addresses for the DM from MAP user addresses. The physical address consists of a word address (one location in an interleaved page of 4096

locations) and a page address. User addresses are converted to physical addresses by an alignment network which assures that overlapped memory accesses will not be in time conflict in a computational task.

Decision processor (DEP)

The DEP executes comparison and modification instructions on a dual 128 word register file within the DEP. This structure efficiently implements a binary search in function generation,[1] as well as other decision oriented operations. Because these decision operations are isolated within the DEP and because the DEP is associated with the MAP, the ARP is simplified and addressing is made more efficient.

Arithmetic processor (ARP)

The ARP provides the very high speed 16 bit arithmetic needed for continuous system simulation. Through overlapped move and arithmetic operations and a very high speed 128 word register file, the ARP efficiently implements the function generation and irregularly structured computations characterizing simulation applications. Arithmetic is in 2's complement fractional and integer formats. Provisions

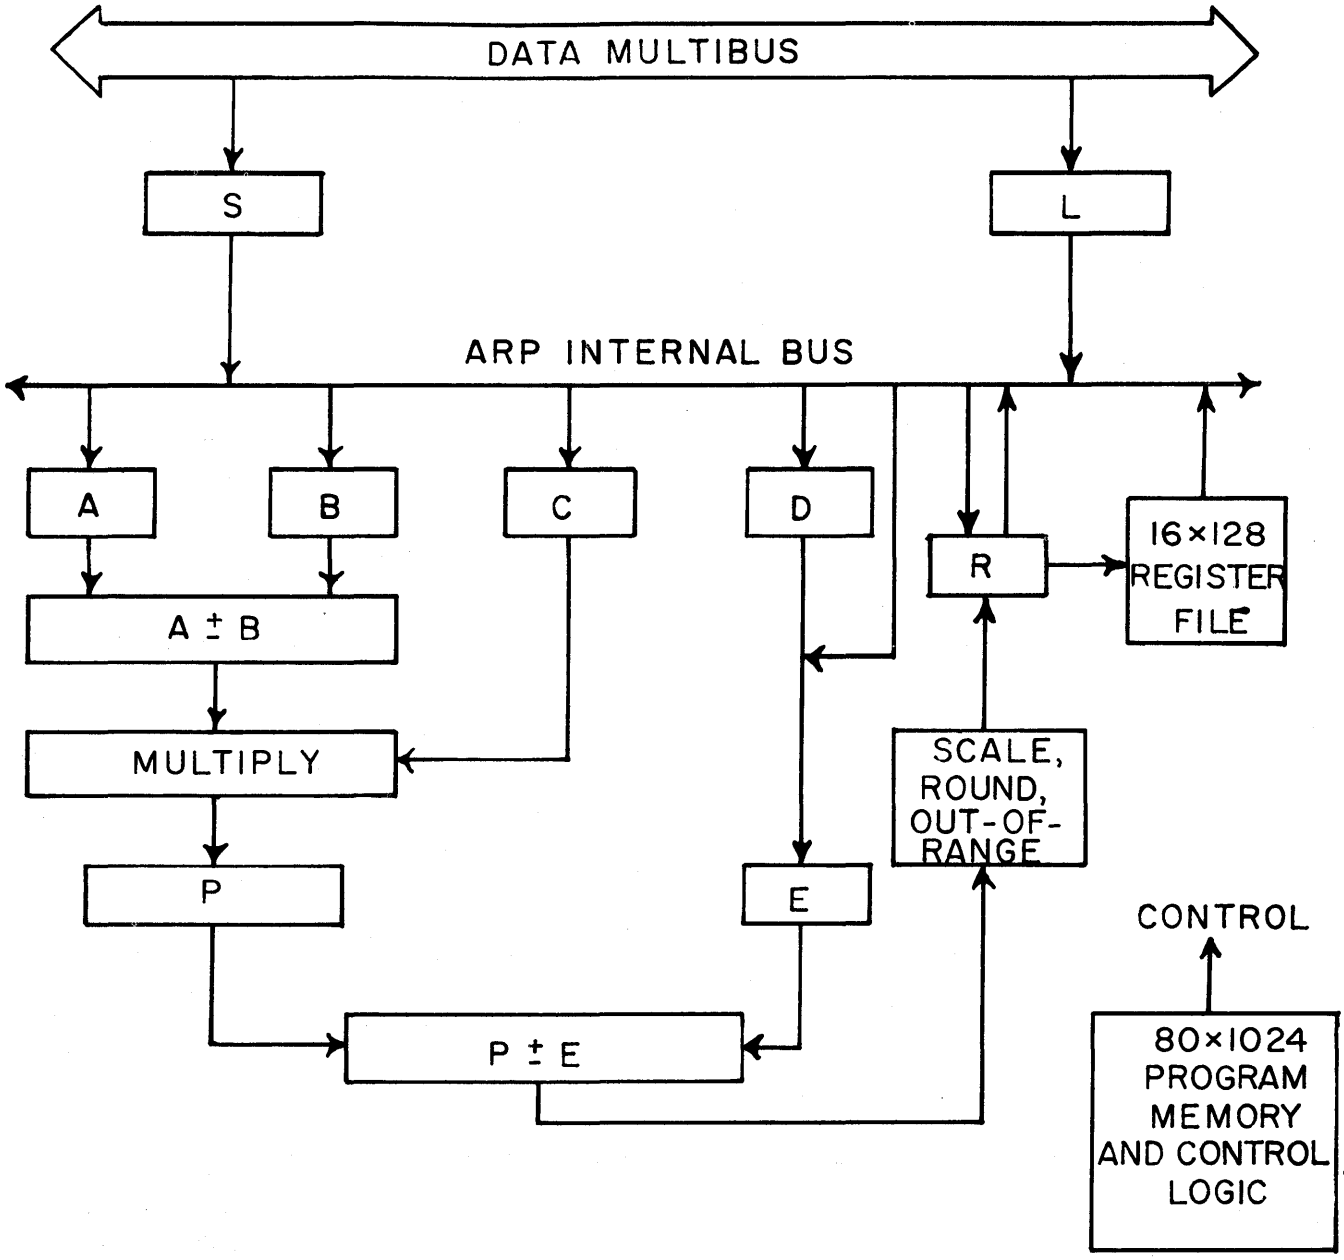

Figure 2—Block diagram of the arithmetic processor

are made for full carrys, scaling and a true out-of-range saturation which avoids modulo 2^{16} wrap-around. These features preserve the effectiveness of the 16 bit format.

The organization of the ARP is shown in Figure 2. Four move subinstructions per instruction set up the operands for the following instruction. This following instruction executes an arithmetic subinstruction of the general form $R=\pm(A\pm B)*C\pm D$ on the operands A, B, C and D, producing the result in 175 nanoseconds. Since all these functions are fully overlapped in a pipelined approach, the result R is computed with a 10 MHz throughput rate. Thus 20 additions and 10 multiplications can be achieved each microsecond.

Numerical integration processor (NIP)

As we outlined earlier, the right hand side of the simulation differential equations is adequately represented by 16 bit arithmetic. The features in the processors described above are effective in implementing these right hand side computations. Many AD-10 systems are currently working in the field performing some or all of these operations. In these situations, the remaining computations and integrations are accomplished in the analog computer subsystem of a hybrid computer system or, in a few cases, in a general purpose digital computer.

The full performance capabilities of the AD-10 for dynamic system simulation are realized when all computations, including integrations, are done within the AD-10. This requires the numerical integration processor (NIP), which is shown in the simplified block diagram of Figure 3. The NIP elements include a 48 bit arithmetic unit, a parallel shifter for accumulating increments to 48 bit words, a 48×1 K register file, buffer stacks and data and control stack subprocessors. The NIP communicates to the other processors through the multibus and is controlled by microprogrammed instructions stored in the 80×1024 program memory.

Data, control and exponent stacks, and indexed addressing to the register file are essential to subroutine implementation of integration algorithms and the effective overlap of integration computation with computation occurring in the other processors. The parallel shift network positions a 16 bit variable according to the sum of four shift factors, E0, E1, E2 and E3. This efficiently implements integration algorithms and allows a "quasi" floating point format for difficult scaling situations which can occur occasionally. The control stack processor permits simple block transfers to other processors and efficiently controls substep logic in Runga-Kutta and other integration formulas. The data stack

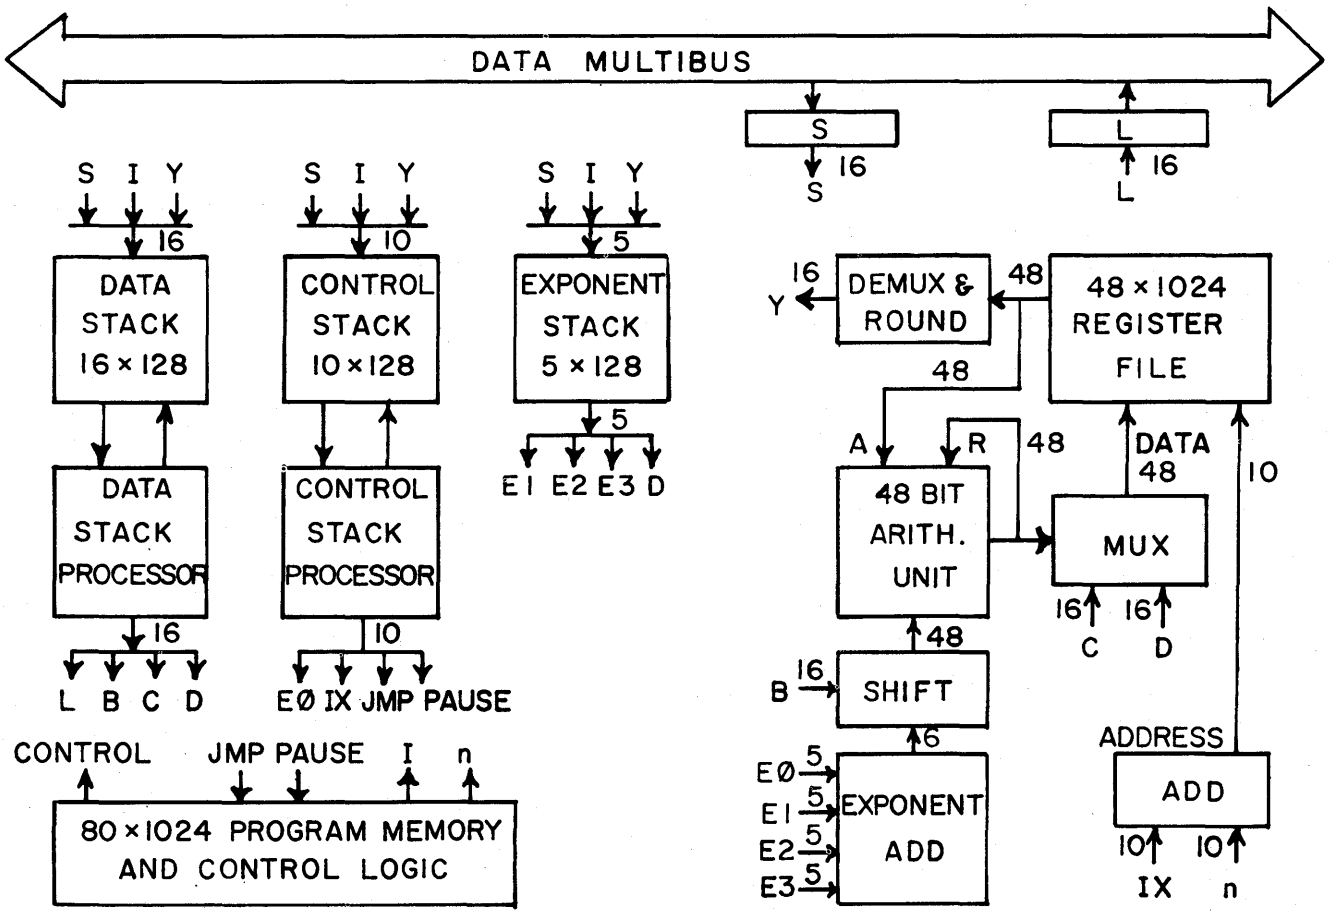

Figure 3—Block diagram of the numerical integration processor

processor is useful for variable step-size algorithms and for implementation of on-off functions, hysteresis, saturation and other simple but common nonlinearities. All these features minimize the interaction of the other processors, maximize overall computing speed and overlap NIP functions with other processor tasks. The general effect is that integration has minimal impact on frame time, which is therefore primarily determined by the other processors.

The instruction fields of the 80 bit NIP instruction are relatively uncoded so NIP programs are microcoded in character. A variety of subprograms are available for implementing a family of integration routines and other functions required in real-time continuous system simulation. The interfacing of these routines to the other processors is very simple, primarily involving data transfers from and to the multibus.

The integration routines are all resident in the NIP so that integration formulas and step size can be changed at run time without any translation requirements in the host. This means that formula selection and step size optimization is a simple process.

SOFTWARE

Since the architecture of the AD-10 is specialized, it is not possible or practical to develop resident software. Instead the host computer and its software systems are used for all program development and interactive control of the AD-10. The Digital Equipment PDP-11 series, operating under RSX-11M, has up to now served in all cases as the host computer for the AD-10, although other host computers can be used.

Available AD-10 software includes interface communication routines, an interactive executive, a cross assembler, a macrofile library, a simulator, and hardware diagnostics. In addition, a high level interactive simulation language is under development.

The interface communication routines are a set of subroutines which perform all the interface control functions between the host PDP-11 and the AD-10. These routines are callable from either Fortran or assembly language programs. They are used by the interactive executive and are also available for user application programs.

The interactive executive (ADX) is an interactive program for loading, running and debugging AD-10 programs. ADX accepts commands from a user at a terminal or from a command file. ADX allows the user to start and stop the AD-10, step its program through specified instruction cycles, and display and modify registers, data memory and program memory. The file structure of RSX-11 is available to ADX to load files created by the cross assembler or to save specified sections of AD-10 data and program memory.

The AD-10 cross assembler generates object modules which are loadable by ADX. The assembler produces a comprehensive program listing, which includes the object code generated for each source statement, a symbol cross reference table and a detailed timing analysis of all multibus transactions which occur during program execution. The timing analysis and multiprocessor features of the assembler simplify the problems of relating the code associated with each processor. Conventional procedural reasoning is still valid in writing programs, even though this might not be expected because of the multiple processors.

User programming, at the assembly level, is simplified by an extensive library of application macrofiles. A macrofile is an AD-10 assembly language routine, in source file form, which can be included in a user application program by specifying input/output parameters or arguments. These routines, optimized for speed and accuracy, account for the great majority of code in most applications.

After assembly a program can be fully simulated in the host computer by the AD-10 simulator. This permits full debugging and program evaluation within the host. The simulator uses ADX for its control so the normal operating environment is preserved in the use of the simulator.

A high level simulation language for the AD-10 is now under development. This language, while having a few constraints not found in other continuous system simulation languages, will allow users to take full advantage of the AD-10 speed with minimum programming effort. The system will emphasize interactive involvement with the model and graphic display of solutions. It will be possible to optimize integration formulas, change scaling, change model parameters and initial conditions, document models and studies, and prepare hardcopy graphics. The AD-10 simulation language will also be compatible with a host simulation language so that the host computer can be used to generate test solutions and scaling information.

EXAMPLE

To illustrate the computational speed of the AD-10 multiprocessor described in this paper, the equations necessary to simulate an aircraft in six degrees of freedom were considered, including extensive aerodynamic functions.[3] One evaluation of all twelve state variables derivatives requires 47 adds, 108 multiplies, and 11 trigonometric functions in addition to computation of 2 two-variable, 8 three-variable, and 7 four-variable functions. Using the Macrofile Library routines for function generation, coordinate transformations and data transfers, as currently available in the standard AD-10 software, the time required for a complete pass through all the equations is less than 100 microseconds.

If an extrapolative type of numerical integration routine is used, then only one pass through the equations is required per numerical integration step. Since operations in the NIP (numerical integration processor) go on concurrently with those in the ARP (arithmetic processor) it is reasonable to assume that numerical integration of the 12 state variables will not add significantly to the frame time. Thus we will assume 100 microseconds per numerical integration step. Using third-order Adams-Bushforth (a popular integration routine for real-time digital simulation), roughly 50 integration frames per cycle of the highest problem frequency are needed for dynamic accuracy of the order of 0.1 percent. Thus the period of the highest problem frequency would be 50 (100) or 5000 microseconds, which corresponds to 200

hertz. Since the highest frequency associated with the rigid-body equations of a typical high performance aircraft is about 1 hertz (the so-called short-period pitching mode) the conclusion is that the AD-10 can solve the flight equations at 200 times real-time.

If the aircraft simulation also includes the flight control system, and perhaps elastic structural modes, then frequencies up to 25 hertz and higher may be present in the problem. Even allowing for the increased equation complexity in this case, it is clear that the AD-10 should be able to handle the real-time simulation comfortably.

CONCLUSIONS

Design of the AD-10 multiprocessor, optimized for continuous system simulation, has been described. The computer is characterized by a large high-speed interleaved memory, very fast arithmetic processor speeds, many high-speed input-output channels, and operation under a host general-purpose digital computer. The AD-10 multiprocessor appears capable of handling the most demanding of real-time aerospace vehicle simulations. Computing speed is approximately two-orders of magnitude faster than the speed of comparably priced general purpose minicomputers in simulating continuous systems. Six-degree-of-freedom aircraft flight equations can be solved at up to 200 times real-time. Such faster-than-real-time solutions could be very cost effective in parameter optimization problems and problems involving stochastic inputs, where large numbers of repetitive solutions are required.

Plasma simulation on the UCLA CHI computer system

by JOHN M. DAWSON, ROBERT W. HUFF and CHENG-CHIN WU
University of California
Los Angeles, California

INTRODUCTION

Computer simulations have played an important role in fusion energy research. Although the basic physical principles of plasma physics are well understood, the coupled physical phenomena are so complex that analytical analyses cannot be easily carried out. Moreover, laboratory experiments are costly. With the enormous power of modern computers, one naturally resorts to computer simulations to gain insights into physical phenomena, as well as to guide the design and planning of experiments.

In order to cope with the rich and disparate phenomena occurring in a plasma, a wide variety of simulation models are required.[1] The models may generally be classified as: particle models, which treat the plasma at the microscopic level by following the motion of a large number of particles; fluid models, which treat plasma on a more macroscopic level; and also hybrid models which are a mixture of the first two models.

It is obvious that one cannot do plasma experiments in a computer with the 10^{12} to 10^{19} particles involved in physical problems of interest. Still, one would hope to have as many as 1 million particles on a mesh system of 64^3 for particle codes. For fluid codes, one may want a system of 64^3 to have better resolution, especially when local structure is present.

This shows that plasma simulations require a large computing capability and therefore have only been carried out on large computers, such as the IBM360/91 or CDC7600. Nevertheless, few attempts have been made for systems as large as mentioned above, for they need several megawords of storage and a considerable amount of computer time for a significant run.

Lately, with the development of computer technology, microprogrammable specialized minicomputers appear to provide the possibility of doing some of the jobs effectively and economically. Because of a successful pilot study[2] initiated by John M. Dawson and Burton D. Fried of the UCLA Plasma Physics Group and Glen J. Culler of Culler/Harrison, Inc. (CHI), a CHI plasma simulation computer system is being installed at UCLA. Our preliminary results indicate that the system offers a significant improvement in performance and, most importantly, it reduces cost by about two orders of magnitude from the IBM360/91.

The CHI plasma simulation system consists of six microprocessors: one array processor (AP-120B, manufactured by Floating Point Systems, Inc.),[3] one macro-processor (MP-32 made by CHI)[4] and four I/O processors (IOP made by CHI). The AP does most of the calculations, the IOP moves data around, and the MP does scheduling and control. Mass data are stored on disk. The parallel processing among and within these processors accounts for most of the performance advantage of the system. Further details of the system are given in the third section of this paper.

Three plasma simulation codes have been tested on the system: a 2-½ dimensional electrostatic particle simulation code,[2] and both 2-½ and 3 dimensional ideal MHD fluid codes.[5] The basic structure of these codes is described in the third section, together with comparative performance data. Conclusions are presented in last section.

THE UCLA CHI COMPUTER SYSTEM

General description of the system

The configuration of the UCLA CHI computer system is shown in Figure 1. It includes a macro-processor (MP-32), an array processor (AP-120B) and four input/output processors (IOP). Data Throughput and capacity of each processor is summarized in Table I. The AP does high speed floating point arithmetic operations. Further descriptions of the AP are given later.

The MP is used for control, I/O, bookkeeping calculations, and integer arithmetic operations, and serves as the host computer for the AP. In the present system it supports an interactive mathematical system (Math System),[7] provides a text editor, file facilities, the necessary assemblers and linkers.

The IOP's are fixed program micro-processors with access to both AP and MP main data memories and the UNIBUS. Their primary function is to provide high level control over access to the disk drives. Each IOP functions as a disk formatter supporting any of the four disk drives. This allows the configuration of individual drive capacities from 5 million to over 60 million 38 bit words. Transfer time per word is under 4 μs. In addition to transferring data between the AP main data memory and disk, the IOP can also transfer data

TABLE I.—Data Throughput and Capacity of the AP-120B, the MP-32A, the IOP and disks of the CHI System

Macro Processor (MP-32A)

(a) A 16-bit fixed point processor with a 1/6 μs machine cycle.

(b) Memories:

64 words scratch pad data memory
512 words fixed instruction memory
64 words writeable instruction memory
65,536 words of 1/3 μs instruction and data memory (CD).

(c) Integer multiplication of two 16-bit words in 1/3 μs.

(d) Functions:

(i) Controls high-speed local station displays.
Display rate: 2 μs/point
< 2 ms for longest line
> 4000 characters/second.

(ii) Schedules IOPs and Array Processor.

(iii) Controls data transfer to modems (1200-9600 baud) and other PDP-11 compatible I/O devices over Universal I/O bus.

Disk-IOPs

(a) Disk capacity: 4 Trident T80 drives - over 16 million 38-bit words each.

(b) IOPs are fixed program micro-processors.

(c) Data transfer rate: Data on all four disks can be simultaneously transferred to/from AP-MD or MP-CD, each at 250,000 words/second. Any IOP can be used for memory transfer between AP-MD and MP-CD at 1,000,000 words/second.

Array Processor (AP-120B)

(a) A 38-bit floating point arithmetic unit with maximum speed of 12 megaflops.

(b) Memories:

(i) Two 32-word data pad memories
2560 words 1/3 μs fixed table memory
65536 words 1/3 μs data memory (MD)
512 words instruction memory

(ii) Data pad access is immediate. Table memory may be referenced every cycle, with an access delay of two cycles. Data memory may be referenced every other cycle, with an access delay of three cycles.

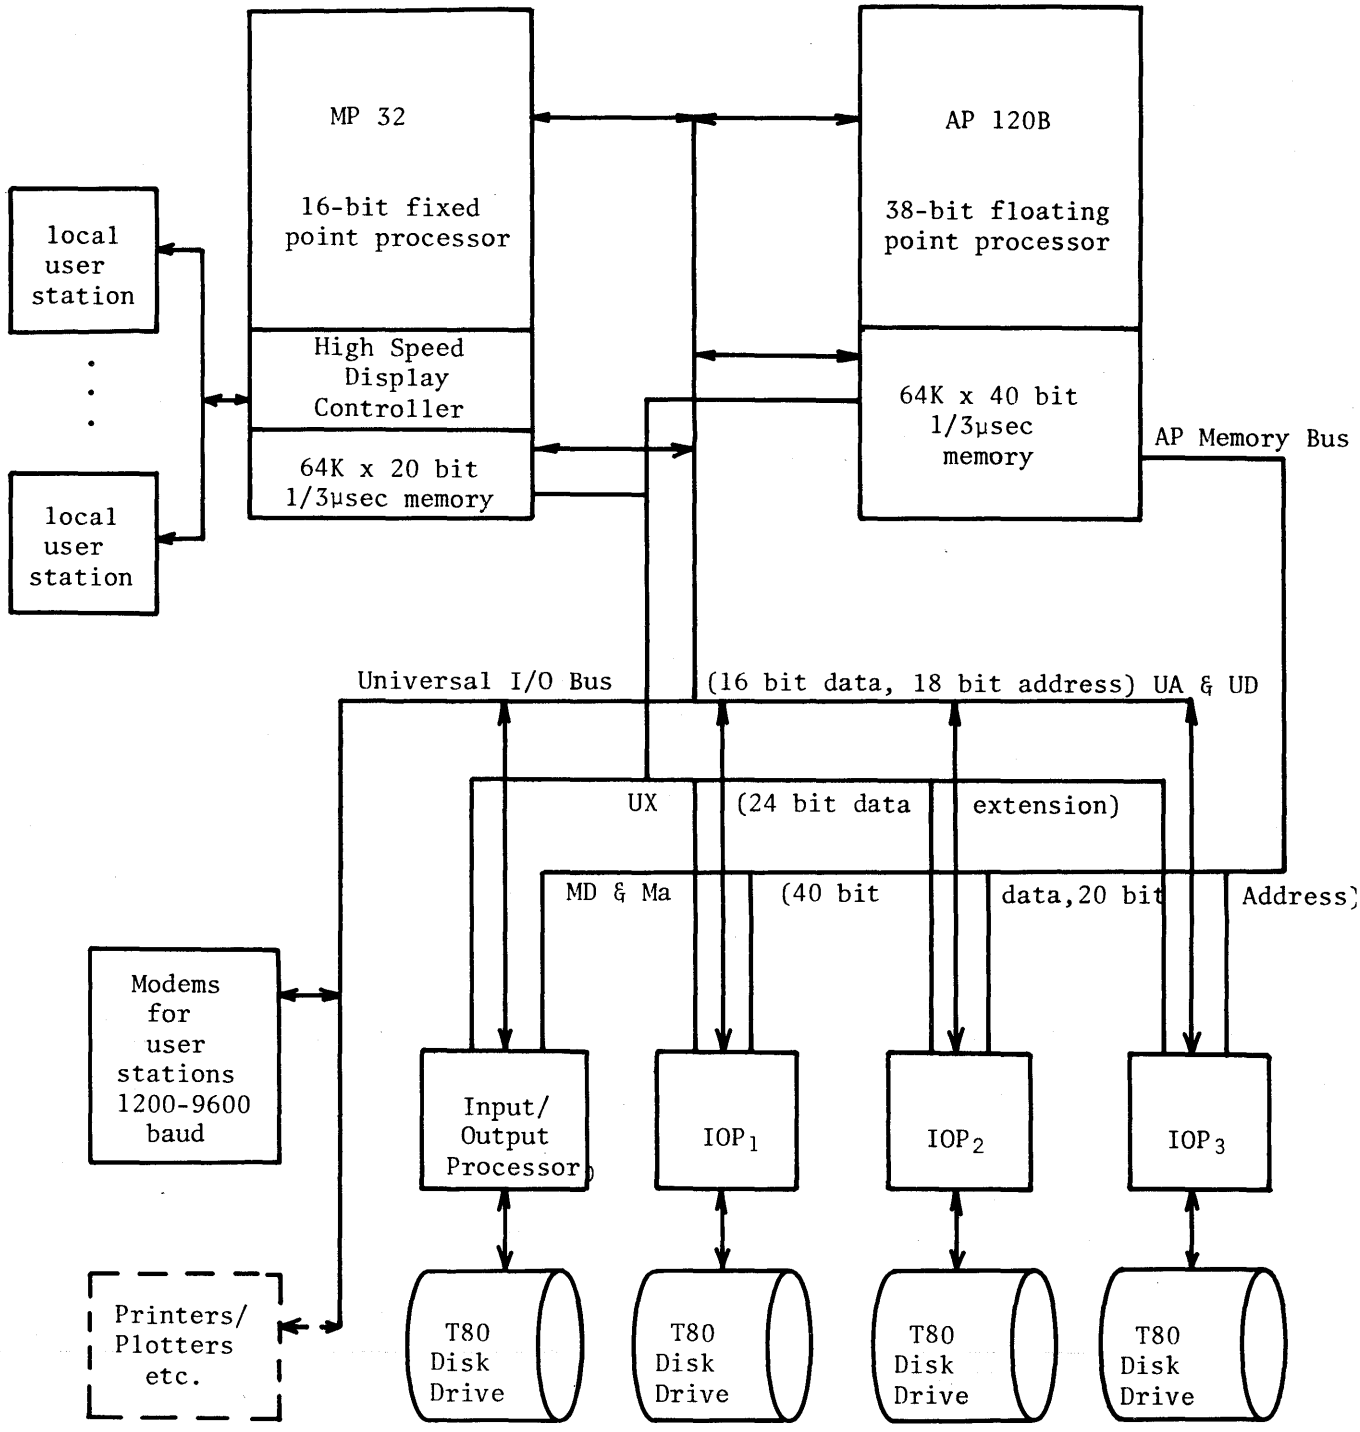

Figure 1—Block diagram of the UCLA CHI computer system

between the MP memory and disk or perform memory to memory transfers between or within either memory.

Each processor can process independently while the whole system is controlled by the MP (host processor). Each processor is scheduled to perform a specific process. It interrupts the host when it completes each process, then begins immediately, without having to wait for service from the MP, on its next process if one has been scheduled for it. This parallel logic computing capability is one of the main features of the system and makes possible the handling of large scale computing problems. An illustration is given in the third section.

AP-120B processor

Since all floating point calculations (therefore most of model calculations) are performed in the AP, it is of importance to explore the structure of the AP.[3] The architecture of the machine is shown in Figure 2; and its features are summarized in Table I.

Special features are noted as follows: (1) Programs, constants, and data each reside in separate, independent memories: program source memory, table memory and main data memory, respectively. Thus, it eliminates memory accessing conflicts. (2) Independent pipelining floating-point multiplier and adder units allow multiply and add operations to each be initiated every $^1/_6$ μs. (3) Two blocks of fast access floating-point accumulators, DPX and DPY with 32 locations each, are available for temporary storage of intermediate results from the multiplier, adder, or memory. (4) Address indexing and counting functions are performed by an inde-

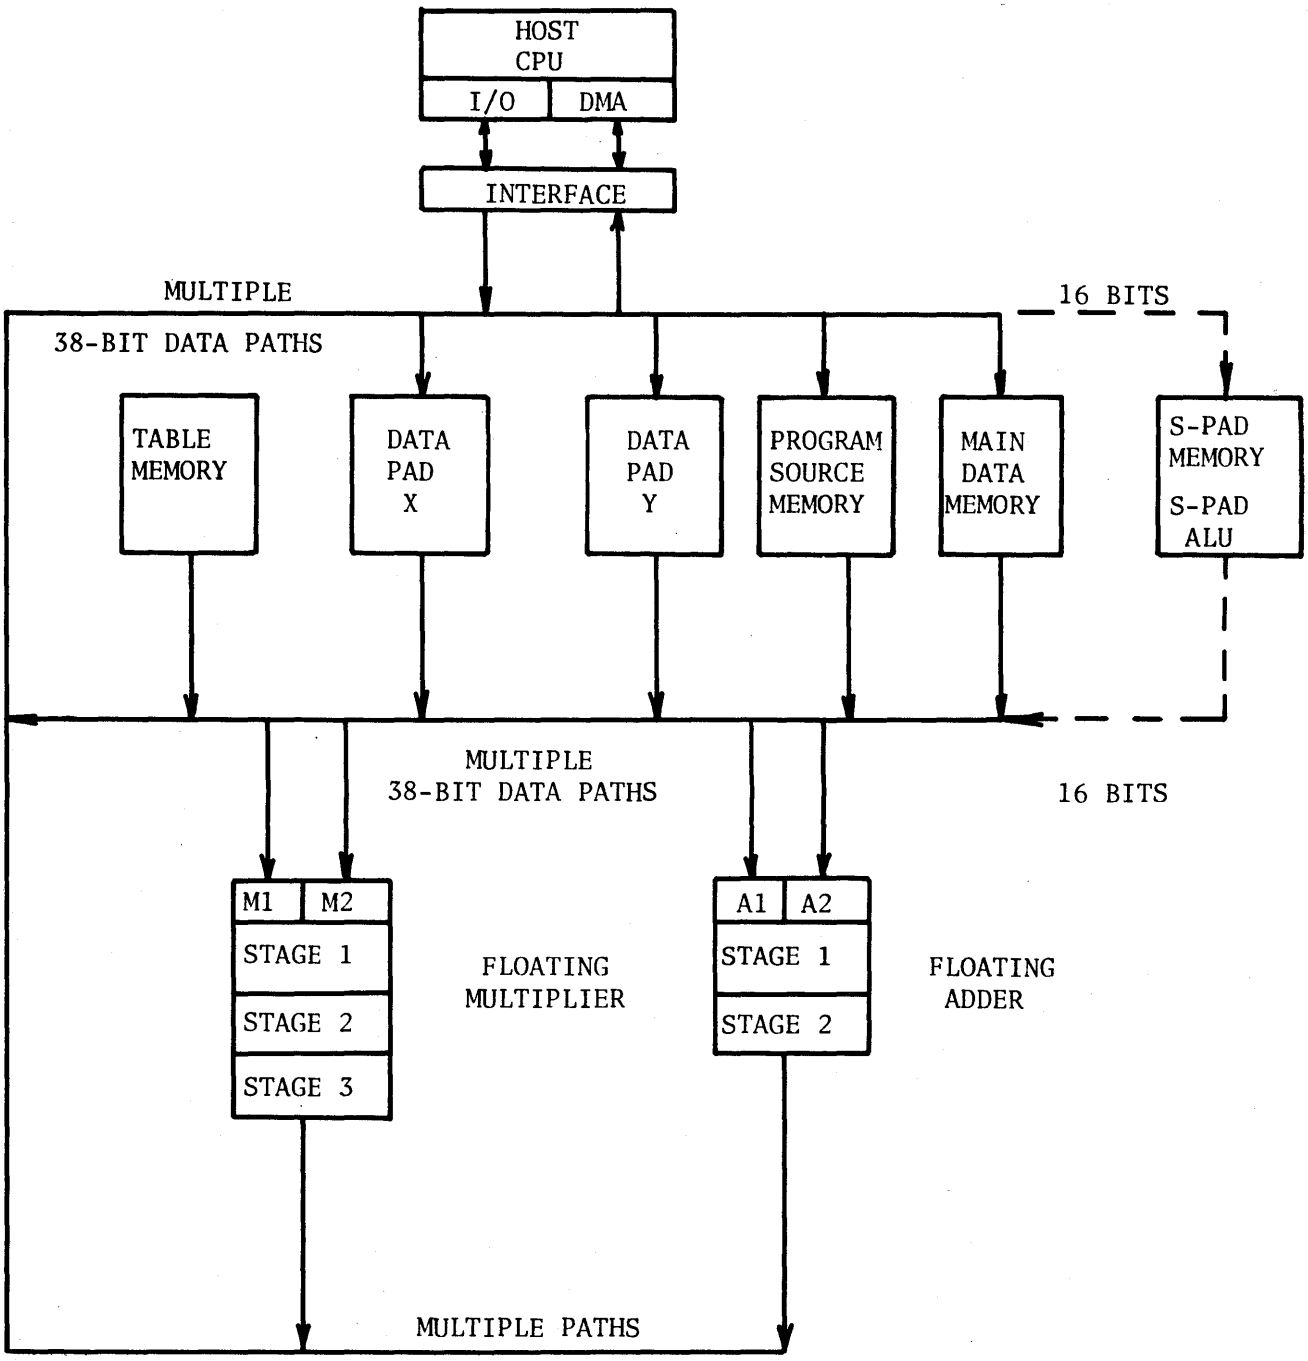

Figure 2—Block diagram of the AP-120B micro-processor (From Reference 3)

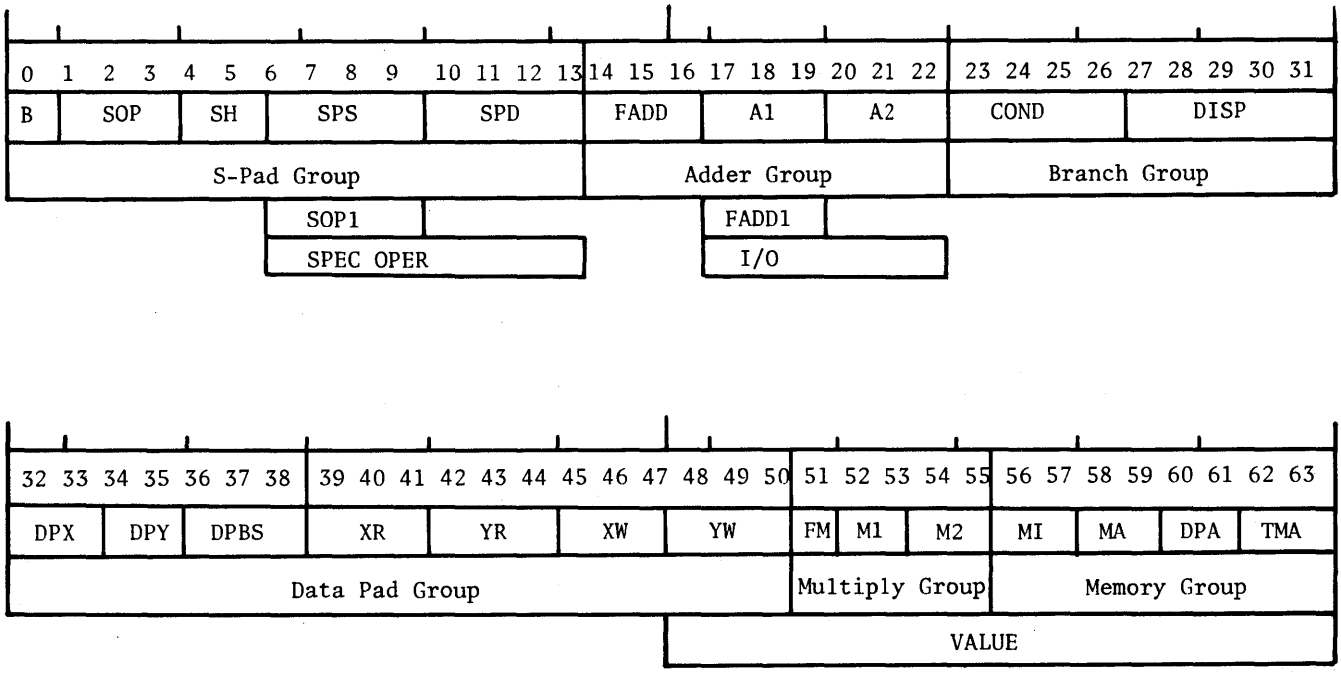

Figure 3—AP-120B Instruction Field Layout (From Reference 3)

pendent integer arithmetic unit (S-Pad and ALU). (5) Floating-point data is represented by 38-bit words which gives a precision of 8.1 decimal digits.

Each instruction word has 64 bits so that many different operations may be performed concurrently during each cycle. The instruction field layout is shown in Figure 3. It is separated into five general areas: program control, address control, arithmetic, memory and I/O. The highly parallel and pipeline structure of the AP-120B make it possible to achieve fast execution with lower speed logic and thus with lower cost. It requires $^1/_2$ μs for a single multiplication and $^1/_3$ μs for a single addition in the AP. But with adder and multiplier units working in parallel and with their pipeline structure, the AP allows multiply and add operations to each be initiated every $^1/_6$ μs. This gives a maximum speed of 12 megaflops comparable with a large general purpose computer. In the three test plasma simulation problems the speed achieved is about 4 megaflops for the fluid codes and 6 megaflops for the particle code.

In order to achieve this high speed capability, each instruction of a micro-coded program should use as many fields as possible. For this reason, our experience in coding plasma simulation codes suggests that calculations done in the manner of particle by particle, or grid-point by grid-point may be more efficient than trying to vectorize the code. Besides, vectorization usually requires several additional arrays for intermediate results. In contrast, vector operations are useful in applications such as digital signal processing, where the AP is called upon to perform vector operations at high speed. The Math System is designed for efficient support of these AP vector operations.

The basic arithmetic operations in the AP are addition and multiplication. The divide operation is carried out in software with speed of 3.83 μs. Hence, it is essential in the programming to use as few divide operations as possible. For instance, there is no divide operation in the $2^1/_2$D particle code; however, one such operation is required in the MHD codes. In the $2^1/_2$D MHD code, the divide operation uses 7 percent of the total processing time of 50 μs per grid point.

As previously mentioned, in the CHI system, the IOP's have a separate data bus into the AP main memory from that used by the AP processor. Thus the CHI system eliminates the bottleneck problem[8] which may exist in other host setups where all data must enter and leave the AP through the interface module and the host computer.

Programming languages

Programming can be carried out in four languages, which include two machine languages, the AP- and the MP- micro languages; and two high level languages, the MP-macro language[6] and the Math System language.[7] The AP micro-instructions have just been mentioned. The MP micro-instruction consists of 28 bits and provides for parallel operations. The MP macro-language is a set of macro-instructions which are pre-programmed in both the AP and the MP micro-languages and is used for system programming.

The Math System language, programmed in the MP micro- and macro-language is an interactive interpreter, and supports operations of mathematical functions applied to real or complex vector data as well as useful graphics. It can execute either interactively or from a program consisting of

```
(+) A, B → C        "C(i): = A(i) + B(i) for all i
(SIN) C             "C(i): = sin C(i) for all i
(DISPLAY)           "plot C(i) vs. i
```

Figure 4—A Math System program for the calculation, $C_i=\sin(A_i+B_i)$, with three vectors *A, B and C*

these mathematical operations. Since the Math System uses vector data which are entities usually occurring in physical problems, programming in this language is more concise and less error-prone than in the standard Fortran language.

A Math System program is shown in Figure 4 for the calculation of $C_i=\sin(A_i+B_i)$ with three vectors A, B and C. The operation $\oplus A,B\rightarrow C$ calculates $C_i=A_i+B_i$ for all i, so does the operation SIN C for $C_i=\sin(C_i)$. The program therefore saves an explicit loop that is required in a Fortran program. The statement DISPLAY will plot C_i against i in terms of its natural units.

In plasma simulation codes, we anticipate using only the Math System language and the AP micro-language. AP micro-programming is done only where the development of maximally efficient routines is warranted, as the particle push routines for particle simulations. The remaining routines, such as initialization, control, and force-calculation routines in the particle codes, which require only a small fraction of total processing time, are easily coded in the Math System language.

The operating system supports both batch and on-line usage. Thus, it allows old production or test runs of a code simultaneous with code development, editing or on-line Math System usage.

PLASMA SIMULATION MODELS AND THEIR TEST RESULTS ON THE CHI SYSTEM

A particle code and a fluid code, which together represent a wide spectrum of plasma simulation models, have been adapted to the CHI computer system. The particle code is the standard 2½ dimensional electrostatic model with a constant magnetic field plus mirroring.[2] The fluid code is an ideal magnetohydrodynamics (MHD) code,[5] which is being implemented in both 2½ and 3-dimensional versions. These are very basic models that include the most important general features of plasma simulations.

In this section, we present basic structures of these codes, the utilization of the resources of the CHI system and their test results. Details of the models and their numerical method aspects will not be discussed here.

A 2½ dimensional electrostatic model with a constant magnetic field

In a particle model, the trajectories of a large number of charged particles (electrons and ions) under the influence of self-consistent fields are followed in time. The particular model considered consists of a large number of charged rods parallel to the z-axis which are allowed to have velocity components in the x, y, and z directions as shown in Figure 5. It allows spatial variation in the x and y directions. The system is periodic in both x and y directions such that particles that leave one side of the system are re-entered at the opposite side. A uniform static magnetic field is permitted to point in an arbitrary direction. The charged rods move under the influence of their self-consistent electric fields and the given magnetic field. In addition, the rods may be reflected at the y-boundaries if a mirroring condition is satisfied by the velocity components parallel and perpendicular to the magnetic field.

The motion of the system is generated in the computer by a leap-frog time difference scheme, using a standard finite-size particle model, in which the charge of a particle is distributed over a finite region about the center of mass, and also using a dipole expansion technique. The finite-size particle model effectively reduces undesirable collisions and also numerical noise from the discrete nature of the spatial grid. However, in the following discussions, only the basics of the model are presented.

Mathematically, the simulation model solves the following equations self-consistently:

$$\vec{\nabla}\cdot\vec{E}(\vec{r})=\rho(\vec{r}), \tag{1}$$

$$\frac{d\vec{v}_i}{dt}=\frac{q_i}{m_i}\left(\vec{E}(\vec{r}_i)+\vec{v}_i\times\vec{B}(\vec{r}_i)\right), \tag{2}$$

$$\frac{d\vec{r}_i}{dt}=\vec{v}_i. \tag{3}$$

$\vec{E}$ and $\vec{B}$ are the electric and magnetic fields, respectively; $\vec{B}$ is assumed to be a constant vector. ρ is the charge density distribution and $\vec{r}_i$, $\vec{v}_i$ stand for the position and velocity of the ith particle with charge q_i and mass m_i.

In the 2½D model, a spatial grid mesh in the x-y plane

(C) Flux-tube charge density.

Figure 6—Program flow of the particle model

is introduced. All macroscopic quantities, such as $\vec{E}$ and ρ are calculated on the grid points. The basic flow of the program is shown in Figure 6. It starts with setting up initial configuration of the system by assigning $\vec{v}_i$ and $\vec{r}_i$ and q_i for each particle and specifying the $\vec{B}$ field.

Inside the loop, calculations are performed in two stages: (a) Force calculation: $\rho(\vec{r})$ is used to solve Eq. (1) for the electric field $\vec{E}$. Eq. (1) is solved efficiently by fast Fourier transforms. (This technique is especially useful when finite-size particle model is used.) (b) Particle push: After $\vec{E}$ is obtained, the particle positions and velocities are advanced in time by means of Eqs. (2) and (3), using the leap-frog method with a dipole expansion of the force. As each particle position is updated, its contribution to $\rho(\vec{r})$, including dipole terms, is calculated. We are now ready to start the next time step.

In the actual code with the finite size particle model and dipole expansion technique, the data required are 6 words per particle, i.e., $\vec{r}$ and $\vec{v}$ with three components each, 9 words per grid points which include E_x, E_y, ρ, D_x, D_y, E_{xx}, E_{xy}, E_{yx}, and E_{yy}. (The last six variables are dipole terms.) Since particles are grouped according to species, it is not necessary to specify charge and mass for each particle individually.

For a 10^6 particle and 64^2 grid-point system, more than 90 percent of the computer time is used in the particle PUSH routine. Therefore the PUSH routine is coded in the AP micro-language with maximal optimization, whereas other routines are efficiently programmed in the Math System. The PUSH routine takes 13 μs per particle which is four times the speed of the corresponding IBM360/91 assembly-language code. The AP PUSH routine is not a direct translation of the corresponding Fortran code, but a new design for an efficient usage of the AP. There are 33 multiplications and 45 additions in the routine, and therefore an effective speed of 6 megaflops is achieved.

The data storage requirement as well as processing timing are given in Table II. To handle the large quantity of data the technique of parallel processing among the AP, the MP and the IOP's is used. To further explain this parallelism, a section of the Math System program is shown in Figure 7. The section is essentially the control program for pushing particles. The actual code, however, is a simple three-statement loop program for this two-disk system.

The instruction, OP PUSH BUFFI causes the AP to initiate or schedule an AP micro-program named PUSH for advancing particles whose descriptors are in the array BUFFI of AP main memory. The execution will begin as soon as the AP has completed all its previously scheduled processes and data BUFF1 is free from operations associated with other processors. If the AP is ready but data block BUFF1 is still being loaded with data by the IOP, the AP will wait until the latter action is completed. The instruction, MOVE INDISK→BUFF1, will instruct an IOP to move data from disk that is used for input to the location BUFF1 in AP main memory. An IOP will perform the operation once it comes to the instruction and neither block of data is being used by other processors. Similar operation is defined for the instruction MOVE BUFF1→OUTDISK.

```
Math System Program                          Processor

. . .

MOVE   INDISK → BUFF3                        IOP1

MOVE   BUFF1 → OUTDISK                       IOP2

OP     PUSH    BUFF2                         AP

MOVE   INDISK → BUFF1                        IOP1

MOVE   BUFF2 → OUTDISK                       IOP2

OP     PUSH    BUFF3                         AP

MOVE   INDISK → BUFF2                        IOP1

MOVE   BUFF3 → OUTDISK                       IOP2

OP     PUSH    BUFF1                         AP

. . .
```

Figure 7—A section of a Math System program for controlling the AP and the IOP's in particle push

Therefore, in executing the program shown in Figure 7, two IOP's and the AP are operating simultaneously: One IOP loads into one block of AP main memory a block of old particle data from one disk, the AP executes PUSH routine in advancing particle data stored in the second block of AP memory, while the other IOP stores a third block of updated particle data from AP memory into the second disk. By choosing adequate blocksize and using enough number of IOP's, it is possible to eliminate restrictions on over-all processing time imposed by I/O.

To handle 10^6 particles, four disks are used with two disks for input, and two disks for output. The two pair of disks are interchanged with respect to I/O at each time step. The size of block is chosen to be 4K words (a track or 680 particle descriptors). It takes 17.7 ms for the AP to update two blocks of data and 20 ms for each IOP to transfer one track of data between disk and AP memory. (The transfer rate of 20 ms per track includes a 20 percent allowance for the loss of one rotation at the cylinder boundary). The over-all processing time is then slightly limited by I/O to 14.7 μs per particle.

Magnetohydrodynamic codes

The set of magnetohydrodynamic equations includes:

$$\frac{\partial \rho}{\partial t} = -\vec{\nabla}\cdot(\rho\vec{v}) + \epsilon\nabla^2\rho, \tag{4}$$

$$\frac{\partial}{\partial t}(\rho v_i) = -\frac{\partial}{\partial x_j}\left(\rho v_i v_j + \left(\rho T + \frac{B^2}{2}\right)\delta_{ij} - B_i B_j\right) + \nu\nabla^2\rho v_i - \lambda\rho v_i - \rho\vec{g}, \tag{5}$$

$$\frac{\partial \vec{B}}{\partial t} = \vec{\nabla}\times(\vec{v}\times\vec{B}) + \eta\nabla^2\vec{B}, \tag{6}$$

TABLE II.—Resource Utilization and Processing Timing for a 10^6 Particle and 64^2 Grid Point Particle Simulation Code on the CHI system

Data:

6 Words/particle x, y, z, v_x, v_y, v_z

9 Words/gridpoint: E_x, E_y, E_{xx}, E_{xy}, E_{yx}, E_{yy}, C, D_x, D_y

The particle descriptors are on disk, 680 particles/track, 1472 tracks, or 736 tracks on each of two disks for input, and the same for output, with the two pairs of disks being interchanged with respect to I/O at each timestep.

AP-Memory Allocation:

Electric Field arrays (6):	24k
Charge and dipole arrays (3):	12K
Particle buffers (5):	20k
Total	56k

Data Transfer Timing:

60 disk rotations/second or 16.7 ms/track, for a transfer rate of 24.5 μs/particle for each of two disks, or an overall rate of 12.2 μs/particle on a track-by-track basis. Loss of one rotation at the cylinder boundary (5 tracks/cylinder) increases this by 20%, giving 15 μs/particle on a cylinder-by-cylinder basis.

Processing Time:

Dominated by the particle-push AP routine for this system size.
Present AP code estimated at 13 μs/particle.
Thus the AP processing is slower than the I/O on a track-by-track basis, but is faster than the I/O on an overall basis.

Overall Timing:

15 μs/particle overall, or 15 seconds/timestep.
16 hours for a run of 4000 timesteps (to $\omega_p t = 1000$ @ $\Delta t = 0.25/\omega_p$)

TABLE III.—Resource Utilization and Processing Timing for a 2-½ D MHD Code

Data:

7 variables: $V_x, V_y, V_z, B_x, B_y, B_z, \rho$.

Each variable occupies an array of dimension $(N + 3)*(N_y + 2)$, where N_x and N_y are the numbers of grids in x- and y-direction, respectively.

The system is periodic in y and bounded in x. Temperature is assumed to be constant.

AP-Memory Allocation:

$7*(N_x + 3)*(N_y + 2) + 30$ words.

With 45K memory, the system can be as large as 80 x 80.

AP-Program Memory:

445 program words.

Processing Time:

55 μsec/grid for a 20 x 20 system.

50 μsec/grid for a 40 x 40 system.

There are $1/2*(N_x + 1)*N_y$ grid calculations per time step in the leap-frog scheme.

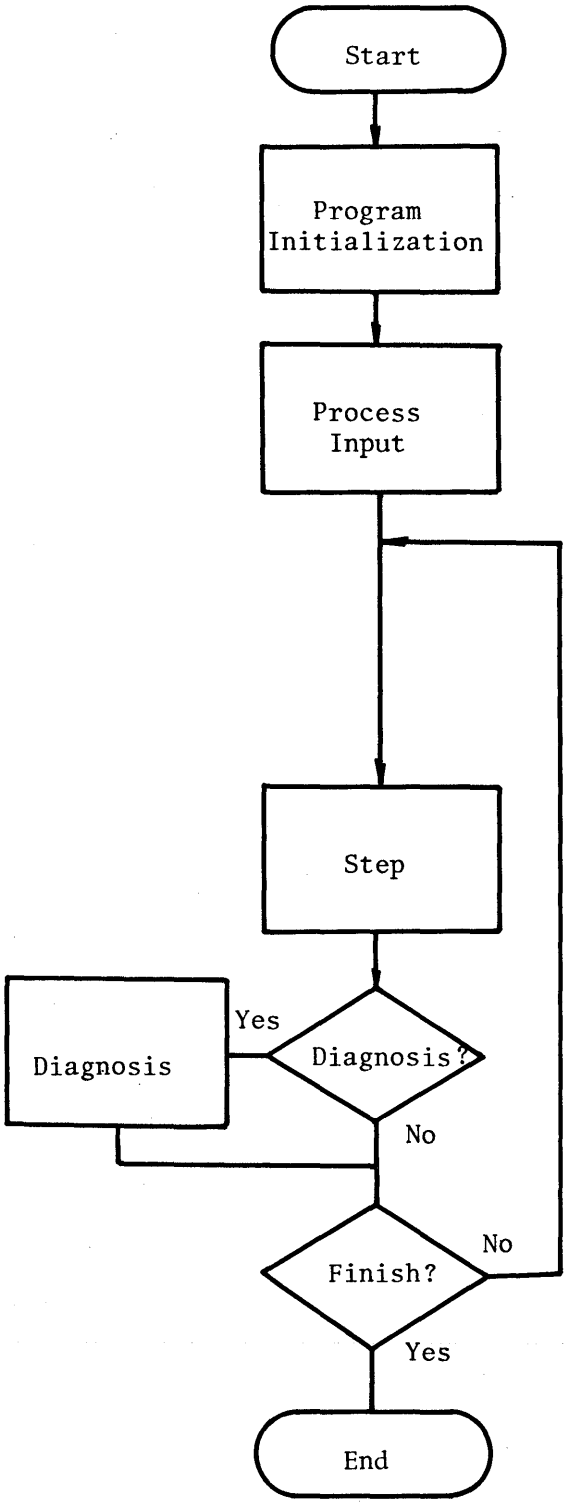
$$\frac{\partial T}{\partial t} = -\vec{\nabla}\cdot(T\vec{v}) + (2-\gamma)T\vec{\nabla}\cdot\vec{v} + \frac{\eta(\gamma-1)}{\rho}(\vec{\nabla}\times\vec{B})^2 + (\gamma-1)\nu\left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} - \delta_{ij}\vec{\nabla}\cdot\vec{v}\right)\frac{\partial v_i}{\partial x_j} + (\gamma-1)\kappa\nabla^2 T. \quad (7)$$

Here, the mass density is denoted by ρ, the velocity by $\vec{v}$, the temperature by T, the magnetic field by $\vec{B}$ and the gravitational acceleration by $\vec{g}$. γ is the ratio of specific heats. The transport coefficients ϵ, ν, λ, η and κ are assumed to be constants.

The computer code solves the equations as an initial-value problem, by integrating them in time using an Eulerian grid and an explicit, conservative, leap-frog finite-difference scheme. The details of the numerical procedures can be found elsewhere.[1,5]

All variables are macroscopic and are defined at grid points. In a three-dimensional code, a three dimensional grid is introduced. For the case of 2½ dimensional code, a two dimensional grid is used, with $\vec{v}$ and $\vec{B}$ still having three components.

The basic flow of the program as shown in Figure 8 is a loop over timestep, similar to that of particle model, except here the routine STEP performs one timestep integration of the MHD equations for all grid points. The routine STEP is coded in the AP micro-language, whereas other routines including initialization and control are in the Math System.



Initialize:
(1) Control parameters
(2) Disk variables

(1) Compute initial plasma configuration, set up initial values for ρ, $\vec{v}$, $\vec{B}$ and T
or

(2) If restart, read input from disks

AP and IOPs (if any) work parallel to integrate MHD equations from time t to t + Δt over all grid points.

Compute various energies, output ρ, $\vec{v}$, $\vec{B}$ and T distributions.

Figure 8—Program flow of the MHD fluid codes

TABLE IV.—Comparison between the CHI System and the IBM360/91 with Respect to the Three Test Plasma Simulation Codes

	IBM360/91	CHI SYSTEM
PARTICLE CODE		
Time/Particle Push	Assembly Code	
CPU	55 μs	13 μs
I/O	- -	0.6 × 24 μs
Overall	55 μs	14 μs
10^6 Particles, 4000 Timesteps		
Time	61 hr	16 hr
CPU Cost	32 k$	- -
I/O Cost	18 k$	- -
Total Cost	50 k$	0.3 k$
2-1/2D MHD CODE	Fortran Code (H-Compiler)	
Time/Gridpoint	130 μs	50 μs
3D MHD CODE	Fortran (H-Compiler)	
Time/Gridpoint	230 μs	90 μs
64^3 System, 4000 Timesteps		
Time	33 hr	13 hr
CPU Cost	17 k$	- -
I/O Cost	10 k$	- -
Total Cost	27 k$	0.24 k$

The routine STEP is coded in such a way that calculations are done grid-point by grid-point, which seems to be the most efficient method in utilizing parallel operations in the AP. The processing time for the $2^1/_2$D code is 50 μs per grid as compared with 130 μs for a corresponding Fortran code on IBM360/91. For the 3D code, it is 90 μs on the CHI computer, while a Fortran code requires 230 μs on the IBM360/91. The number of floating point operations is 101 multiplications, 92 additions and 1 division for the $2^1/_2$ code and 184 multiplications, 174 additions and 1 division for the 3D code. Both codes reach an effective speed of about 4 megaflops.

The storage requirement, processing timing and other statistics of the $2^1/_2$D code is given in Table III. This code is an isothermal one, in which temperature is a constant, so there are seven equations instead of eight. The AP main memory is big enough to store data for a system as large as 80^2.

In case of the 3D code, disks must be used; for instance, it requires two megawords of data in a 64^3 system. In each grid point calculation, eight variables defined on the grid point and its six nearest neighbor points, or a total of 56 numbers are used. However, some of these data can be saved for calculations at the next grid point in the column or adjacent grid point in the next column, so the need of data transfer is reduced. The technique of parallel processing between the IOP's and the AP is used.

Comparison with results on the IBM360/91

The comparison of these plasma simulation codes on the CHI system and the corresponding Fortran (or Assembly) codes on the IBM360/91 are given in Table IV. For executing a one-million-particle simulation or a 64^3 3D MHD code on the IBM360/91, we assume disks are used for storage. The I/O charges are based on this assumption.

The speed of the particle code is four times faster than the IBM assembly-language code. For the MHD codes, the speed advantage is not as good. Nevertheless, all codes attain an effective speed of 4 to 6 megaflops. Most importantly, the CHI system shows a tremendous savings in total cost, with better than a two-order-of-magnitude decrease in cost from the IBM360/91. The figures for the IBM360/91 are actual costs if the programs were run at UCLA. For the CHI computer system, estimates are based on the assumption that computer time charge is directly proportional to the price of the computer system.

In addition, we should point out that the CHI system achieves better accuracy than the IBM360/91 in single precision. One example is that the kinetic energy calculated in the $2^1/_2$D MHD code on the CHI machine is two digits more accurate than on the IBM360/91 in single precision.

CONCLUSION

We have presented a general description of the UCLA CHI computer system and have emphasized its special features, namely, two levels of parallelism in the system. Parallel processing among the AP, the MP, and the IOP's allows execution of large-scale problems, and a high degree of internal parallelism within each processor allows fast operations at very moderate cost. In addition the CHI system provides a time sharing operating system and supports a high level language, the Math System, which is particularly useful in solving physics related problems.

The test results for three plasma simulation models clearly show the capabilities of the system. It performs high speed execution of large problems at relatively low cost. Since the plasma simulation models are similar in structure to many simulation models in other research fields, the CHI computer system is expected to have a wide range of applications.[8]

Multiple microcomputer systems for solving certain fluid flow problems

by JOHN STEINHOFF
Grumman Aerospace Corporation
Bethpage, New York

INTRODUCTION

In the last several years, minicomputer based systems have been considered or used for an increasing number of scientific computing tasks. For example, Kottler and McGill[1] used a minicomputer system to solve a series of problems, including a partial differential equation for pollutant dispersal. Also, in 1973, Steven Orszag[2] compared a minicomputer system to large general purpose machines for solving some time dependent hydrodynamics codes. The conclusions were that minicomputers could be more cost effective than the large machines. In particular, Orszag concluded that the minicomputer was more cost effective than a CDC 7600 but less than a CDC STAR for moderate resolution hydrodynamics codes. For these problems, the data bases are large and the system is essentially a disk based one, where data flows from a large data base on the disk to the computer. When these studies were done, disk speed was not a restriction and the limiting factor was the computational speed of the minicomputer.

In the last several years, improvements in LSI technology have made it possible to assemble reliable computational devices with a much lower cost per computation than minicomputers. These devices, ranging from moderately priced (~$100,000) fast systems with tightly coupled multiple functional units to very inexpensive simple units can be very cost effective when used with a minicomputer as host. They have had a large impact on the signal processing field,[3] in some cases proving to be faster than large machines such as the CDC 7600. They can also be effective for real-time simulation, as described in Reference 4.

In this paper we will describe a study that was done on the effectiveness of a minicomputer based system with moving head disk and peripheral processor for a class of fluid flow problems.

It is easy to see that a moderately priced system can be assembled that would have a (disk) data capacity and contiguous block throughput and a (peripheral) computational speed of a large multi-million dollar machine. The extent to which this potential can be realized for our problem depends on, among other things;

- Whether data can be transferred between disk and a relatively small random access memory at close to contiguous-block rate during the computation.
- Whether the elements of the peripheral processor can be kept operating efficiently (in parallel).
- Whether the system can be programmed efficiently.

We will describe a disk data allocation scheme that avoids excessive disk accesses and achieves a high data throughput rate, and a scheme to use a set of peripheral processors efficiently, for the problem considered. We will also describe progress that we have made in assembling and operating a prototype system. At this time we have not obtained enough programming experience to comment on the ease of use of the system. The types of problems that we are looking at will be run for long periods of time, justifying the extensive use of assembly language programs. Once the possibility of effectively solving these problems has been established, it will be worthwhile to develop software routines which can be used in higher level language programs.

Finally, we will describe a scheme to assemble a very fast system consisting of a set of modules arranged in a simple configuration. This system will have the capacity and speed to economically solve some very large problems.

DYNAMICAL EQUATIONS

The basic problem involves the solution of turbulent flow of a viscous, incompressible fluid, using the Large Eddy Simulation approach. In this approach, the Navier Stokes equations which describe the detailed dynamics are first spatially filtered resulting in a damping of the high spatial frequency modes of the turbulent flow. After removal of these modes, which cannot be resolved on feasible computers, only the resolvable "large eddies" are treated explicitly. A sub-grid model is used to compute the stresses caused by the removed "small eddies." The resulting equations, when discretized, are tractable on current very large computers. The approach leads to good predictions for some quantities, such as the filtered energy spectrum in isotropic turbulent decay.

Our initial approach will be similar to that of the Stanford Group.[5,6] Most of this work has been done on a CDC 7600 and we should have a good basis for comparison.

The equations that we are solving are

$$\frac{\partial u_i}{\partial t} = v_i - \frac{\partial P}{\partial x_i} \tag{1}$$

$$\frac{\partial^2}{\partial x_i^2} P = \frac{\partial}{\partial x_i} v_i \tag{2}$$

$$v_i = -\left(1 - C_\Delta \frac{\partial^2}{\partial x_k^2}\right) u_j \left(\frac{\partial u_i}{\partial x_j} - \frac{\partial u_j}{\partial x_i}\right) - \frac{\partial}{\partial x_j} \tau_{ij} + \nu \frac{\partial^2}{\partial x_j^2} u_i \tag{3}$$

where u_i are the filtered velocities, P is the pressure, ν is the molecular viscosity, τ_{ij} the model term for the high frequency modes and C_Δ is a constant depending on the filtering function. The most popular model for τ_{ij} is based on the Smagorinsky model:

$$\tau_{ij} = -2\nu_T s_{ij}$$

$$s_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)$$

$$\nu_T = c(2 s_{ij} s_{ij})^{1/2}.$$

In the above equations, repeated indices imply summation.

The basic approach is to use (1) and (3) to compute u_i at a new time step, with P computed using (2). This method enforces incompressibility by predicting zero divergence for u_i at a new time step, if u_i has zero divergence at the current time step. The Adams-Bashforth method, which is second-order accurate in Δt, is used to integrate u_i:

$$u_i^{(n+1)} = u_i^{(n)} + \Delta t \left[\frac{3}{2}\frac{\partial u_i^{(n)}}{\partial t} - \frac{1}{2}\frac{\partial u_i^{(n-1)}}{\partial t}\right]. \tag{4}$$

Various finite difference methods have been used to approximate the spatial derivatives. Our example will involve second order equations for the filter related terms (containing C_Δ) and fourth order terms for all other derivatives. Other difference formulae, involving a fixed number of neighboring points, can be computed on our system with schemes similar to the one we will describe. In one dimension, the approximations to the first derivative are:

$$\delta a(x) = \frac{1}{2\Delta x}[a(x+\Delta x) - a(x-\Delta x)]$$

$$\delta a(x) = \frac{1}{12\Delta x}[-a(x+2\Delta x) + 8a(x+\Delta x) - 8a(x-\Delta x) + a(x-2\Delta x)]$$

Our initial problems will involve homogeneous flows. The periodic boundary conditions used in these flows are simple to handle and represent a first study for our system. Other boundary conditions, such as no-slip ones, result in additional problems from the numerical analysis[7] as well as programming point of view. Especially when higher order methods are used, different operations must be done at grid points near boundaries. Unlike array processors, our system will be able to do a number of these different tasks in parallel, but the programming will be more difficult. For the periodic boundary conditions used, the Poisson equation for the pressure can be solved directly using three-dimensional Fourier transforms.

COMPUTING SYSTEM

The basic computing system considered for the study consists of a moving head disk, a minicomputer and a set of bipolar microcomputers connected to the minicomputer by a time-multiplexed bus (see Figure 1). A prototype system is currently being constructed in the Research Department at Grumman.

The capacities of available minicomputer disks run up to 300 megabytes (Trident T-300) at a cost of about $20,000, with (contiguous block) transfer rates up to about 500,000 bytes per second. The access times are about 10 to 70 milliseconds depending on how many tracks the head must pass over. The particular disk used in our system has a 10 megabyte capacity and 160,000 byte/second transfer rate. For the problem considered, the disk characteristics are very important.

The host minicomputer used in the prototype system is a Data General NOVA 800, with a random access memory of 32,000 16 bit words and an 800 ns. basic cycle time. It is not clear whether a higher performance minicomputer would result in higher throughput for our problem. Although the NOVA 800 cost more when purchased, minicomputers with similar performance now cost less than $10,000.

The peripheral processor considered is of the type being constructed in the Research Department. It consists of a set of independent 16 bit machines, each with a cycle time of 180 ns., separate high speed cache data memory (1K word) and microprogram memory (2K word) together with a larger 16-32K MOS data memory. For our problem, no direct intermodule communication is necessary and a single time-multiplexed data bus allows each microcomputer, when enabled, to communicate to the host via direct memory access (DMA). The number of microprocessor modules that can be

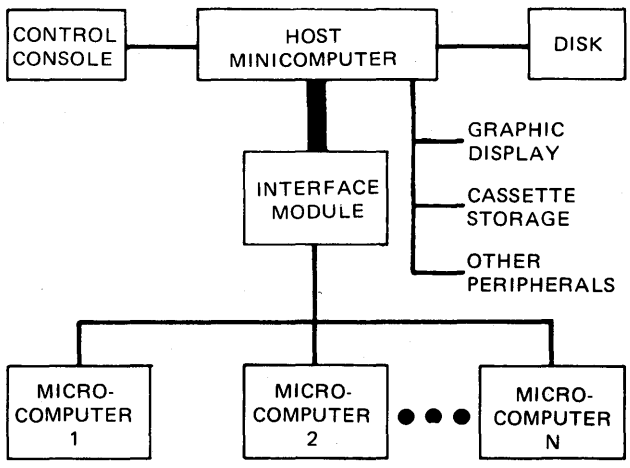

Figure 1—Computing system organization

used effectively depends mainly on the disk transfer rate for available disks. The cost of each module is about $4,000.

IMPLEMENTATION

Data flow

The grid that we are using contains $(64)^3$ nodes (the largest size run on the 7600) and the resulting data base for the problem is at least several million words, depending on how it is decomposed. Hence, for a modest system such as ours a moving head disk must be used for data storage. For available disks, the access time is three orders of magnitude longer than the time required to transfer a (32 bit) word. Also, this transfer time is an order of magnitude longer than the read time for the random access memories used in the system. Thus it is essential to use a data allocation scheme that minimizes disk accesses, and an algorithm that minimizes the total number of variables transferred to and from disk each time step.

For our problem, we can reduce the disk variables to two three-vector arrays and a scalar array:

$$\tilde{u}_i^{(n)},\ v_i^{(n)} \text{ and } \tilde{P}^{(n)},$$

where

$$\tilde{u}_i^{(n)} = u_i^{(n)} + \tfrac{3}{2}\Delta t v_i^{(n)} - \tfrac{1}{2}\Delta t v_i^{(n-1)} + \tfrac{1}{2}\Delta t \frac{\partial}{\partial x_i} P^{(n-1)}$$

and $v_i^{(n)}$ and $P^{(n)}$ are defined in (3) and (2). Then,

$$u_i^{(n+1)} = \tilde{u}_i^{(n)} - \tfrac{3}{2}\Delta t \frac{\partial}{\partial x_i} P^{(n)}$$

In the above, $\tilde{P}^{(n)}$ is the one-dimensional Fourier transform of $P^{(n)}$ (the reason for storing $\tilde{P}^{(n)}$ and not $P^{(n)}$ will be explained below), and n refers to the time step.

The computations required at each time step can be divided into two classes: a semi-local class where finite difference approximations to the partial derivatives are computed and the velocities are updated; and a global class where Poisson's equation is solved by a direct method. The data flow requirements for these two classes are quite different. Data allocation and computational schemes have been formulated that require a relatively small number of disk accesses and a near-minimum number of variables to be read from and written to disk for these classes of computations.

First, the data allocation scheme will be described. The $\tilde{u}_i$, v_i and $\tilde{P}$ arrays are partitioned into "records" that span 4 units (out of 64) in the x_1 direction, 8 units in the x_3 direction and all 64 units in the x_2 direction (see Figure 2). These records are arranged on disk in 16 segments (8 records each) that correspond to different sets of x_1 values and all 64 x_3 values, together with extra "scratchpad" space (for two records). Although the segments are arranged sequentially on the disk, they are depicted in Figure 2 next to each other. In the figure, the index represents the position of the record in the x_1-x_3 plane. The positions are shown for a particular stage in the sweep through the $\tilde{u}_i$ array, to be described below.

There are three computational phases at each time step. In the first phase, $\tilde{u}_i^{(n)}$, $v_i^{(n)}$, $\tilde{P}^{(n)}$ are read from disk and $\tilde{u}_i^{(n+1)}$, $v_i^{(n+1)}$ written back. This phase requires 8 sweeps in the x_1 direction (for different x_3 values), each sweep taking 16 steps (see Figure 3). At each step a set of $\tilde{P}_i^{(n)}$ values are read from disk and $P^{(n)}$ computed by Fourier transform in the x_2 direction. Then $\delta_i P^{(n)}$ is computed, $\tilde{u}_i^{(n)}$ read and $u_i^{(n+1)}$ computed. Then τ_{ij} and $v_i^{(n+1)}$ are computed. Finally, $v_i^{(n)}$ is read from disk and $\tilde{u}_i^{(n+1)}$ computed and written back to disk together with $v_i^{(n+1)}$. It is easy to see that, since each record contains all 64 values of x_2, once these are in random access memory any partial derivatives as well as Fourier transforms can be computed in this direction. Also, x_1 derivatives can be computed efficiently by storing some values from the previous steps since the sweep is in the x_1 direction. Only for the x_3 derivatives do we need to read some variables more than once: As pictured in Figure 3 for each sweep, a band must be read that is wider than the width of the sweep ($8x_3$ units). Also, we cannot write over variables during a sweep if the old ones are needed again for the next sweep. This is illustrated in Figure 2, where the positions of the updated $\tilde{u}_i^{(n+1)}$ records and the old $\tilde{u}_i^{(n)}$ records are shown with our scheme. Only one disk access is needed to read the $\tilde{u}_i^{(n)}$ variables required for the next step (including overlays) and write the updated ones. Also, at each step one access is required to read the $\tilde{P}^{(n)}$ variables (including overlap) and one to read and write the $v_i^{(n)}$ variables. (Steps near the edges of the grid require extra accesses because of the periodic boundary conditions).

The second phase required at each time step involves computing $\rho^{(n)} \equiv \delta_i v_i^{(n)}$, the source function for Poisson's equation (2). The procedure used in the first phase is used

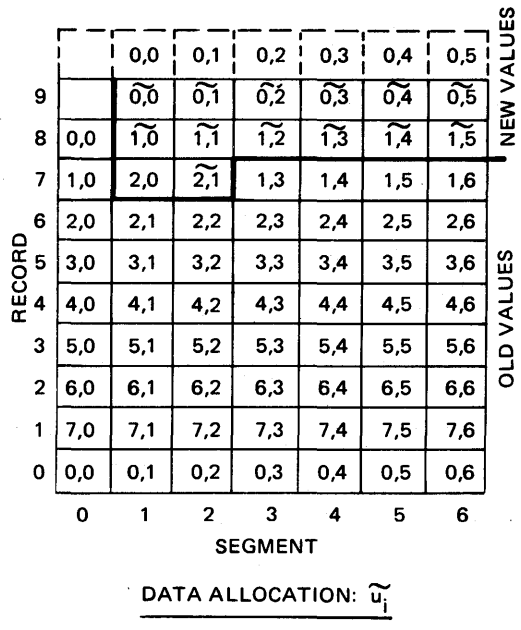

Figure 2

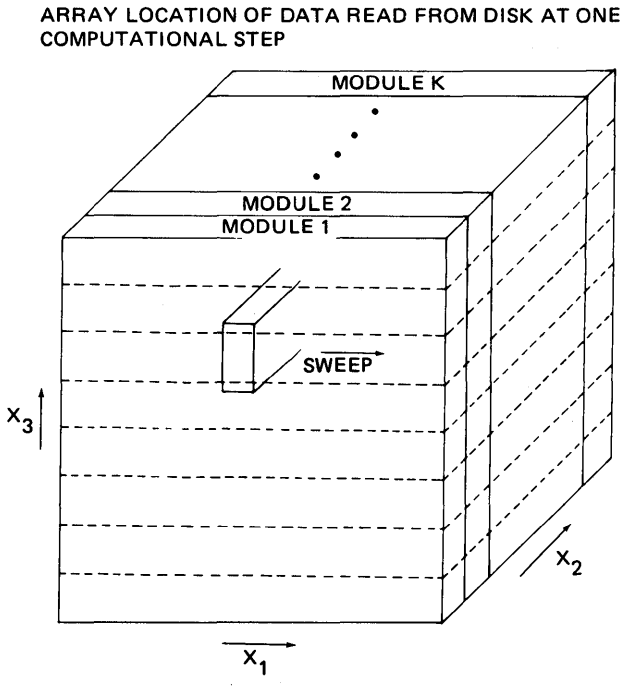

Figure 3—Array location of data read from disk at one computational step

here, but the $\rho^{(n)}$ data is first Fourier transformed in the x_2 direction before being written onto disk (as $\tilde{\rho}^{(n)}$).

The third phase involves taking x_1 and x_3 transforms of the $\tilde{\rho}^{(n)}$ array, dividing each element by a (constant) function of position, and taking inverse x_1 and x_3 transforms. The Poisson solution is complete when the transformed variables (now denoted $\tilde{P}^{(n)}$) are transformed in the x_2 direction at each step as they are read (in the first phase of the next time step). In the third phase, essentially, a transpose must be done so that entire x_1-x_3 planes of data can be brought into random access memory.

There is an extra degree of freedom in our disk addressing that was not used in the first two phases, but which will be important here: The disk has four separately addressable surfaces. Thus, if data corresponding to all x_2 values is properly arranged on the four surfaces, then we can read a set of entire x_1-x_3 planes corresponding to $^1/_4$ of the different x_2 values by reading one surface. This can be done at close to contiguous-block rates: where all the variables that pass under the one recording head are used. The total reading (or writing) time is essentially the same whether we are reading $^1/_4$ of the $\tilde{\rho}^{(n)}$ array, or any smaller fraction. For a system with 96K 16 bit words of random access memory, we can store $^3/_{16}$ of the array and essentially read and write the variables at $^3/_4$ contiguous-block rate. The total number of variables of each type transferred to and from disk together with the total number of accesses and timing estimates are given for the three phases in Table I.

Microcomputer operation

The microcomputer modules each have an independent instruction, data and scratchpad memory. Most of the random access memory resides in the microcomputer data memories. A simple control scheme that we are currently implementing on the prototype system (with two modules) involves a time-multiplexed bus attached to each microcomputer. The host (minicomputer) selects each module in turn by enabling its output buffers. The selected module transfers data to and from the host by DMA. When the transfer is complete, based on a signal from the module, the host selects the next one and the module starts computing.

The arithmetic operation count for the three phases is given in Table II in terms of the number of (one-dimensional) FFT's, square roots, divisions and other additions and multiplications. The total computing time estimates for one module are also given assuming characteristics similar to the

*TIME FOR ONE 16 BIT MODULE

ones used in our system. It can be seen that the throughput of ~2 modules will approximately match the disk transfer rate for our prototype system, and ~26 modules for a system with a faster disk.

A simple module data allocation scheme, to be used in our system, involves partitioning the data set at each step so that each module has data corresponding to the same x_1, x_3 values but different sets of x_2 values (with the exception of the Fourier transforms in the x_2 direction, which will be done separately in each module.) As in the disk allocation scheme, some $\tilde{u}_i^{(n)}$ and $P^{(n)}$ data must be accessed twice, but from the host instead of the disk and by two separate modules. This redundant data set is directly proportional to the number of modules used, and is approximately 7 K (16 bit) words per extra module. A 4 K buffer space is also necessary for each module. Thus, the total memory requirements increase by ~11K for each module added. For systems with more than several modules, an alternative to redundant storage would be to use inter-module communication. The time-shared bus will become saturated if used with more than ~6 modules. Beyond this number, a ring network with direct intermodule transfers would be a very efficient scheme.

Assuming buffered operation, the total time for one time step will be about 210 seconds for our system with 2 modules and 90 seconds for a system with a faster available disk and 6 modules. The time quoted for a similar algorithm (coded in Fortran) on a CDC 7600 is 180 seconds per time step. An assembly language coded version should run several times faster. Between 50 and 200 time steps are required to resolve a significant portion of turbulent kinetic energy decay in many of these simulations, resulting in a total solution time of several hours per case.

A straightforward way to double the performance of the system would be to use two disks and either 12 16 bit modules or 6 expanded 32 bit ones. Such a system, with 300 megabyte disks would be able to solve $(256)^3$ problems, with 200 time steps taking ~5 days; a reasonable time for a moderately priced, dedicated system.

MULTI-MODULE SYSTEMS

We looked at ways to increase the solution speed for our problem by utilizing more modules, and at ways to increase the grid size (data base) by utilizing more disks. It turned out that a very simple configuration consisting of 8 of the systems described above could be used to give a speed increase of ~7 and a data base increase of 8. Our reason for looking at larger systems was mainly to give an example of a highly parallel implementation of a particular flow problem. If other types of flow problems prove to be amenable to this type of architecture, or if the system cost decreases enough in the future, it may be worthwhile to build such a system.

We define a *unit* to be a minicomputer, set of microcomputers (16 or 32 bits) and one or two disks as described above. The configuration studied is quite simple: we just have to dual-port each disk and form a ring configuration (see Figure 4). For the $(64)^3$ problem, 8 sweeps (in the x_1 direction) were required for a single unit for the first two phases of each time step. We could then use 8 units—one for each sweep. With some minor exceptions, each module could read the same variables (during a sweep) as if it were doing the entire problem. These variables would be available on the two disks (or four disks) connected to each minicomputer. If the disk transfers were coordinated so that each left-hand disk were accessed at the same time by each minicomputer and then each right-hand disk, there would be no disk conflicts. This synchronization would require the testing of a flag only after the transfer of several hundred variables, and could be done using straightforward software techniques and standard interprocessor busses (IPB's). An advantage of this scheme is that one unit by itself could use essentially the same program for these phases and solve the entire problem. Also, by changing the (x_3) width of the sweep of each unit and the number of sweeps each unit must take, we could conveniently use any number of units up to 8. This should simplify development of the full system and decrease time lost due to failures. The computational speed should increase roughly linearly (in these phases) with the number of units.

We now describe a scheme for the third phase. For the single unit, approximately 10 percent of the disk transfer time was associated with this phase. With 8 units, we can segment the data ($\tilde{p}$ array) in the x_2 direction into 8 groups and rearrange the groups among the units. Each unit then would have to transfer 7 groups to the other 7 units. By transferring around the ring first in one direction then in the other, the rearrangement can be done in seven steps. During the operation, each piece of data moves an average of 2 units and we finally have 8 entire $(x_1\text{-}x_3)$ planes of data in

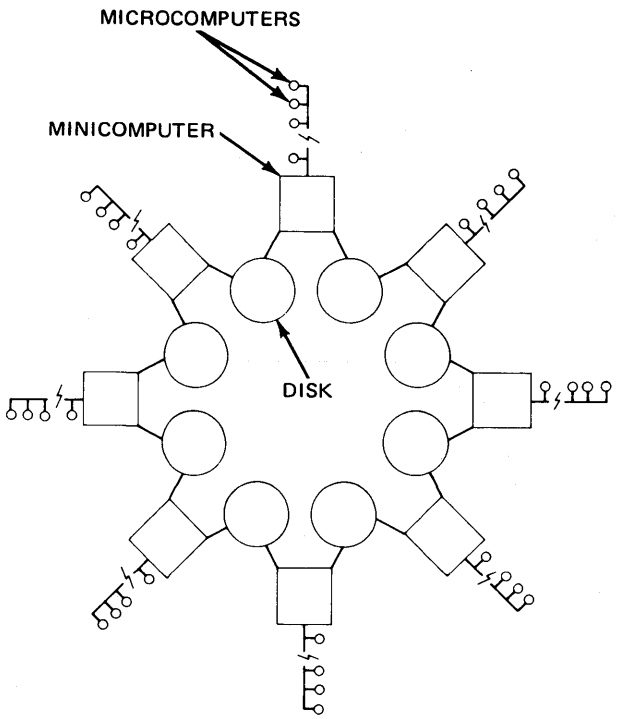

Figure 4—Multi-module system

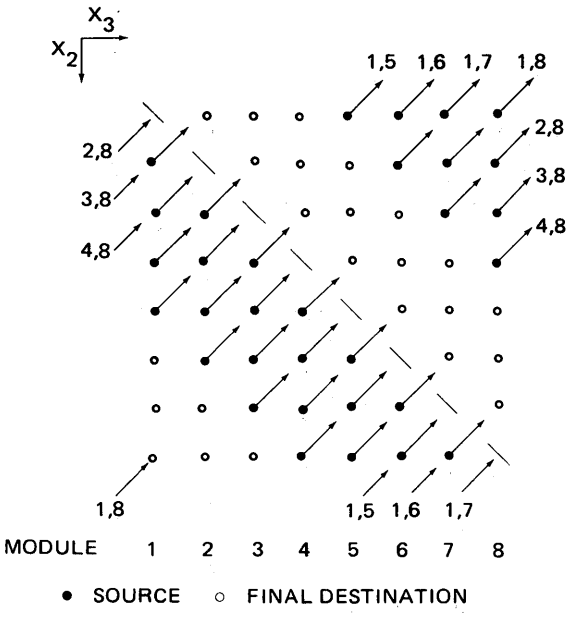

Figure 5—Transpose—First step

each unit (corresponding to different x_2 values). The flow of the data (in one direction) is depicted in Figure 5. Each solid line represents a transfer at the first step. The number of groups transferred by each unit is 4, 3, 2 and 1 for the respective right-steps, and 3, 2 and 1 for the left-steps. (Most of these transfers can be overlapped with the first two phases.) The entire phase should take about $^3/_8$ as long as for a single unit. To complete the phase, we then have to do a two-dimensional (x_1-x_3) transform in each unit, a division, an inverse transform, and then an inter-unit transfer again. The time required for the total time step (all three phases) is ~6 sec., compared to 44 sec. for one (dual disk) unit, giving a speedup of ~7.

For a $(256)^3$ array, we have 640 and 320 seconds per time step, respectively, for single and dual disk systems. For 200 time steps, this gives ~40 and 20 hours. Dual 300 Mbyte disks and 6 32 bit microcomputers would allow a $(512)^3$ solution (200-400 time steps) in 6-12 days.

There are some advantages to using the system that we have described. First, since it is a one-dimensional configuration with simple connections, adding new units or disconnecting failed ones should be straightforward, both in software and hardware. This also applies to each unit, which is a linear configuration of microcomputers. Second, although we have 48-96 (32 or 16 bit) microcomputers operating in parallel, only groups of 6-12 microcomputers need be coordinated, and only a group of 8 units need be coordinated. Third, each unit can have its own operating system and do an entire problem by itself, with any number of microcomputers.

This type of simple arrangement is very efficient for all the operations required except the one-dimensional Fourier transforms in the x_3 direction. Since a relatively small amount of data is associated with this operation, the overall system is efficient.

DISCUSSION

We have described a series of machines, assembled from available subsystems, that can have a throughput ranging from a fraction of that of the CDC 7600 to an order of magnitude greater than the 7600 for a specific time dependent three dimensional flow problem. The cost of the machines range from approximately $50,000 to over $500,000, and, for each, the cost for a solution to the problem studied is almost two orders of magnitude less than for the 7600. In these machines, extensive use of buffering and software synchronization can be made so that inter-component connections are very simple. Also, the systems can be highly modular, with more powerful machines consisting of sets of simpler machines connected together. Thus, a program to develop machines along these lines and gradually increase complexity and computational speed should be fairly straightforward.

The systems use sets of microcomputers to do most of the computations, and the problem is decomposed into parts to be solved independently by each microcomputer, as if it were doing the problem sequentially. This "macroparallel" approach should be compared to other approaches, such as one where sets of tightly coupled functional units operate concurrently on a single data stream. The AP8-120B peripheral processor is the most popular version of this.

We have described specialized algorithms to solve our problem on the machines considered. The main part of these algorithms concerns data flow. We found that special attention must be paid to this if effective use is to be made of the moving head disks. Use of these disks will be necessary, at least over the next few years, for economical storage of very large data bases in modest systems.

The problem studied represents a specific type of computational method (two time level, explicit) and a particular set of boundary conditions (periodic). Other methods (e.g., implicit) and boundary conditions should also be considered. Like our method, versions of implicit methods have semi-local and global classes of computations. Also, these global classes often involve solutions of one-dimensional tridiagonal equations in three independent directions, and a comparison with our study would be interesting.

Finally, software will, of course, be very important if wider classes of problems are to be solved. Since the microcomputers operate sequentially, higher level language implementation should not be too difficult, although efficient use of the small high speed control stores may prove otherwise. Another difficulty appears to be in the efficient use of the disk. Perhaps classes of data flow algorithms can be coded and used with a higher level language.

Applications of minicomputers to Library Systems and Services

SESSION CHAIRMAN—LAURA J. RAINEY
Rockwell International

Panel Members

Audrey N. Grosch—University of Minnesota
Charles M. Goldstein—National Library of Medicine
Karl M. Pearson, Jr.—California Library Authority for Systems and Services

SELECTING A MINICOMPUTER SYSTEM—Audrey N. Grosch

Factors influencing the choice of minicomputer systems for library automation will be discussed. Specific conditions to be treated will be:

Whether already tailored, packaged systems provide the necessary functional capability;
Whether program development and hardware systems will be configured and produced by one system vendor or by custom programming by a firm specializing in programming for a given manufacturer's smaller or larger configurations;
Whether the library has in-house capability for hardware/software evaluation as opposed to using contractors or consultants for this choice;
Whether total program development for applications will be done using commercially available DBMS (Data Base Management System) software packages such as IMAGE, MUMPS, DBMS-11;
Whether parent organization has standardized toward one manufacturer for machines to be used in connected mode to a large main frame computer;
Whether the system will be a stand alone or remote link to a main frame computer or a shared use of a larger minicomputer configuration having a multi-user, multi-tasking operating system.

Some characteristics of minicomputers presently available, together with a description of the range of peripheral devices will also be presented along with some procurement guidelines.

LIBRARY AUTOMATION PROGRAM AT THE LISTER HILL NATIONAL CENTER FOR BIOMEDICAL COMMUNICATION—Charles M. Goldstein

Lister Hill National Center for Biomedical Communication at the National Library of Medicine is supporting an R & D program in library automation. One aim of this program is to develop an integrated minicomputer based library system to satisfy the following objectives:

Transportability
Expandability
Multiple levels of on-line user
interbase and systems network access

Transportability refers to the ability to implement the system on more than one type of computer as well as easily maintain the program, to wit, a higher order language implementation. Expandability is defined as the ability to respond to increased loads by scaling up the equipment without changes in the program. Systems network access implies automatic access to network resources by the system without manual intervention on the part of the user. An example of the latter would be automatic access to a network available catalog file, if an item is not found in a local file.

The initial modules under development are circulation and acquisition modules. The potential impact of such systems on small, medium, and large libraries, as well as their potential impact on a National Library Network architecture will be discussed.

MINICOMPUTERS IN LIBRARY NETWORKING—Karl M. Pearson, Jr.

Shortly after minicomputers appeared in library applications as the base for turnkey circulation control systems, their value for networking applications was realized. First, they have been put to use as front-end processors and communication controllers for the centralized, on-line catalog systems, most notable, OCLC and BALLOTS. Next, they

have begun appearing in regional service centers. The New England Library Network (NELINET) has installed a minicomputer as an interface between member libraries and OCLC. In addition to serving as a data concentrator and communications handler, experiments have been run using the minicomputer as a sophisticated message store and forwarding device to facilitate interlibrary loan.

Several libraries have procured minicomputers for general in-house data processing needs, particularly for economical text editing, data checking, and on-line file maintenance. Many of these computers also serve in a distributed processing role in which they can link to a host maxicomputer for large-scale processing requiring extended sorting and formating of large bibliographic records.

Future developments are likely to see a minicomputer based communication network to pass bibliographic data from one utility to another, (e.g., between OCLC and the Library of Congress), to transmit interlibrary loan transactions, and allow user access to any library data base regardless of the type of terminal being used.

PART II—METHODOLOGY

Performance measurement and evaluation

Computer systems performance analysis has matured rapidly within the last decade. Ten years ago, the field was just beginning to gain prominence. Results were sparse and general methodologies were lacking. The efforts of individual researchers were exciting but difficult to interrelate.

The present state-of-the-art performance is a dramatic improvement over that of ten years ago. Although the performance problem cannot be regarded as solved, a very significant degree of progress has been made. General purpose tools are transitioning from the feasibility investigation stage to the prototype stage. Major components of a possible structure for the field can be discerned and are reflected in the following discussion.

The four performance analysis sessions at the 1978 National Computer Conference were structured to provide a unique opportunity to learn about some of the most exciting current developments in the field. The presentations and their associated papers describe some surprisingly sophisticated tools which are currently at the prototype stage together with a context for their appreciation.

NCC78 performance sessions covered a spectrum of issues from enduser and installation manager requirements to theoretical developments which are the prerequisite to future implementation of even more sophisticated tools. To accomplish this, the sessions were structured to focus on: Computer Performance Management, Computer Performance Technology, Computer Performance Modeling, Mathematical Analysis of Computer Performance and End User Performance Considerations.

COMPUTER PERFORMANCE MANAGEMENT

Evaluating performance from the viewpoint of an enduser or installation manager is complicated by two factors. The first is the immense volume of performance statistics which can be collected using current hardware or software monitors. The second is the problem of handling the collected information. The Computer Performance Management session, chaired by Phil Kiviat, focused on these two problems.

Solving the first problem requires prior determination of those performance measures which are relevant for the needs of endusers and installation managers. In contrast with other areas of science and technology, the need is not for more

data but for the right data. Presentations and the associated papers concerned with this issue covered both the types of measures which are useful and their relationship to the dependence between data processing staff and data processing users.

Given that the desired data has been identified, the next requirement is automating its handling. This requires a management information system for performance data. Major issues which must be considered in the development of Performance Management Systems are described in the context of recent work in this area.

COMPUTER PERFORMANCE TECHNOLOGY

Unacceptable system performance requires changing either the system or its workload. Provided that the system and its workload can be appropriately characterized, performance prediction techniques can be used to evaluate the likely results of specific changes and to answer "what if" questions.

The Computer Performance Technology session, chaired by Steve Kimbleton, described new techniques for characterizing the workload of a computer system through classifying it into clusters. In addition, a new approach for characterizing individual jobs was described. Taken together, these two characterizations provide a more effective means for developing the required input information for performance prediction tools. A fast, user oriented queuing network based performance prediction technique was also described.

COMPUTER PERFORMANCE MODELING

Modeling plays a key role in evaluating "what if" types of questions. Model development can be pursued via either analytic or simulation based approaches. Selection of either approach usually forces a tradeoff between the design insight provided by analytic models and the level of detail which can be reflected in simulation models. As a result, careful consideration of the goals of the model user is required.

The Computer Performance Modeling session, chaired by Jeff Buzen, described the requirements of an installation manager for effectively using modeling techniques. A new hybrid approach based on combining simulation and analytic techniques thereby permitting both increased levels of detail and faster speed was also described. In addition, a model for investigating peripheral processor performance was also presented.

MATHEMATICAL ANALYSIS OF COMPUTER PERFORMANCE

Computer system models are a key source of design insight. Developing analytic forms of such models requires close interaction between researchers in the areas of queuing and other types of stochastic processes and model oriented performance analysts.

The Mathematical Analysis of Computer Performance session, chaired by Hisashi Kobayashi, described some recent results in the interdisciplinary area of systems modeling. New techniques for evaluating the performance of queuing systems were presented. These results included a new entropy based approach to obtaining the time dependent behavior of certain queues and the distribution of the cycle time of a closed queuing network. In addition, new results in evaluating the performance of processor scheduling algorithms were also described.

END USER PERFORMANCE CONSIDERATIONS

System performance, as viewed by an end user, can be improved by enhancing the performance associated with a given program or, alternatively, by simplifying the user's interaction with the system. This session chaired by Shirley Watkins, is concerned with aiding the end user in efficiently using computer resources through simplifying their use or evaluation. The first paper will describe a technique for faster and simpler program design verification through using a data generator for program testing.

The second paper looks at the end user-system relationship in the context of providing an adaptive system interface. These formal presentations will be complemented by an informal panel discussion.

How to improve your performance through obfuscatory measurement*

by DAVID F. STEVENS
University of California
Berkeley, California

INTRODUCTION

It is best, I believe, to make it clear at the outset that this monograph has a somewhat obfuscatory title . . . for it is not my intent actually to show you how to improve your performance (that being a merely technical exercise devoid of true intellectual challenge), but rather to show you how to claim—and substantiate—superlative performance, even in the face of extreme user discontent.

As I have noted elsewhere,[1] there are two basic elements of success in computer center management: the achievement of saturation and the demonstration of efficiency. That earlier paper was somewhat deficient in that it concentrated upon the one (achievement of saturation, independently of the true—users'—workload) and slighted the other; it is hoped that this effort will somewhat redress the balance.

At this point I should, in all modesty, note that none of the techniques discussed here are my own creation. My small contribution consists only in the recognition of these scattered efforts as elements of a significant whole. I should be quite surprised, in fact, if all who read this treatise have not already either employed or encountered every measure discussed herein. What has heretofore been lacking is a true appreciation of the difference between a system viewed through the rose-colored glasses provided by these measures, and that same system viewed in the cold light of reality. It is my belief that the craftsman who understands his tools uses them most effectively; it is my hope that, after having read this paper, you will have a more complete understanding of obfuscatory measurement: what it is, what it can do for you, and, perhaps, how to devise your own obfuscatory measures. To that end, then, I will define what I mean by "obfuscatory measurement", provide some general rules and principles for the creation of obfuscatory measures, and give a number of examples to demonstrate the power of obfuscation and hint at the astonishing variety of forms it may take.

* This work was done with support from the United States Department of Energy. The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. W-7405-ENG-48. Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U.S. Government purposes.

OBFUSCATORY MEASUREMENT DEFINED

"Obfuscatory measurement" is measurement which obscures that which it should illuminate.

To be quite precise, *any* measurement which gives a false impression is obfuscatory; we are here concerned, however, only with those which allow DP Management to paint a brighter picture than that seen by the users, for it is only those which contribute to their—the DP Managers'—success. Although you may be unfamiliar with the term, you will discover that you are familiar with many of the measures . . . for many (if not, indeed, most) of the performance measures in common use today are obfuscatory. Succinctly stated, obfuscatory measures

- measure the wrong things
- measure the right things . . . wrongly
- measure something else (i.e. other than that which they purport to measure)
- measure nothing at all (or at least no meaningful thing)

Furthermore, since systems, like people, respond to measures by which they are evaluated, these measures contribute to success (as defined in Reference 1), by rewarding pessimal performance, thus increasing saturation.

GENERAL RULES, PRINCIPLES, AND TECHNIQUES

1. Select your measures with care—Not all measures are appropriate to all situations. You should neither attack the fly with the cannon, nor the elephant with the feather-duster. Tailor your measures to the tractability of your users and the gullibility of your upper management . . . and always have a couple in reserve, just in case. . . .
2. When in doubt, seek the advice of your mainframe vendor—Remember, your vendor cannot sell you additional equipment until your upper management is convinced of the saturation and effective utilization of your existing configuration. Furthermore, your vendor has a wealth of experience in dealing with upper managements just like yours. . . . Obfuscation is the very

essence of the salesperson's art; as you seek legal advice from a lawyer, you should seek obfuscatory advice from your vendor.

3. The easier a measure is to obtain, the more likely it is to be obfuscatory—This is one of the few cases known to modern science where Murphy's Law operates in favor of the practitioner. (There is no great mystery here, however: it is often the generosity of the vendor which made the measure easy to obtain.)

   Two specific kinds of easy measure are worthy of individual mention: *means* and *percentages*. As we shall see in the discussion of Availability, suitable definition of the base can turn any measurement into a praiseworthy percentage. As for the mean, while it frequently lacks meaning, it often exhibits meanness. Even though a number of articles in the recent literature (notably a pair by Gary Carlson[2] and one by Jain[3] have emphasized the obfuscatory nature of "indiscriminate" use of statistical concepts, the mean is so beloved by the average person that its utility is expected to continue relatively undiminished. One can still, for instance, report a favorable mean in preference to a realistic median in most circumstances. It is also often fruitful to ignore the distribution. More details on this technique may be found in Reference 4.

4. Overextend analogies—Concepts which are meaningful in other fields can sometimes be transferred into the computer performance arena, where they are invalid, without loss of prestige. It helps, of course, if the concept is so familiar that it is accepted without question in its new context. MTBI is such a measure.

5. Creative Definition—This is an indispensable element of the obfuscator's arsenal . . . for the most misleading percentage you can devise won't help you unless you can convince someone that it measures *something*. If yours is an elementary situation, actual definition is not important: a catchy name is all that is required . . . (Remember "CPU efficiency"? was there anything efficient about it? A modern example is "depth of multiprogramming".)

   If you find yourself in deeper waters, some measure of definition must be supplied . . . but it is best if it is either ambiguous or incompletely specified. ("Availability" as "percentage of time available" is, as we shall see, an excellent example of this technique.)

OBFUSCATION IN PRACTICE—SOME SPECIFIC EXAMPLES AT WORK

Some of these measures, most particularly Availability and MTBI, have been discussed extensively elsewhere;[1,4] inasmuch as they are among the most widely employed obfuscatory measures, however, they are included here—briefly—for completeness. We will look at four general classes of measures, giving at least two examples of each. This should provide an ample foundation upon which you can construct the obfuscatory program most suited to your specific situation. (The contents of this section are summarized in Exhibit I for quick reference, together with a listing of comparable honest measures—which are offered in the belief that it is as desirable to know your enemy as to know your friends.)

1. Measures of Availability and Reliability
   (a) Availability

   Usually expressed as a percentage, "availability" is taken by the uninitiated to indicate the amount of time the system is usable, whereas in fact it indicates the amount of *scheduled* time the system is available *to the computer center*. By reducing the base to scheduled time a significant increase in percentage is obtained. It is further increased by including many periods of time when it is not, in fact, fully usable: start-up times, time spent re-running lost or interrupted jobs, and time devoted to the "run-down" before a scheduled interruption. Exhibit II illustrates the cumulative effect of all these adjustments. It shows a week in the life of a one-shift operation, with one period of preventive maintenance (PM), a daily system development shot (SD), two unscheduled periods of down-time (15 minutes on Tuesday and an hour on Friday); start-up requires half an hour, and "run-down" starts a half-hour before system development time and an hour before the end of the shift. Naive and obfuscatory measures stand in rather sharp contrast.

   (b) MTBI (Mean Time Between Interruptions)

   MTBF (the mean time between failures) is so well accepted as a reliability measure in engineering contexts that practically no one questions its DP analog, MTBI. That the causes of failure in the two fields are largely unrelated is largely ignored: failures in mechanical systems are caused by wear and fatigue (to which software is impervious); failures in computing systems are caused by unexpected input (to which mechanical systems are rarely exposed) and trivial overflows (which, if they cause damage at all, cause trivial damage: will an overflow on the meter crash a taxi?). The user-oriented measure which most closely corresponds to MTBI is the mean (or median) service interval. To see how they compare, we return to the sample week of Exhibit II. The mean service interval, even giving full credit for the run-down periods, is 2.23 hours (26.75/12), and the median is 2.5. The *conservative* way to calculate MTBI is to divide "hours available" by "number of interruptions plus 1": 32.75/3=10.9 hours . . . more than three times as long as the *longest* service interval.

2. Measures of Throughput
   (a) Utilization

   When the obfuscator is asked for measures of throughput she has ample industry precedent for responding with measures of utilization. Utilization measures are advantageous because they reward ineffective programming (which is much easier to

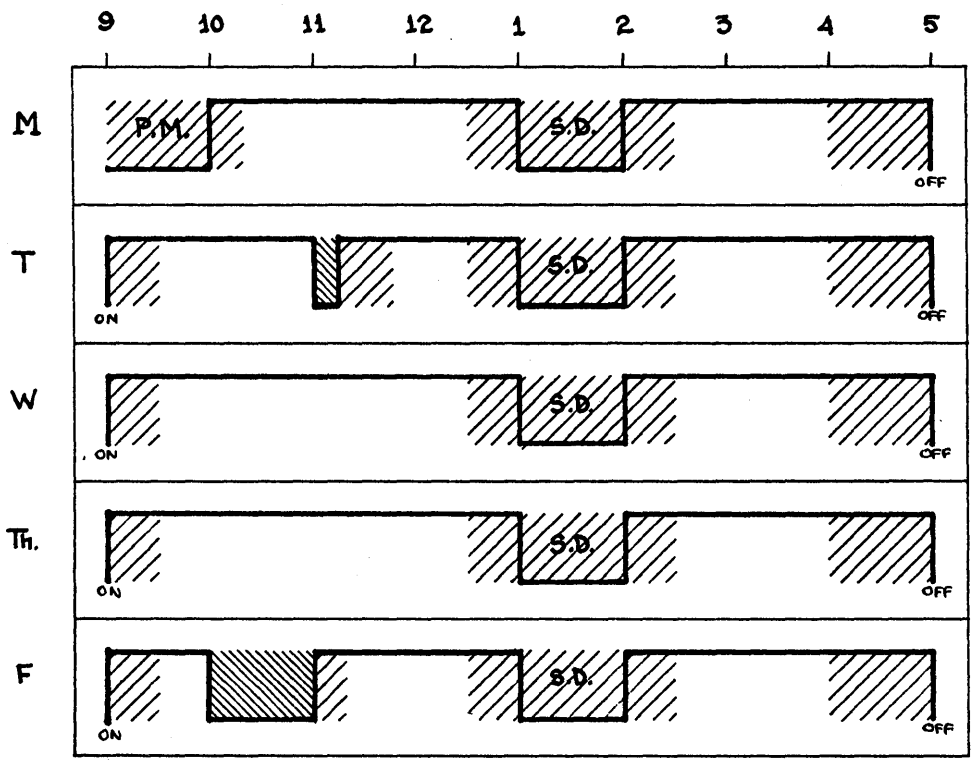
Class	Honest Measures	Sample Obfuscatory Measures (and what they actually measure)
Availability and Reliability	True availability to the users. Mean and median service interval.	Availability (% uptime) MTBI (mean scheduled time to crash)
Throughput	Work delivered (in user units).	Utilization (resource occupancy) Efficiency (utilization)
Turnaround	Processing time vs. system wait time, by category.	Interactive response time Turnaround time (as long as you stick to means, they measure nothing meaningful)
General Productivity	Concurrency: the number of CP and channel activities occurring simultaneously. Existence (or not) of saturation. Capacity relative to workload. Functions delivered; quality of code.	Overlap (existence of overlap) Depth of multiprogramming (number of active initiators) Saturation (work, productive or not, as % of "capacity") Lines of code (prolixity)

Exhibit I

obtain than the other kind). Your path here is not quite as free as it used to be, what with the introduction of distinguishable "system" and "problem" states for CPU utilization . . . but it remains the case (thanks to your friendly mainframe vendor) that much of what is called "problem state" is actually system overhead. And it seems extremely unlikely that anyone is going to come up with a meter which distinguishes between "system" and "problem" channel activity states!

(b) Efficiency

This is actually a vestige of the past, but one which has validity in some contexts, and adds a certain panache to your reports. It may be freely used in place of "utilization" (the two are identical in meaning), but I would advise against using them both to refer to the same quantity: such a juxtaposition might inspire tiresome questions. "CPU utilization" and "channel efficiency", on the other hand, provide a nice appearance of breadth.



D.P. MGMT. (AVAIL/SCHED)	USER (AVAIL/TOTAL)
6/6	3.5/8
6.75/7	3.75/8
7/7	4.5/8
7/7	4.5/8
6/7	3/8
32.75/34	19.25/40
96%	48%

Exhibit II

3. Measures of Turnaround
   (a) (Interactive) Response Time
   This has superseded "turnaround time" as the most commonly quoted measure of turnaround, but the principles of use are the same. It is most important here to remember that the mean can be manipulated by stacking the extremes. To be specific, you can achieve essentially any response time you wish by requiring a suitable number of trivial interchanges—with zero response time—to take place during any interactive session. (This is easily seen to be the inverse of the situation shown in Exhibit III, wherein a Miraculous improvement in "mean service interval" is achieved by introducing an unused—and hence uninterrupted—weekend service.)

   Another fact to be borne in mind is that, in some situations, response which is *too* quick creates tension, which causes errors . . . and errors lead to wasted work, thus bringing saturation (and hence success) ever closer. (A better strategy, however, is to strive for consistently unexpected response time, whether it be quicker or slower than anticipated . . . but this is somewhat off the subject of this paper.)

   (b) Turnaround Time
   Since the good turnaround times are the small ones, this is a situation where the median, surprisingly enough, favors the obfuscator. Nevertheless, I recommend sticking with the mean. For not only is the median a dangerous precedent to set, the mean is, as we have seen above, quite a tractable index. As in the case of response time the enterprising manager can cause enough small jobs to be submitted to achieve whatever mean turnaround time is deemed necessary.

4. Measures of General Productivity
   (a) Overlap; Depth of Multiprogramming
   These two measures are grouped together not because they are thought to be equivalent (they are not), but because they address the same problem: a vague understanding on the part of upper management that some multiplicity of processing is desirable. They make a good combination, not only because they obfuscate in different ways, but also

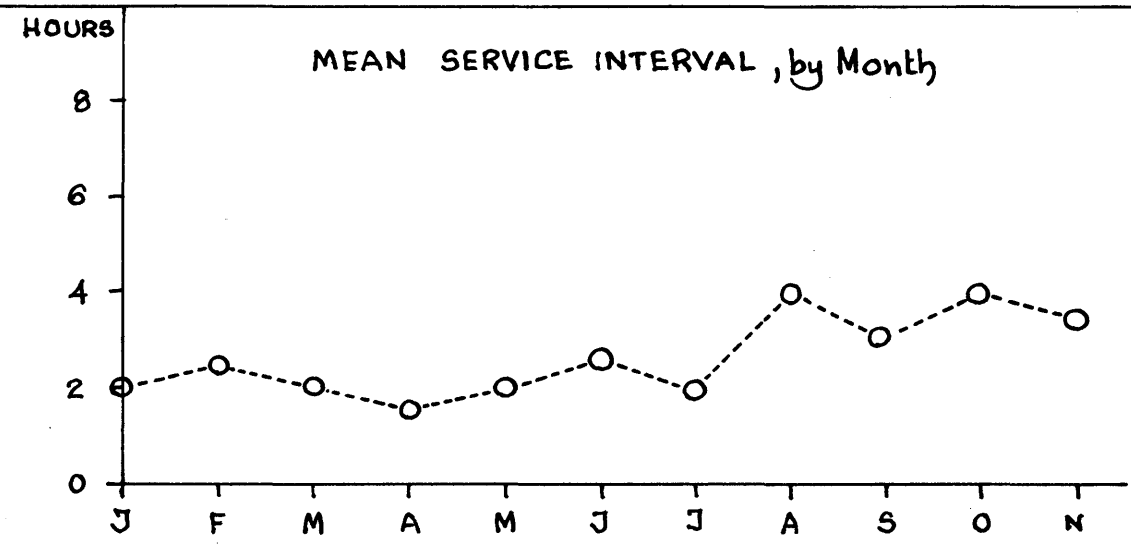


EXHIBIT 3a.

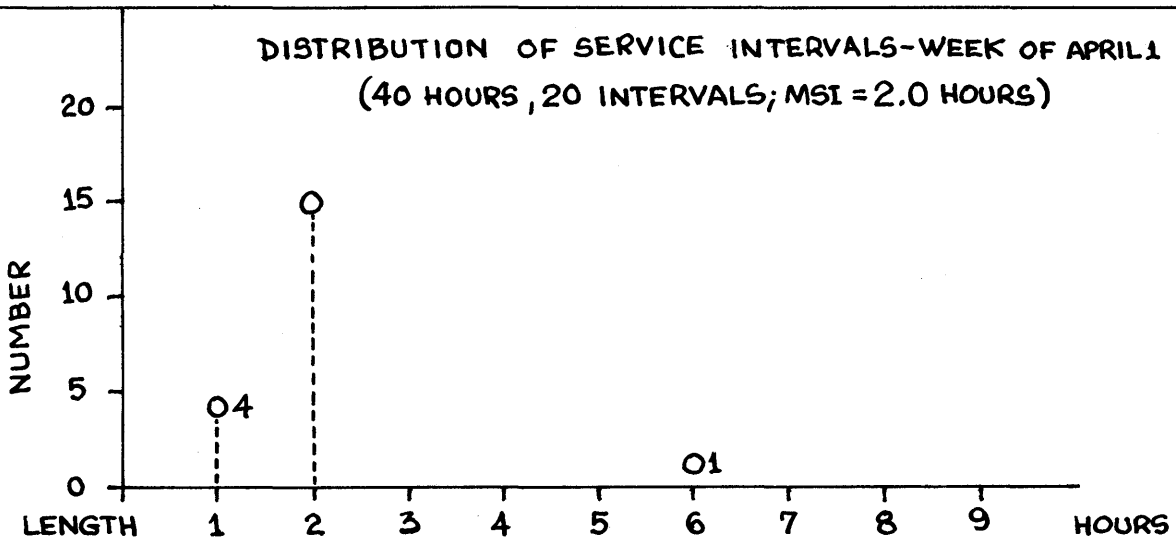

EXHIBIT 3b.

KAPUS

Exhibit IV

because the two together give no more accurate a picture than either one singly.

Overlap is in fact somewhat less obfuscatory than depth of multiprogramming, for it measures the percentage of time that some amount of simultaneity is experienced; it does not, however, consider the level of simultaneity. (Thus two simultaneous processes are every bit as good as seven.) It may be this very touch of honesty, paradoxically, which makes overlap so useful as an obfuscatory measure.

Depth of multiprogramming, on the other hand, is pure obfuscation: it counts initiators instead of processes. In many shops, large values of depth of multiprogramming survive as tribute to the memory salesperson's art, while all the jobs lie quiescent awaiting the pleasure of the Resource Manager or some other such system magus.

(b) Saturation

The obfuscatory nature of "saturation" lies in the fact that saturation is not a measure but a binary condition: the change in the quality of a service which moves from an unsaturated condition to a saturated one is an abrupt discontinuity: service effectively stops and the input queue becomes infinite. References to "80 percent of saturation" thus really mean "80 percent of capacity", and are doubly obfuscatory because saturation can be largely independent of capacity. We can best illustrate this by means of an example: Consider a long, narrow footbridge with a capacity of 2000 pounds. Thirty-nine small boys, each weighing less than 50 pounds, would not exhaust its capacity but would surely saturate it (they wouldn't all fit at once) for quite a while. A single man leading an elephant, on the other hand, would not saturate the bridge but would exceed its capacity (see Exhibit IV).

A useful related obfuscation is the measurement of throughput as a percentage of capacity, for many people ignore the basic fact that "capacity" changes with workload and environment. They consider "capacity" a configuration constant, despite the fact that they know full well that any reasonable multiprogramming system has a smaller capacity when restricted to highly compute-bound jobs than when fed a mixture of compute- and I/O-bound work. This blind spot can be exploited in other ways; it is much less well-known, for example, that any multiprogramming system strongly dominated by priority considerations has a smaller capacity than a system free to assign requested resources (such as the CPU) in an optimal fashion.[5] A word to the wise, one hopes, is sufficient. . . .

(c) Lines of Code

This measure, being directed at human productivity, might be considered by some to be somewhat outside the scope of this paper, but programmer performance *is* an element of computer center performance and lines-of-code *is* superbly obfuscatory. More importantly, lines-of-code is perhaps the best embodiment of one of the great philosophical rocks upon which Obfuscatory Measurement is founded:

> It is nearly always possible to substitute numbers for judgment.

A timid person might hesitate to use lines-of-code on the grounds that it is patently absurd (is the Beer Bottle Song ["One hundred bottles of beer on the wall. . . ."] better than a Shakesphere sonnet? a limerick than a haiku? this paper than the Gettysburg Address?), inasmuch as it ignores quality. Such a person severely underestimates the power of numbers to convince and confuse . . . in a word, to *obfuscate*.

L'ENVOI

It must, alas, be admitted that an occasional obfuscator is taken to task for an excess of creative zeal. Should that unhappy fate befall you I can offer no defense better than that provided by Pooh Bah, who under such like circumstances,[6] claimed that his obfuscation was "merely corroborative detail, intended to add artistic verisimilitude to an otherwise bald and unconvincing narrative."

Perceptions of performance

by RICHARD J. CIESLOWSKI
Aetna Life and Casualty
Hartford, Connecticut

INTRODUCTION

Most businesses view the data processing staff as a centralized resource, providing a specialized service to all segments of an organization. Centralization has occurred in response to the instrinsic cost and expertise benefits available through a concentration on this discipline. The inevitable separation from the client organization results in the establishment of a consultant/client relationship, e.g., the personnel responsible to support and accomplish the organization's operational objectives reside in a separately managed and controlled area. This presents a significant problem—one which often results in the operational area being accountable for an objective, while the data processor holds the key to its accomplishment. The data processor, who is charged with maintaining a high level of technical data processing competence along with developing an understanding of the clients objectives must clearly understand his position. On the other hand, the client, who has ultimate accountability for results, often has little, if any, data processing knowledge or ability to deal effectively with the data processor.

Given this framework, how do data processor and client personnel communicate effectively? Can the data processing systems developed perform as required? Can specific performance measurement criteria be developed?

A plan must be developed to help both the data processor and client address these questions. The basic principles of the plan must be simple and capable of application across a wide range of client requirements.

STANDARDS OF PERFORMANCE TECHNIQUE

Given a corporation's major investment in data processing systems and resources, an effective process to ensure required human intervention can consist of the following steps:

- Establish "Standards of Performance" for each data processing system
- Measure the system's performance as it compares with each standard each month.
- Recognize and reward the performance contributions of both data processor and client personnel.

In labor-intensive corporations, effective expense control programs must concentrate on salary costs and, in turn, on the number of personnel required in a support role. This is the critical controllable expense.

I have found that where "Standards of Performance" are instituted, people are motivated to produce more than the results desired. The data processor and client begin to communicate effectively. And why not? For the first time they have a common base—a commonly understood and held set of measurement criteria.

ILLUSTRATIONS

A case in point: One of the larger data processing systems I have personally been associated with was an employee human resource data bank which supported both Personnel and Payroll functions of one of the largest multiple-line insurance companys in the United States. The system accommodates the personnel/payroll records of an active staff of over 30,000 employees throughout the United States, Canada, and Puerto Rico.

In the course of a year, the system manipulates, calculates and processes in excess of 1.2 million transactions. Associated with this is the annual production and distribution of over 350,000 personnel reports and 860,000 paychecks.

An integral part of the system was a client staff of 39 employees who were charged with the specific responsibility of inputting, pre-editing, coding, balancing, researching, analyzing, distributing and controlling this employee data. A staff of 19 data processors were required to support the technical aspects of the system. (Exhibit I illustrates the relationships.) The "system" in a real sense consists not only of the data processing equipment, but the manual support functions that people must perform.

Two years after installation, the system was perceived to be performing unfavorably. The data processors could not consistently satisfy the Payroll and Personnel client's "needs." Work was backlogged. Flexibility to handle new demands was limited. Processing costs were high—service levels, poor. Problems of this nature continued in spite of a 33 percent addition to staff over a two year period. The problem diagnosed was a lack of advanced data processing technology.

At this point, a Project Team, composed of data process-

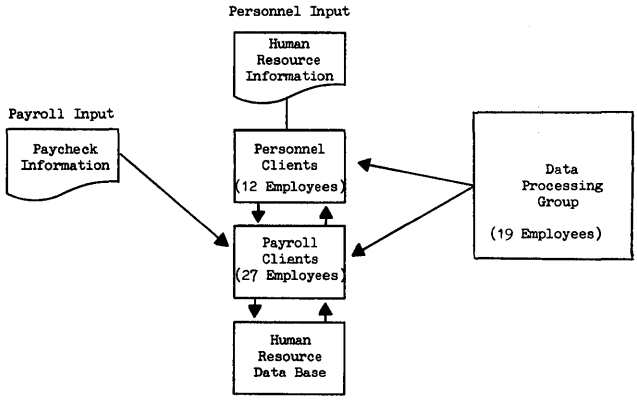

Exhibit I—Work relationships before standards of performance

ing and client personnel, was commissioned to investigate the feasibility of installing a more sophisticated technology. The first step taken by the team was to develop a set of objective criteria, against which system performance could be measured. These were termed "Standards of Performance." Using them as a basis, the existing technology was evaluated. To everyone's surprise, the existing system met the desired performance levels. In short, while the perception of poor performance existed, when evaluated against specific, desired criteria, we were able to demonstrate that the system was performing satisfactorily.

Unfortunately, as is often the case, it's the perceptions that people have that counts. Our real problem therefore, was one of education—to correct an erroneous judgment. The culprit was identified as a real lack of understanding of system requirements and capabilities from both the data processor and client perspectives. The data processor was expending a large proportion of effort on activities that were not critical to the client personnel's operations. In turn, the clients were not communicating their essential needs to the data processor. To further compound the problem, in the final analysis, the Human Resource System was in fact adequately servicing the end users and was more than meeting their expectations. In the course of the project team's interview process all end users contacted were in agreement on this point. In spite of a constantly increasing input volume the system continued to produce secure, controlled, timely, and accurate output.

The Project Team recommended that an "Operational Improvement" was warranted rather than installing a new data processing technology. That is, all manual input handling activities be combined into a single unit, with efficient workflow and procedures. Work measurement controls were installed to insure high productivity levels. In addition, the team recommended maintaining a strict adherence to the Human Resource System's "Standards of Performance."

The recommendations were accepted by management and vigorously implemented. Immediate cost avoidance stemming from cancellation of the projected data processing developmental effort was $200,000. More importantly, however, system performance was perceived to be and was in fact meeting specific expectations!

A longer term benefit was shown when two years after performance standards were implemented, a 50 percent reduction in data processor and a 10 percent reduction in client resources were achieved as a direct result of improved communications and working relationships. Clearly, the catalyst was an agreed upon set of performance standards. (Exhibit II illustrates the results.)

I don't pretend to suggest that all data processing problems are the result of erroneous perceptions or that they can be readily solved. Another case in point—performance standards were developed which, when applied, soon highlighted the fact that results were less than desired. An in depth probe revealed:

- Standards were ignored. While performance criteria were sound, they were ignored or inconsistently applied.
- Management placed little emphasis on monitoring actual results. This was visible to the employees since normal supervisor recordkeeping was delegated downward.
- Results were not reviewed between the data processor and client personnel. No ongoing constructive dialogue existed.

When the results of the review were presented to management they were accepted and constructively addressed. Within three months performance had returned to satisfactory levels. Again this was accomplished without the need to launch a new data processing system's development effort.

PERFORMANCE MEASUREMENT BENEFITS

When "Standards of Performance" are installed in an area, their impact while subtle, is dramatic in terms of results. For the first time the data processor and client have the same reliable and objective criteria on which to evaluate their collective performance. Usually some disturbing facts surface:

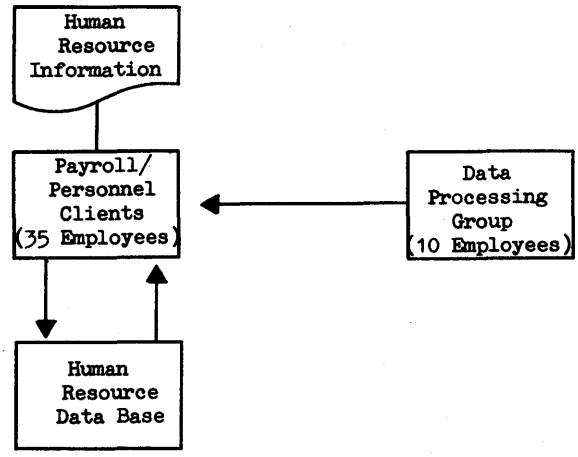

Exhibit II—Work relationships after standards of performance

- The data processing supervisor is not normally allocating his personnel to the critical client tasks. Too much attention is focused on mechanical efficiency.
- Advancements in technology are not usually an answer to performance problems.
- The client realizes he has not effectively utilized his available data processing resource. This realization can be a determining factor in greatly extending the life span of an existing data processing system, while at the same time realizing an attendant increase in performance. The cost avoidance, associated with not developing replacement systems is almost always substantial.

Once the standards are in place, communication between client and data processor and repetitive performance feedback is assured. This dialogue is an essential product of the "Standards of Performance" technique. It is the key to developing a balanced, factual perspective to data processing evaluation.

Positive results are visible in terms of reduced overtime and work backlogs. When standards are used, effective client/data processor communications are established. There is almost always a significant reduction in data processor resources required. Individual and group performance can be judged based on objective measurable results. Managers are in a better position to recognize and reward performance (or lack thereof). The net impact is a reduction in cost for salary expense, while, at the same time realizing an improvement in system performance.

STANDARDS DEVELOPMENT APPROACH

The approach employed to arrive at a data processing system's "Standards of Performance" is based on applying the management principles taught in the Louis A. Allen Project Seminar (Management Planning and Control) to the data processing environment.

"—ESTABLISH THE KEY OBJECTIVE: Identify the key data processing environment objective.
—ESTABLISH CRITICAL OBJECTIVES: Statements of the most important (continuing) results which must be accomplished if the key objective is to be realized.
—DEVELOP STANDARDS: Standards developed for each critical objective establish the criteria for effective performance."[1]

The crucial management ingredient underlying this approach is the need to reach understanding and agreement between data processor and client.

STANDARDS DEVELOPMENT ILLUSTRATION

"Standards of Performance" for a hypothetical career management system could be constructed as follows:

KEY OBJECTIVE

To provide a reporting framework which supports the development, installation, and maintenance of personnel career management programs within the corporation. Further, to be responsive to report users' status and information needs.

CRITICAL OBJECTIVE 1

To provide calculation and report development flexibility so that personnel career management reports can be tailored to report user needs on a timely, economical basis.

STANDARDS

- To develop new reports in not more than 34 elapsed days.
- To modify existing reports in not more than 22 elapsed days.
- To enable client report generation in not more than 10 elapsed days.
- To set-up a new employee "On File" in not more than three elapsed days.
- To revise input forms in not more than 11 elapsed days.

Report development performance measures are intended to eliminate the inefficient usage of reports. Emphasis is placed on delivering exception reports and summary level reports rapidly. Flexibility must be developed so that report users do not feel a need to request voluminous detailed reports. This need is normally generated in reaction to an unresponsive or a costly developmental process.

Specific measurement criteria can be visualized in terms of a two dimensional matrix. (Exhibit III illustrates sample relationships). Procedurally, this matrix can be developed in the following three steps:

STEP 1—*REPORT REQUIREMENTS* are analyzed in terms of critical client needs. Report categories must be clearly defined and capable of being measured. Additionally, the data processor and client must be in complete agreement with the categories selected.
STEP 2—*FUNCTIONS* that must be performed, to insure error-free reports, are documented for all participants. Typically this will include report recipients in addition to the data processor and client. It is usually found that lines of responsibility are not clearly defined, which causes inefficiencies and duplication of effort.
STEP 3—*ELAPSED TIMES* must be assigned for each REPORT REQUIREMENT and will reflect past performance and future requirements. Times must be reasonable, attainable and should reflect a common, understood, and agreed to goal.

The end result of setting report development measurement criteria will be a common understanding of the report development process for both the client and data processor, along with supporting a framework for client communications with report requestors. The client can now pursue, on

Function	REPORT REQUIREMENTS				
	Develop New Reports	Modify Existing Reports	Client Report Generation	New Employee Set-Up	Revision of Input Forms
Initial Report User Contact	1*	1	1	1	1
Finalize Specifications Report User & Client	1	1	1	2	10
Finalize Specifications Client & Data Processor	5	3	-	-	-
Analysis & Costing Client & Data Processor	5	3	-	-	-
Programming	10	5	2	-	-
Unit Test Data Generation (Client)	5	3	3	-	-
Unit Testing	3	2	2	-	-
Verify Results (Client)	1	1	1	-	-
Report Acceptance (Data Processor)	3	3	-	-	-
TOTALS	34	22	10	3	11

* All time estimates are in terms of elapsed days.

Exhibit III—Personnel career management report matrix

a factual basis, report delivery dates and can advise on the risks involved in attempting to unreasonably accelerate delivery dates.

CRITICAL OBJECTIVE 2

Complete data processing production runs accurately and on schedule.

STANDARDS

- 95 percent of all production runs will be completed within five (5) working days from receipt of the latest input item or input cut off date. This will apply unless other specific schedules are established.
- Machine resources will not exceed $5,000 monthly.

These measurement criteria are intended to be applied after the initial report development process is completed. The measurements ensure that recurring reports are delivered on a timely basis—it makes no sense to develop a report in a rapid and cost effective manner and then not monitor the recurring delivery process.

CRITICAL OBJECTIVE 3

Implement minor report changes (1-10 days) on a timely basis.

STANDARDS

- Resolve 98 percent of priority "A" changes prior to the next update (unless other arrangements agreeable to client and data processor have been made).
- All changes will be prioritized through the combined efforts of client and data processor personnel. Adding changes after the monthly schedule is established will result in a re-prioritization of existing planned work. Monthly planning of this activity should result in 95 percent of scheduled changes being completed without change.
- Implement 95 percent of all priority "B" (Balancing

problems, report format/content changes) changes and 90 percent of all priority "C" (noncritical) changes on a monthly basis as reflected on the agreed-upon monthly maintenance schedule.

It must be noted that for proper application of these standards the prioritization process must be agreed to and understood by both client and data processor. The priority process is negotiable, however typical priority definitions are as follows:

A. Essential to next production processing cycle.
B. Desirable change—but not essential to next cycle process.
C. Changes to improve system performance, control, input and report processing.

Once the reports are developed and the ongoing data processing system is installed, requirements for system change occur. The origin of change is complex and can be generated from report user, client, or data processor personnel. However generated, change requirements must be controlled in a manner that identifies the most critical requirements. The intent is to meet maintenance measurement criteria while minimizing client and data processor staffing needs.

DEVELOPMENT TIMING

Defining a system's standard of performance benefits both the client and the data processor. Ideally these performance criteria should be established early in a data processing system's developmental process. The standards ensure that the client fully communicates critical needs. Since the standards are normally given in terms of response times (elapsed days) to perform an activity, the data processor has the necessary information to answer difficult system design questions—while fulfilling customer requirements with a minimum investment of data processor resources.

The standards of performance can also be developed for systems already installed. Typically maintenance activities can generate an unacceptable level of resource commitment in response to undefined but assumed objectives. Again, the standards can document the clients critical needs and can serve as a vehicle to evaluate an existing system's performance. Closely monitored, it can also indicate a need to upgrade or replace the existing system.

INGREDIENTS FOR SUCCESS

The following four elements are necessary to ensure the success of the "Standards of Performance" technique.

STEP 1—ESTABLISH STANDARDS OF PERFORMANCE: The critical activity is to first establish the standards. Without sound standards the technique will fail. These performance standards cannot normally be established by methods such as time ladder studies, random sampling, stopwatch techniques, or modal time analysis. In other words the type of standards we are dealing with are not translatable to engineered time standards; reliance is placed on a combination of historical trends and consensus agreement.

STEP 2—PURSUE DATA PROCESSOR AND CLIENT UNDERSTANDING AND AGREEMENT: Having developed the standards, we must now set agreed to elapsed times and arrive at a complete understanding of requirements in both data processor and client areas. This must be done at the highest management levels in both areas. Again, without complete understanding and agreement, the chances of success are reduced.

STEP 3—REGULARLY MONITOR THE PERFORMANCE CRITERIA: The performance results must be discussed and acted upon on a monthly basis. This dialogue is yet another ingredient in ensuring the success of the technique since most standards cannot be as precise as an engineered time standard. A continuing reevaluation is the method used to test the standards as initially established and to answer such questions as: ARE RESULTS MEETING STANDARDS? IF NOT, WHY NOT?

STEP 4—REFINE STANDARDS WHEN NECESSARY: Given the imprecise nature of the standards, we must be willing to reevaluate them. Many external factors, such as client reorganizations or end user requirement changes can render some standards obsolete. Without continuous evaluation and updating all gains initially made can be lost.

CONCLUSION

No data processing effort should be attempted without first establishing "Standards of Performance." Differing client requirements and objectives may require a unique set of performance criteria, however, there is no doubt that measurement criteria are mandatory.

The challenge to improve is a shared responsibility. Here is a new technique which, if properly applied, will result in high "system productivity" and the achievement of clearly defined levels of performance with communications which effectively link all parties of "The System." Remember "The System" consists of automatic data processing equipment plus the personnel that make it go and *Perceptions*. While it is important to understand and control the people/machine relationship, it is equally as important that client and data processor share a common perception of performance.

Effects of peripheral processor wait list positioning on system performance

by RONNIE G. WARD, BECKY B. TURNER and GALEYN JOE HUBBARD
University of Texas at Arlington
Arlington, Texas

INTRODUCTION

Strauss[1] developed a simple analytic model of the HASP Execution Task Monitor (HETM) for use in studying performance improvements that result from HETM's application and whether or not HETM should be modified to consider different memory speeds of OS/MFT partitions at a specific installation. The cyclic-server multiprogramming model he developed is demonstrably valid.[2] That is, using service rates fitted to the model, predicted results approximate measured results reasonably well, and one may have confidence that the model accurately reflects system performance.

In IBM's OS, one or more job classes are assigned to each system initiator program, which selects jobs to introduce into the system on a priority basis within class. OS uses preemptive priority CPU task dispatching. Tasks are represented to the operating system using a task control block (TCB). The set of TCB's corresponding to active tasks are chained in priority order (highest to lowest). The dispatcher assigns the CPU to the first ready task found by scanning the TCB chain in priority order. An event completion that causes a higher priority task to become ready generates a task switch and a running lower priority task will be preempted. HETM regularly examines the CPU utilization of OS tasks and rearranges the TCB chain in an attempt to more equitably distribute CPU service. As Strauss points out, the effect is to keep I/O bound tasks active without unduly harming service to CPU bound tasks.

When an executing program solicits an I/O operation, the I/O supervisor[3] associates a request element (RE) with the intended work. If the I/O operation cannot be started immediately, the RE is positioned in a wait list associated with the addressed device. An installation may specify at system generation time the wait list positioning policy to be used for each device. For example, an installation may choose for DASD devices either first-come first-served (FCFS) queuing, dispatching priority positioning, or seek address positioning.

The purpose of this paper is to quantify in terms of the results of an analytic model the effect wait list positioning can have on system performance. In systems where CPU or channel time is a bottleneck, the model can be used to study the importance of wait list positioning in increasing or decreasing job class response. The analytic model of different wait list positioning strategies is first presented. The HETM stability condition given in Reference 1 is then re-examined. Finally, performance predictions of the positioning policies are discussed and related to system and job class performance.

THE ANALYTIC MODEL

Figure 1 depicts a simple cyclic exponential server model that is a closed network permitting no exogenous arrivals or departures. There are three task classes α, β, and γ specified by their CPU service rates μ_i and peripheral service rates δ_i where i is α, β, or γ. The characters a, b, and c denote the tasks ranked by preemptive CPU priority; task a can preempt b which can preempt c for CPU service. A mapping is defined as a permutation of the α, β, γ tasks onto the priority designations a, b, c. It is the HETM reordering of the OS TCB chain that determines a particular mapping. The tasks a, b, and c are serviced by an exponential process CPU server with mean rate μ_i. Following CPU service, the task enters a peripheral processor (PP) wait list and eventually receives exponential process peripheral service with mean rate δ_i. After PP service, the task may enter the CPU queue or be serviced by the CPU. The tasks cycle continuously through a CPU-PP service loop.

The system is modeled in steady state during HASP intervals between changes to the TCB chain. Analytic and simulation studies have shown this to be a reasonable assumption.[1]

In the model, each of the tasks can be in any one of the following five places in the system:

0. Waiting for CPU service.
1. Obtaining CPU service.
2. At the end of the PP wait list.
3. At the head of the PP wait list.
4. Obtaining PP service.

The state of the system is completely specified by the contents of four of the five positions. A four component state

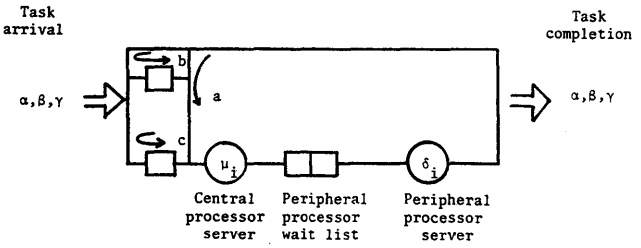

Figure 1—Cyclic exponential server model

vector v is used to denote the system state where the jth component of v denotes the jth position of the system and the contents of each component can be a, b, c, or x (x denotes an empty position). For example, the state $v=axbc$ indicates that a "class a" task is receiving cpu service, a "class b" task is at the head of the I/O queue, a "class c" task is receiving PP service, and the second position in the PP wait list is unoccupied.

Using this notation, the possible state vectors v_i^k of five PP wait list positioning strategies are written as follows:

$$v_{1\le i\le 16}^{1} = \begin{array}{c} 1\ 2\ 3\ 4\ 5\ 6\ 7\ 8\ 9\ 10\ 11\ 12\ 13\ 14\ 15\ 16 \\ \hline \left\{\begin{array}{l} a\ b\ c\ a\ x\ c\ a\ a\ x\ b\ x\ b\ x\ a\ x\ x \\ x\ x\ x\ x\ c\ x\ x\ x\ c\ x\ a\ x\ b\ x\ b\ a \\ x\ x\ b\ x\ b\ a\ c\ x\ a\ c\ c\ a\ c\ b\ a\ b \\ x\ a\ a\ b\ a\ b\ b\ c\ b\ a\ b\ c\ a\ c\ c\ c \end{array}\right. \end{array}$$

FCFS and RANDOM positioning (k=1)

$$v_{1\le i\le 11}^{2} = \left\{\begin{array}{l} a\ b\ c\ a\ x\ c\ a\ x\ x\ b\ x \\ x\ x\ x\ x\ b\ x\ x\ a\ b\ x\ a \\ x\ x\ b\ x\ c\ a\ b\ c\ a\ a\ b \\ x\ a\ a\ b\ a\ b\ c\ b\ c\ c\ c \end{array}\right.$$

Last-come First-served (LCFS) (k=2)

$$v_{1\le i\le 12}^{3} = \begin{array}{c} 1\ 2\ 3\ 4\ 5\ 6\ 7\ 8\ 9\ 10\ 11\ 12\ 13\ 14\ 15\ 16 \\ \hline \left\{\begin{array}{l} a\ b\ c\ x\ a\ a\ c\ x\ a\ b\ b\ x \\ x\ x\ x\ c\ x\ x\ x\ c\ x\ x\ x\ b \\ x\ x\ b\ b\ x\ c\ a\ a\ x\ c\ a\ a \\ x\ a\ a\ a\ b\ b\ b\ b\ c\ a\ c\ c \end{array}\right. \end{array}$$

Dispatching Priority Positioning (k=3)

$$v_{1\le i\le 10}^{4} = \left\{\begin{array}{l} a\ b\ c\ x\ a\ a\ c\ x\ x\ b \\ x\ x\ x\ b\ x\ x\ x\ a\ a\ x \\ x\ x\ b\ c\ x\ b\ a\ b\ c\ a \\ x\ a\ a\ a\ b\ c\ b\ c\ b\ c \end{array}\right.$$

Inverse Dispatching Priority Positioning (k=4)

The application of a wait list positioning policy other than FCFS is quickly observed by studying the state transitions. For example, $v_6^3 \rightarrow v_8^3$ since the a task would position ahead of the c task after completing CPU service. On the other hand, $v_7^4 \rightarrow v_9^4$ since an inverse priority scheme is used.

As pointed out in Reference 4, FCFS scheduling is an appropriate model of secondary storage I/O devices because preemptive scheduling is usually not possible or efficient. However, given that the device is not preemptable, task positioning in the device wait list can still influence the performance measures for an individual job class. Typically, analytic models presented in papers such as in References 5 and 6 assume that device scheduling is independent of the processes generating the requests. However, this may not always be the case as already discussed in the instance of OS.[3] With the above models, it is possible to determine analytically the impact of wait list positioning on job class performance. Note that LCFS scheduling is feasible only for interjob requests.

Each state v_i^k has an associated steady state probability $P_{v_i^k}$. These equilibrium probabilities can be determined by solving the system balance equations [1,4]. That is, for all states v_i^k,

$$\sum_j P_{v_j^k} \times (\text{rate of flow from } v_j^k \text{ to } v_i^k) = P_{v_i^k} \times (\text{rate of flow out of } v_i^k)$$

From these probabilities, the task CPU utilization, PP utilization, queue time, and cycling rates may be determined.[1,2] Also note that the distinction between FCFS and random positioning is in the state transitions and balance equations. For example, under FCFS, the c task exiting the CPU results in $v_3^1 \rightarrow v_5^1$. However, under random positioning we could also have the transition $v_3^1 \rightarrow v_{13}^1$ with an equal probability (.5). The flow into certain states is therefore altered. For instance, the balance equation for v_5^1 under FCFS is

$$\delta_a P_{xcba} = \mu_c P_{cxba}$$

and under random positioning we would have

$$\delta_a P_{xcba} = .5\mu_c P_{cxba} + .5\mu_b P_{bxca}$$

Another interesting model result aside from service center utilizations and task throughputs is the task switching rate TSW^k. A task switch occurs when a higher priority task becomes ready to use the CPU. For the above models, we have for TSW^1 and TSW^3:

$$\delta_a(P_{bxxa} + P_{cxba} + P_{bxca}) + \delta_b P_{cxab}$$

and for TSW^2 and TSW^4:

$$\delta_a(P_{bxxa} + P_{cxba}) + \delta_b P_{cxab}$$

Note that although the method of calculation may be the same, the results will differ because of different valued state probabilities. The TSW^k give an indication of the operating system overhead due to task switching. Naturally, the lower the value the lower the overhead. Similar overhead measures can be obtained for wait list positioning using a priority scheme.

HETM STABILITY CONDITION

At each HASP interval, HETM rearranges the subset of the OS dispatching chain constituted by an installation spec-

ified dynamic priority group. Tasks are ranked in inverse order of their CPU utilization histories. Equation (1) is used to determine the CPU utilization history $h_{t,n}$ of the nth task at HASP interval t.

$$h_{t,n}=\text{cpu}_{t,n}+h_{t-1,n}-H_t/N \tag{1}$$

N is the number of tasks in the dynamic priority group, $\text{cpu}_{t,n}$ is the CPU counts observed for the nth task during the tth HASP interval, and $H_t=\sum_{i=1}^{N}(\text{cpu}_{t,i}+h_{t-1,i})$.

Adopting the notational conventions of Reference 2:

$$\underline{h}_t=\begin{bmatrix} h_{t_d} \\ h_{t,\beta} \\ h_{t,\gamma} \end{bmatrix}, \quad C_t=\begin{bmatrix} \text{cpu}_{t,\alpha} \\ \text{cpu}_{t,\beta} \\ \text{cpu}_{t,\gamma} \end{bmatrix} \tag{2}$$

equation (1) can be rewritten for the three job model as:

$$\underline{h}_t=A(\underline{h}_{t-1}+C_t) \tag{3}$$

where

$$A=\frac{1}{3}\begin{bmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{bmatrix}$$

Strauss[1] gives the solution to (3) as:

$$\underline{h}_t=A\left(\sum_{j=1}^{t} C_j+h_0\right) \tag{4}$$

For a simple stable mapping (i.e. the mapping for the next HASP interval is the same as the previous) with $\underline{h}_0=0$, equation (4) reduces to

$$\underline{h}_t=tAC \tag{5}$$

where C is the CPU utilization vector associated with the repeating mapping.

For higher order repeating mapping patterns, Strauss[1] determines that if h_t is to repeat every $R>1$ control intervals, then h_{mR} must equal h_{nR} for all integers m and n. Thus from (4):

$$\underline{h}_{mR}=A\left(\sum_{j=(m-1)R+1}^{mR} C_j\right)+\underline{h}_{(m-1)R} \tag{6}$$

Clearly, for h_{mR} to equal $h_{(m-1)R}$ (and thus repeat the mapping pattern), we must have

$$A\left(\sum_{j=(m-1)R+1}^{mR} C_j\right)=0.$$

Since A is idempotent, the vector C^R of (7) must have equal components.

$$C^R=\begin{bmatrix} \text{cpu}_\alpha{}^R \\ \text{cpu}_\beta{}^R \\ \text{cpu}_\gamma{}^R \end{bmatrix}=\sum_{j=1}^{R} C_j \tag{7}$$

To relax the requirement that C^R have equal components consider the following. Let s_1, s_2, s_3 and s_1', s_2', s_3' be mutations of α, β, γ such that the mappings generated by $\underline{h}_t$ and $\underline{h}_{t'}$ $(t\neq t')$ imply $h_{t,s_1}\leq h_{t,s_2}\leq h_{t,s_3}$ and $h_{t',s_1'}\leq h_{t',s_2'}\leq h_{t',s_3'}$. Define $\underline{h}_t\sim\underline{h}_{t'}$ if and only if $s_1=s_1'$, $s_2=s_2'$, and $s_3=s_3'$. Then $\sim$ is an equivalence relation.

Let E be the equivalence class formed by $\underline{h}_{(m-1)R}$ (i.e. if $W=\{\underline{h}_t \mid t>0\}$, then $E=\{\underline{h}_t\epsilon W \mid \underline{h}_{(m-1)R}\sim\underline{h}_t\}$). Deriving a stability condition requires that $\underline{h}_{mR}\sim\underline{h}_{(m-1)R}$. In order to have $\underline{h}_{mR}\epsilon E$, we must have some permutation s_1, s_2, s_3 of α, β, γ such that

$$h_{mR,s_1}\leq h_{mR,s_2}\leq h_{mR,s_3} \tag{8}$$

and

$$h_{(m-1)R,s_1}\leq h_{(m-1)R,s_2}\leq h_{(m-1)R,s_3} \tag{9}$$

Thus, if we let k_1, k_2, k_3 be the permutation of 1, 2, 3 for the mapping s_1, s_2, s_3 corresponding to the α, β, γ index of h_t, from (8) we get:

$$\begin{aligned} A_{k_1}{}^*C^R+h_{(m-1)R,s_1}\leq A_{k_2}{}^*C^R \\ +\underline{h}_{(m-1)R,s_2}\leq A_{k_3}{}^*C^R+\underline{h}_{(m-1)R,s_3} \end{aligned} \tag{10}$$

where $A_i{}^*$ denotes the ith row vector of A. Using (9), we may guarantee (10) if

$$A_{k_1}{}^*C^R\leq A_{k_2}{}^*C^R\leq A_{k_3}{}^*C^R.$$

Adding $1/3(\text{cpu}_\alpha{}^R+\text{cpu}_\beta{}^R+\text{cpu}_\gamma{}^R)$ to each term yields

$$\text{cpu}_{s_1}{}^R\leq\text{cpu}_{s_2}{}^R\leq\text{cpu}_{s_3}{}^R.$$

We assume in the above discussion that equal history values imply that α precedes β which precedes γ.

PERFORMANCE COMPARISONS

This section discusses the relative performances of the five wait list positioning policies. The models presented in an earlier section were solved for the two sets of μ_i and δ_i presented in Table I.[1,2] These parameters are both interesting and representative. The μ_i and δ_i of Example 1 were derived by fitting the model to an OS/MFT system operating under HASP. Example 2 parameters are presented in Reference 1 and it can be seen that α is a light CPU, heavy I/O task; β is a moderate CPU, light I/O task; and γ is a heavy CPU, moderate I/O task. It should be noted that since the balance equations are homogeneous, a given set of utilizations can result from an infinite set of service rates. The relative values of the service rates are therefore important, and representative values such as those in Example 2 may be used.

The model predictions for all possible mappings using the parameters of Table I are presented in Tables II-VI for Example 1, and Tables VII-XI for Example 2. Using the derived stability condition, the different wait list positioning models were examined for stable mapping patterns through simple simulation. For Example 1, #4 appears to be a first order stable mapping when limiting on the history values[1] is imposed. For Example 2, #1 is a first order stable mapping. The model predictions are compared using these two stable mappings.

Clearly, with both sets of data and under all positioning policies, total PP utilization does not significantly vary. This results from the PP device not being preemptable. However, total CPU utilization fluctuates significantly, most noticea-

bly in Example 1. For this case, the *c* task spends more time in the wait list under priority positioning and total system utilization is lowest, but throughput is maximized. Situated there, the *c* task cannot get to the CPU, thereby lowering total CPU utilization. Likewise, since both the *a* and *b* tasks position ahead of it in the wait list and given that their CPU use is comparatively light, their throughput jumps, raising overall system throughput. Obviously, *a* and *b* task turnaround time decreases while the *c* task's increases. Furthermore, task switching overhead drops under priority positioning. Again, this occurs since the *c* task is in the PP wait list a larger percentage of the time.

Over the range of μ_i to δ_i, with equal job class characteristics, the *a* task will have better CPU and PP utilization under priority wait list positioning. This results in a lower response time and increased throughput. The same holds true for the *c* task under inverse priority positioning. Under priority positioning, the *c* task will always suffer greater response time and less throughput as does the *a* task under inverse positioning. This can be observed in Figures 2 and 3.

These results suggest a desirable scheduling strategy for either CPU bound systems, or more likely, batch systems supporting an interactive computing load. Faster turnaround will result for the high priority interactive requests at the expense of lower priority (batch) jobs. This is especially true

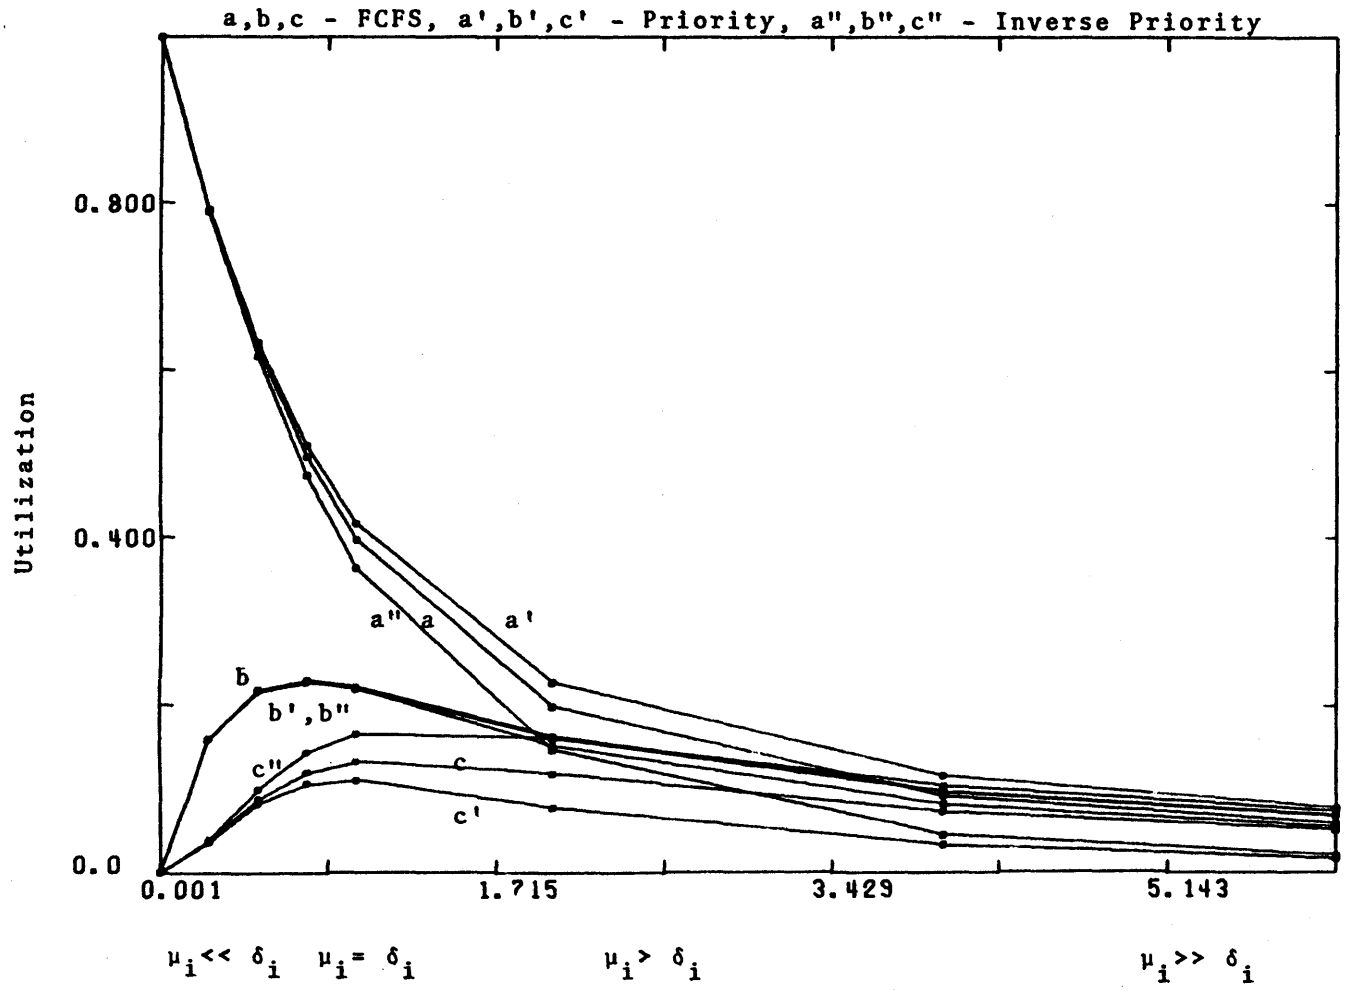

Figure 2—CPU utilization with equal job class characteristics over the range of service rates

for OS since it was not initially designed to support conversational systems.

When priority wait list positioning is utilized under OS with HASP, a curiosity develops. At the time a task is created, OS assigns it a dispatching priority. At the University of Texas Regional Computer Center all batch job tasks are created with the same dispatching priority. Since HETM does not alter the dispatching priority when it rearranges the TCB chain and the I/O Supervisor makes use of it to determine queue position, then, in effect, random I/O scheduling occurs. Moreover, even if different priority values were assigned (or changed through the CHAP macro), I/O scheduling would not always reflect HETM's current arrangement of the TCB chain. In essence, this is a HETM shortcoming. The TCB chain ordering represents the most recent information regarding task characteristics, which are known to change dramatically during execution. By not updating dispatching priorities to coincide with the TCB chain ordering, under priority wait list positioning HETM is ignoring an aspect of the problem it was intended to solve.

With inverse dispatching priority positioning, it can be observed that neither *a* nor *b* task throughput is adversely affected. As one would expect, CPU utilization increases with this positioning policy. This results because the CPU bound job (α) is assigned to the *c* task. Given that PP use remains relatively unchanged, total system utilization will tend to maximize under this policy. This can be seen in the two examples. Also, observe that a more balanced cycling rate is a consequence. Inasmuch as the outcomes of this policy are not calamitous for the *a* task, systems with an under utilized CPU may find this scheduling strategy attractive. The model also predicts, however, an increase in operating system overhead due to task switching.

Though inferences concerning real system performance are being made, it would be inappropriate to cite percentage changes in the models' predicted utilizations. This would attach an unsupported significance to the model results. This kind of observation can only be made in a specific situation using a perhaps more detailed model (one with additional PP devices and more job classes) with fitted service rates. Four job models were formulated and solved using representative service rates and the above observations remain true with

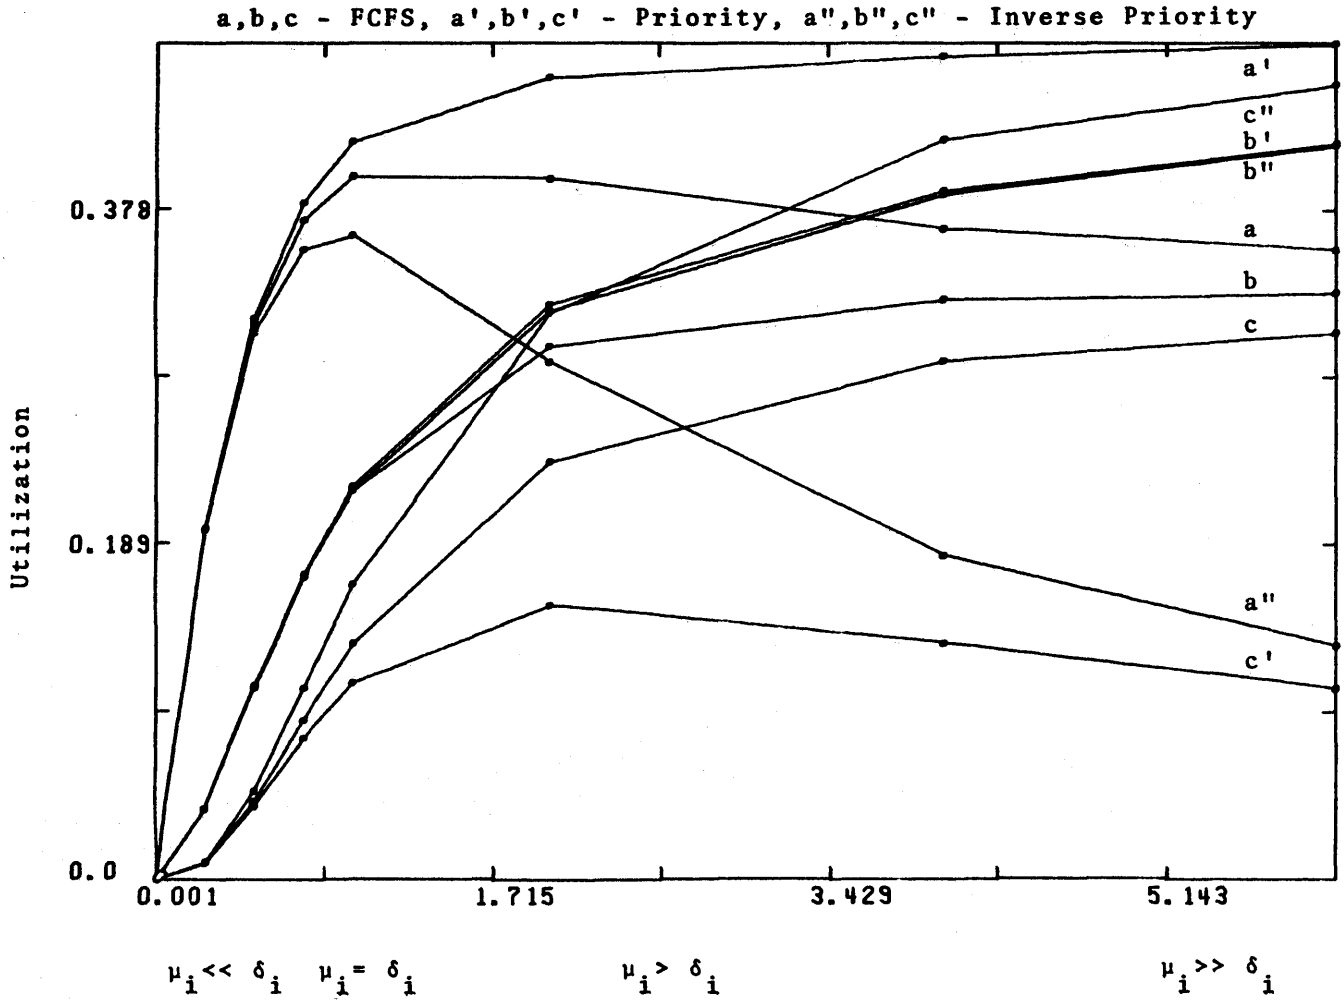

Figure 3—PP utilization with equal job class characteristics over the range of service rates

marked changes in the percentage differences of the predicted utilizations. The details of these models are not presented.

CONCLUSIONS

Five peripheral processor wait list positioning policies are presented. Relative performances are compared using a simple analytical model of a multiprogramming system with preemptive priority CPU dispatching on different classes of jobs.

Using fitted[2] service rates, priority wait list positioning was found to maximize throughput while minimizing total system utilization. High priority jobs receive better throughput and decreased response time. On the other hand, inverse dispatching priority positioning tends to maximize total system utilization and is not ruinous to high priority job response.

INTRODUCTION

This paper presents the design philosophy used in the BEST/1 computer performance evaluator. Essentially, BEST/1 is a modeling tool which has been developed to address the "what if" questions that arise when evaluating computer system performance. These questions are of importance in such areas as capacity planning, performance tuning, hardware vendor selection and new system design.

From a design standpoint, the most significant features of BEST/1 are those which relate to ease of use. The following five objectives were considered most essential in this regard:

- The analyst who is familiar with the basic terms and concepts of computer performance evaluation should require no special training in order to use BEST/1. That is, the internal algorithms and procedures used by BEST/1 should be insulated from the user to the maximum extent possible.
- The level of effort required to set up and evaluate a BEST/1 model should be commensurate with the analyst's objectives. First order models should be easy to set up and evaluate, with more refined models requiring progressively more effort in terms of data collection and analysis.
- The input data required by BEST/1 should be easy to understand and obtain. Detailed measurements of internal system activity should not be necessary when studying simple questions.
- BEST/1 should operate interactively so that an analyst can have the benefit of working through a problem and exploring a number of related "what if" questions during a single analysis session. The speed requirements associated with interactive operation are also important in sensitivity studies where a wide range of parameter settings have to be explored.
- BEST/1 should generate a set of output reports which are easy to understand and apply.

In order to achieve these objectives, the BEST/1 design is based on an approach which is commonly employed in applications-oriented higher level languages. That is, a user visible front end has been developed which enables analysts to specify models and carry out analyses using concepts and terms which are generally familiar to individuals working in the area of computer performance evaluation. This user visible front end is then automatically translated into an internal BEST/1 analysis model which is insulated from the user in much the same way as machine language programs are insulated from the user of any higher level language. Thus, the most important design features of BEST/1 are those which relate to its user visible front end. These features are discussed in detail in the remainder of this paper.

It should be noted that, in order to meet the objective of interactive operation, the internal BEST/1 analysis models are based on extensions to the theory of multiple class queueing network models. However, the BEST/1 user need not be concerned with the mathematical details of this theory, just as the user of an applications-oriented higher level language need not be concerned with the details of a particular machine language. For this reason, the mathematical foundations of BEST/1 will not be emphasized in this paper. For discussions of the theory, see the references listed in the bibliography.

BEST/1 MODELING CONCEPTS

BEST/1 is an analysis tool which is capable of calculating the performance of almost any computer system on the basis of parameters which characterize that system's hardware, software, and workload. The performance factors which are calculated by BEST/1 include throughput, response time, queue length, processor utilization, and so on. See Figure 1.

The performance calculation function performed by BEST/1 is similar to the function performed by a benchmark experiment. That is, a BEST/1 analysis and a benchmark experiment both enable the analyst to evaluate the way a computer system will perform under a specific set of conditions. However, in the case of a benchmark experiment

* Currently affiliated with Booz, Allen Hamilton, Inc., Los Angeles, California
** Currently affiliated with IBM Corporation, San Jose, California

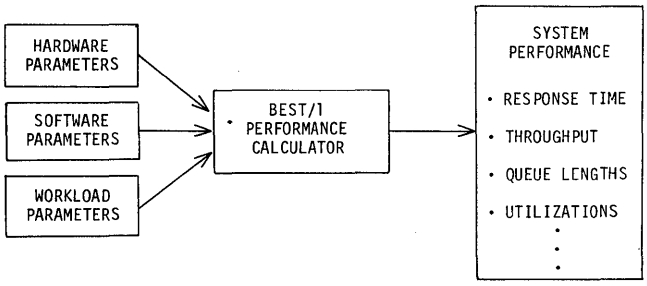

Figure 1—Basic BEST/1 functionality

this evaluation is made by running a set of programs on an actual system. In contrast, BEST/1 makes this evaluation on the basis of certain numerical parameters which are either measured directly or estimated by the analyst.

THE WORKLOAD CONCEPT

As illustrated in Figure 2, BEST/1 is based on the concept that performance issues arise when workloads of various types are processed by a computer system. In this context, the term "workload" refers to a stream of jobs or transactions arriving at a computer system from some external source. For example, a stream of batch jobs submitted by local or remote users could constitute a batch workload, a stream of transactions generated by time sharing terminals could constitute a time sharing workload, and so on.

The significance of the workload concept lies in the fact that analysts are usually most concerned with performance factors which are defined on a "per workload" basis. This is because users normally perceive throughput and response time as being associated with individual workloads rather than with the system as a whole. In fact, it is generally meaningless to discuss throughput or response for an entire system in cases where several workloads are present.

BEST/1 explicitly recognizes the central importance of workloads and uses the workload concept as a focal point for developing system models and organizing input parameters. In particular, BEST/1 allows the analyst to specify a model in terms of certain generic workload types. Each workload type has an associated set of parameters which characterize the special features of that workload. The three principal workload types recognized by BEST/1 are discussed below.

TIME SHARING WORKLOADS

The general nature of interactive or time sharing workloads is illustrated in Figure 3. Essentially, each time sharing workload is associated with a set of terminals. The users at the terminals are assumed to generate transactions which arrive at the system and undergo processing. When a transaction has been completed, a response is printed on the user's terminal. The user then generates a new transaction and the cycle repeats.

Figure 2—The workload concept

In the case of time sharing workloads, the analyst specifies the number of terminals and the average "think time" (i.e., the average time between the system's response to a given transaction and the user's initiation of the next transaction). The principal performance factors calculated by BEST/1 for these workloads are the response time per transaction and the throughput rate in transactions per hour.

TRANSACTION PROCESSING WORKLOADS

Transaction processing workloads are similar to interactive workloads in that the external load is assumed to be generated by users at terminals. However, instead of specifying the external load in terms of number of terminals and think time, the analyst simply specifies a total arrival rate in "transactions per hour" as illustrated in Figure 4. Most analysts find it convenient to characterize transaction processing workloads in this manner.

Since the arrival rate is specified as an input parameter, and since throughput is equal to arrival rate (as long as system capacity is not exceeded), the most important performance value computed by BEST/1 for transaction processing workloads is the response time. BEST/1 also calculates the maximum attainable throughput rate in cases where this value is less than the arrival rate specified in the input file.

BATCH PROCESSING WORKLOADS

In the case of batch processing workloads, analysts are usually most interested in system performance during time periods when the input queues are backlogged (i.e., when

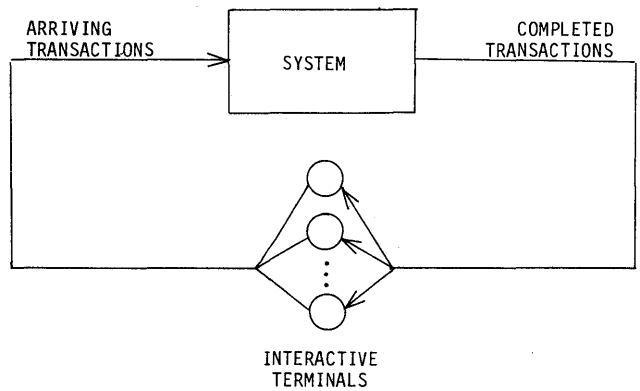

Figure 3—Time sharing workloads

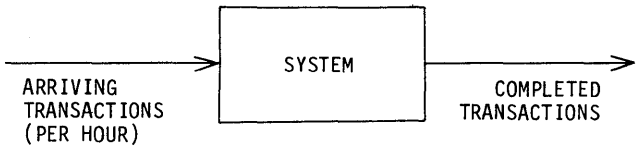

Figure 4—Transaction processing workloads

there is always at least one job waiting to be loaded into main memory). BEST/1 enables the analyst to specify batch workloads which have this "backlog" property. Schematically, these workloads are represented as shown in Figure 5. The closed loop in this figure indicates that, in a backlog situation, new jobs are loaded into main memory whenever an active job completes and memory space becomes available. Both throughput and response time (turnaround time) are computed for these workloads.

TOTAL NUMBER OF WORKLOADS

The total number of workloads which may be included in a single BEST/1 model is not limited to three. For example, a single BEST/1 model could include two transaction processing workloads, three batch processing workloads, and two time sharing workloads. Alternatively, a model could consist solely of one time sharing, one batch processing, or one transaction processing workload. In Release 4.0 the total number of workloads which may be included in a single BEST/1 model is equal to 9.

JOBS AND TRANSACTIONS

Each of the basic workload types discussed above makes use of the concept of a "job" or a "transaction". Essentially, these terms both refer to a unit of work which arrives at a system from an external source, undergoes a certain amount of processing, and is eventually completed. Throughput is expressed in jobs or transactions per hour, and response time (or turnaround time) is expressed on a per job or per transaction basis.

It is clear that the terms job and transaction refer to the same essential concept; however, the former term is more commonly used for batch processing workloads, whereas the latter is more common in the case of time sharing and transaction processing. In the following discussion of BEST/1, the two terms will be regarded as being interchangeable. However, the term "transaction" will be favored in most cases and should be understood to refer to either a batch job or an on-line transaction.

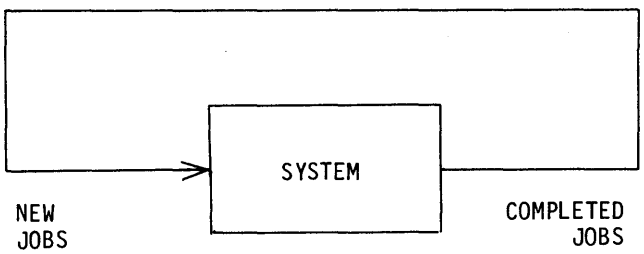

Figure 5—Batch processing workloads

SPECIAL WORKLOADS

By suitable selection and adjustment of parameters, the three basic workload types defined above can be used to represent a number of special workloads which are of importance in evaluating particular systems. These workloads include periodic real time requests, system overhead activities, and job streams with deadlines and critical paths.

TREATMENT OF MULTIPROGRAMMING

Figures 3-5 utilize a single box (SYSTEM) to represent the location of a transaction from the instant it arrives at a system to the instant it departs. The activity which takes place between these two points is described in greater detail in Figure 6.

The interpretation of Figure 6 is straightforward. Small rectangles indicate the locations of queues, and circles represent servers such as CPU's or I/O devices. As indicated in the diagram, an arriving transaction may at first have to wait in the memory queue until space becomes available. Once it is loaded into memory, the transaction is placed in the CPU queue where it waits until a processor becomes available. The transaction then receives a burst of CPU processing which terminates when an I/O request is generated. At this point, the transaction proceeds to the appropriate I/O device queue. When it reaches the head of the queue associated with that device, an I/O transfer is initiated. Upon completing this transfer, the transaction returns to the CPU queue. The alternating cycle of CPU bursts and I/O transfers continues until the processing requirements of the transaction are satisfied. The transaction then terminates and leaves the system via the "COMPLETED TRANSACTIONS" arrow.

BEST/1 enables the analyst to represent cases where several transactions are in main memory and active at the same

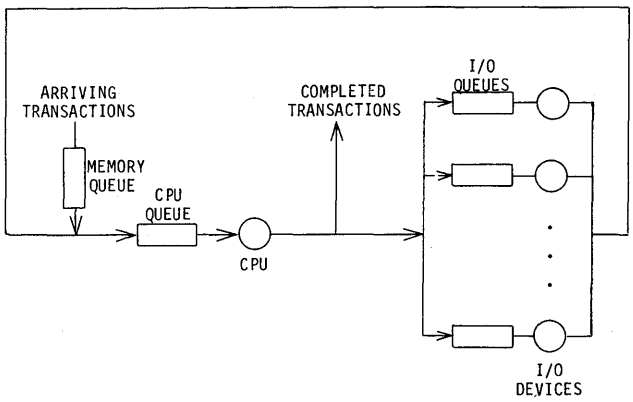

Figure 6—Multiprogramming activity

time. One transaction may be using the CPU while another is using an I/O device. Similarly, several I/O devices may be providing service to several different transactions at the same time.

This overlap of processing activity—which is generated by several transactions that are sharing the main memory of a single computer system—is generally referred to as multiprogramming. Multiprogramming tends to raise the utilization of system resources and thereby improve certain measures of overall performance. However, the queueing delays associated with multiprogramming can have an adverse effect on other measures of system performance. BEST/1 has the ability to explicitly represent the multiprogramming activity described above, and the analyst can use BEST/1 to determine the effectiveness of multiprogramming in various applications.

THE SERVER CONCEPT

As discussed in the preceding section, a job or transaction which has arrived at a system and has been loaded into main memory spends its time alternating between the following two states:

- Using active processing resources such as CPU's and I/O devices
- Waiting to use such resources

In the context of BEST/1, active processing resources are referred to as servers. That is, servers are points within a system where queues can form and where processing can be carried out. Each circle in Figure 6 corresponds to a different server.

One of the most important aspects of Figure 6 is the assumption that each server in the network is capable of independent operation. That is, it is assumed that the CPU can be processing one request at the same time that an I/O server is processing another request. Likewise, it is assumed that two or more I/O servers can be processing requests at the same time.

The assumption of simultaneous processing capability plays a critical role when the real I/O devices in a computer system are mapped into BEST/1 servers. For example, in the case of a string of high speed magnetic tape drives connected to a single controller and channel, it is only possible for one device to be actively transferring data at any time. Hence the entire string of tape drives should be represented as a single I/O server in Figure 6. On the other hand, if each tape drive were connected to a dedicated channel and controller, simultaneous operation would be possible and each device would be represented as a separate I/O server.

The issues that arise when representing disks and drums are somewhat more complex. In virtually all modern disk drives and controllers, seek overlap is possible. This means that any number of disks can be carrying out independent seek operations at the same time. Simultaneous overlap of the rotational latency time is also possible for disks and drums which employ rotational position sensing (RPS). However, the number of actual data transfers which can take place at the same time is limited to the number of parallel I/O channels that are connected to a particular controller and string of devices.

In cases such as these it is preferable to represent each disk and drum as a separate I/O server within BEST/1. That is, each disk and drum is assumed to be capable of independent simultaneous operation. The service time at each device must then be adjusted to account for the additional delays that arise because of channel contention. For example, disk service time—which is normally the sum of seek, rotational latency, and data transfer time—must be increased so that it becomes the sum of seek, rotational latency, data transfer, and channel queueing time. The increased service time represents a real effect since measurement devices would actually record the disk as being busy during channel queueing time.

BEST/1 provides facilities for calculating the amount of channel queueing that will arise within a particular configuration, and for automatically increasing I/O service times accordingly. Thus, channel contention is accounted for even though channels are not explicitly shown in Figure 6.

THE DOMAIN CONCEPT

As illustrated in Figure 7 the three principal components of a BEST/1 model are a set of workloads, a set of servers, and a set of memory domains. Essentially, memory domains are mechanisms for controlling the sharing of memory among various workloads. All multiple workload systems incorporate some mechanism of this type to prevent one or two workloads from monopolizing main memory in an uncontrolled manner. For example, time sharing transactions may be assigned to a domain with a maximum multiprogramming level of 5 while batch jobs are assigned to a domain with a maximum multiprogramming level of 7. This means that no more than 5 time sharing transactions and 7 batch jobs would be allowed to enter main memory at a

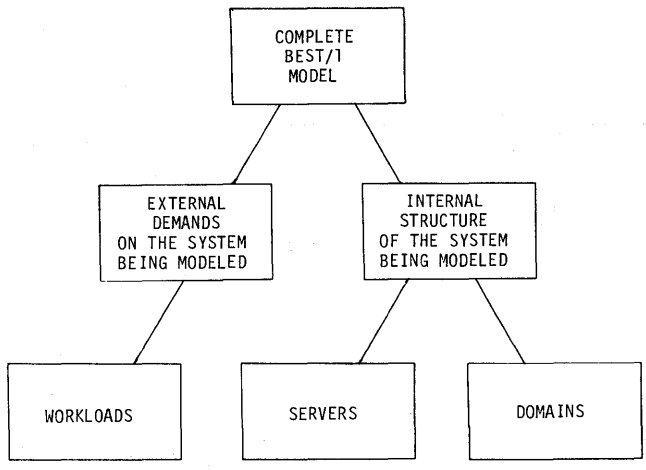

Figure 7—Components of a BEST/1 model

single time. Terms such as "partition", "region" and "initiator" are used in different operating systems to refer to the concepts of multiprogramming level and domain.

The specific mechanisms used to implement the memory domain concept vary somewhat from one system to another. BEST/1 allows a wide range of mechanisms to be modeled. Essentially, the analyst can characterize domains in terms of their maximum multiprogramming levels, their average multiprogramming levels, or in terms of certain distributions.

Note that memory domains are closely associated with workloads. In particular, each workload must be assigned to some domain. BEST/1 permits several workloads to be assigned to the same domain; alternatively, each workload may be assigned to a separate domain if desired.

As a final point, it should be clear from the preceding discussion that the memory queue shown in Figure 6 actually represents a set of queues, one corresponding to each domain. BEST/1 treats the queues separately, and values such as queue length and waiting time are computed individually for each memory queue.

BEST/1 INPUT PARAMETERS

Figure 8 presents an example of all the input data needed by BEST/1 for a typical application. In this case, the system being evaluated is processing three workloads: Workload 1 represents a stream of batch processing jobs, Workload 2 represents a transaction processing application, and Workload 3 represents the load generated by a set of time sharing users.

The BEST/1 input parameters used to characterize this application are grouped together on a "per workload" basis. For each workload, there are a set of workload descriptors and a set of service requirements. These two sets of parameters are discussed below.

WORKLOAD DESCRIPTORS

The workload descriptors in Figure 8 are used to specify the following information:

- The workload type: batch processing (BP), time sharing (TS), or transaction processing (TP)
- A label used to identify the workload on output reports
- Information about the multiprogramming level of the domain which is associated with the workload
- For time sharing and transaction processing workloads, information about the external factors which generate arriving transactions

In all cases, the first workload descriptor in the formatted BEST/1 input file contains the workload type and the workload label. The second descriptor characterizes the multiprogramming level of the workload's domain. For Workload 1, the average multiprogramming level attained during times when there is a backlog in the input queue is specified as

```

Figure 8—Basic input file

3.8. Workloads 2 and 3 are assigned maximum multiprogramming levels of 4 and 6 respectively.

Additional descriptors are used in Workloads 2 and 3 to characterize the external factors which generate arriving transactions. For Workload 2, these factors are characterized by specifying an average arrival rate of 4000 transactions per hour. For Workload 3, the external factors are specified as 30 terminals with average think times of 25 seconds.

SERVICE REQUIREMENTS

The second set of input parameters that are provided for each workload are referred to as the workload's service requirements. Essentially, these parameters specify the total amount of service time that is required, per transaction, at each server in the system. For example, each Workload 1 transaction (i.e., each batch job) requires an average of 13000 msec of processing at Server 1 (the CPU), 1099 msec of processing at Server 2 (Drum 1), 1940 msec of processing at Server 3 (Drum 2), and so on. The service requirements per transaction are specified separately for each workload as indicated in Figure 8.

Note that the service requirements in Figure 8 refer only to the time that a transaction spends actually using a server. The time spent waiting in a queue before reaching the server is not included in the input data, but is instead computed by BEST/1 and used to generate output reports.

EXTENDED EXAMPLE

BEST/1 enables the analyst to extend the basic system description of Figure 8 in a number of ways. These extensions are introduced by associating additional descriptors with each workload, and also by adding certain "special server parameters" to the end of the input file. Figure 9 provides an indication of the range of extensions which are available to the analyst.

Figure 9—Extended input file

WORKLOAD DIFFERENTIATION

The most obvious difference between Figure 8 and Figure 9 is the fact that a fourth workload has been added. In this particular case, the additional workload is not intended to represent a new application being added to the system, although additional workloads could obviously be used for such purposes. Rather the new workload represents a more detailed model of the same system represented in Figure 8.

In the case of Figure 8 the transaction processing application is represented, using Workload 2, as a single input stream arriving at a rate of 4000 transactions per hour. BEST/1 will treat this workload as a single entity and will report response time, queue length, and other performance values for the workload as a whole.

Suppose, however, that the analyst now wishes to explicitly represent the fact that 80 percent of the Workload 2 input stream corresponds to data base inquiry transactions, and 20 percent corresponds to data base update transactions. In other words, suppose the analyst wishes to obtain separate performance values for each of the two transaction types.

In this case the analyst can use two separate workloads to represent the transaction processing application. As illustrated in Figure 9, Workload 2 is now used to represent the data base inquiry transactions. The arrival rate is set to 3200 transactions per hour (80 percent of 4000), and the service requirements are explicitly shown. In addition, Workload 4 is now used to represent the data base update transactions. The arrival rate is 800 transactions, and a different set of service requirements are provided. BEST/1 will then be able to compute response time, throughput, and other performance values for each transaction type.

LEVELS OF DETAIL

It should be emphasized at this point that the model represented by Figure 9 is not intrinsically "more correct" than the model represented by Figure 8. Both are "correct" in the sense that they both enable the analyst to investigate a certain set of questions concerning the performance of a real system. Since the model associated with Figure 9 is more detailed, a more detailed set of questions can be studied. However, the analyst is required to provide a more detailed set of input data in this case: specifically, the separate service requirements for each of the two transaction types.

Because of the ease with which the level of detail can be altered, BEST/1 enables the analyst to select an initial level of detail, run through a number of cases, and then increase the level of detail if necessary for those cases which warrant further analysis.

The ability to adjust the level of detail in a BEST/1 analysis is also important in applications involving capacity planning, design of new systems, and other situations where performance prediction is involved. In these cases the information available to the analyst tends to become more and more detailed as time progresses. BEST/1 thus enables the analyst to use the most detailed model that is feasible at each stage, and to increase the detail in the model as more refined information becomes available.

SHARED DOMAINS

Another important extension of Figure 8 which is illustrated in Figure 9 is the concept of the shared domain. It is implicitly assumed that each workload in Figure 8 has a separate domain and a separate memory queue. However, this is not the case for Workloads 2 and 4 in Figure 9. Rather, these two workloads are assumed to compete for the single domain which was assigned to Workload 2 in Figure 8.

The concept of two workloads sharing a single domain is easy to represent in BEST/1. As illustrated in Figure 9, this is done by placing a domain identifier rather than a multiprogramming level in the descriptors of Workloads 2 and 4. A separate domain descriptor is then added to the end of the input file to indicate the multiprogramming level associated with that shared domain. This is shown in Figure 9.

Note that the analyst is not required to use a shared domain in this case. For example, Workload 2 could have been assigned a maximum multiprogramming level of 3, and Workload 4 could have been assigned a maximum multiprogramming level of 1. This corresponds to a situation where each workload has a separate domain. BEST/1 will, of course, calculate a different set of performance values in this case. The analyst can then determine which memory allocation strategy is most appropriate in terms of the performance objectives of the original system.

PRIORITIES

BEST/1 permits the analyst to associate a CPU dispatching priority with each workload. In the case of Figure 8 no priorities were specified so BEST/1 assigned the same default priority to all workloads. Figure 9 illustrates the way priorities are added to the workload descriptors. As indicated in the figure, the transaction processing workloads have highest priority, the time sharing workload has intermediate priority, and the batch processing workload has lowest priority.

In cases where priorities are specified, BEST/1 uses the conventional "preemptive-resume" dispatching algorithm found in most operating systems. In other words, a high priority request which arrives at the CPU interrupts and preempts any lower priority requests that may be present. Lower priority requests resume processing from the point of preemption after higher priority requests release the CPU.

MULTIPROCESSORS

BEST/1 input files sometimes include "special server parameters" which refer to the servers within the system rather than individual workloads. The number of CPU's in a multiprocessor configuration is such a parameter. Figure

GENERATION OF OUTPUT REPORTS

Once a particular set of input data has been specified, the BEST/1 user may request an evaluation. This will cause BEST/1 to analyze the data and generate the "Principal Results" report. After examining this report, the analyst may request one or more additional reports.

BEST/1 generates a number of different reports which provide detailed information about the performance of the system being evaluated. The report titles are listed in Figure 10.

PRINCIPAL RESULTS

Figure 11 illustrates the Principal Results report generated by BEST/1 from the input data shown in Figure 8. This report is organized by workload. For each workload, the report indicates the average response time per transactions, the average throughput in transactions per hour, and the CPU utilization associated with that workload. Total CPU utilization is also reported.

For example, in Figure 11 the batch processing throughput is 102 jobs per hour and the response times for transaction processing and time sharing are 3.17 seconds and 3.31 seconds respectively.

RESPONSE TIME PROFILE

Figure 12 illustrates the Response Time Profile report generated by BEST/1 from the input data shown in Figure 8. Essentially, this report gives the analyst a breakdown of the response time values that appear in the Principal Results report. That is, this report gives the response time, in milliseconds, at each server in the system. By adding up these individual response times, the total response time per transaction is obtained.

Note that main memory is represented in this report by "Server O". Thus, the response time at Server O corresponds to the delay a transaction experiences before being loaded into its memory domain. This delay only arises when the number of transactions at the system (for a given workload) exceeds the maximum multiprogramming level of the domain associated with that workload.

The Response Time Profile is particularly useful when it is necessary to determine why a workload's response time value is so high, and how important each server and queue really is insofar as overall response time is concerned.

INTERACTIVE DIALOG

The primary mode of operation for BEST/1 is through interactive time sharing terminals. When operating in this mode, the analyst has access to a variety of functions. These functions are requested through an interactive dialog that has been extensively refined and enhanced during several years of actual use.

The complete interactive dialog is specified in the BEST/1 User's Guide. Some typical functions which are easy to carry out using the dialog are listed below:

- Add servers or workloads
- Change server speed
- Change arrival rate, number of terminals, CPU dispatching priority, multiprogramming level, etc.
- Request one or more optional reports
- Save an input file for future use
- Direct output to any desired device
- Execute a pre-defined set of interactive commands stored in a file

It should be emphasized that this is only a partial list of the functionality available to the BEST/1 user.

In all cases, the interactive dialog has been structured using concepts that can be easily and directly understood by

the computer performance analyst. Knowledge of the underlying mathematical theory is not required to set up BEST/1 models or exercise the interactive dialog.

SUBROUTINE INTERFACE

Users are sometimes interested in carrying out complex iterative analysis procedures which repeatedly invoke BEST/1. For example, a user may wish to increase a workload's arrival rate until the resulting response time reaches some threshold.

Some cases can, of course, be treated using the BEST/1 interactive dialog. However, it is sometimes preferable to simply write a program which repeatedly calls BEST/1, analyzes the output, and adjusts certain BEST/1 input parameters until a condition has been satisfied or a set of cases has been examined.

In order to facilitate this process, there is a special interface which allows BEST/1 to be called as a subroutine by a FORTRAN program. The FORTRAN program can then be executed interactively or in batch processing mode.

ACKNOWLEDGMENTS

Special thanks are due to Professors Peter J. Denning and Stuart E. Madnick and to Dr. Gary Sockut for their helpful suggestions and comments regarding the design of BEST/1.

Job scripts—A workload description based on system event data*

by ROBERT L. MEAD and HERBERT D. SCHWETMAN
Purdue University
West Lafayette, Indiana

INTRODUCTION

Job scripts, a detailed description of a job's resource demands, can serve not only as input for a simulation model, but as a representation of the system's workload as well. Heretofore, most representation efforts have dealt with either benchmark or synthetic job techniques. This paper presents a workload representation based on a set of job scripts, each representing a single job in the workload, that is designed for use with simulation models. This representation differs from the synthetic job approach in the form of the representation, the intended usage, and the level of detailed involved. The scripts have been used as input for a trace-driven simulation model of the CDC6500 system at Purdue University and have also been used to increase the understanding of the execution time characteristics of programs.

The accurate representation of the workload is an important problem in the modeling and evaluation of computer systems. In 1972, Grenander and Tsao[1] stated, "We believe that no real significant advance in the evaluation of systems can be expected until some breakthrough is made in the characterization of the workload." Since that time, advances have been made in understanding program behavior in terms of memory reference behavior,[2–6] and some work has appeared on CPU usage behavior.[7] Job scripts can be used to increase the understanding of how programs utilize CPUs, data channels, and I/O processors. One outgrowth of this investigation has been *activity plots* which depict a program's file and device usage patterns, in much the same way that page reference maps show the pattern of memory demands.

The paper begins by summarizing earlier efforts in workload representation. The form of the job script and the generation techniques are presented. The issues of accuracy and the reproducibility of the job script are discussed, and data is presented to demonstrate that the scripts are reproducible and accurate. The advantages, limitations, and usefulness of job scripts are presented, along with some examples of the activity plots mentioned previously.

PREVIOUS WORK

As early as 1965 it was apparent that carefully choosing a representative workload was important when evaluating a computer system. Joslin[8,9] stressed the importance of knowing the nature of a workload to be represented by a benchmark and demonstrated that the performance of a system could vary depending upon the benchmark chosen. DeMeis and Weizer[10] represented interactive programs with *pseudo-programs* that were built around a loop of clocking instructions. Also in 1969, Buchholz[11] first introduced the idea of a *synthetic program,* a parameterized cyclic program that performed no useful work, but that was designed to consume a desired amount of CPU and I/O time. Wood and Forman[12] used accounting data and the output from a hardware monitor to parameterize synthetic programs in order to test the throughput of IBM 360 configurations. Synthetic programs have also been used in a number of other efforts. Schwetman and Browne[13] used an event driven software monitor to provide parameters for a synthetic job stream generator, and Kernighan and Hamilton[14] successfully used synthetic jobs to represent individual jobs in a standard benchmark. Sreenivasan and Kleinman[15] describe a technique for generating a synthetic workload by matching the joint probability densities of the real and synthetic workloads. Agrawala and Mohr[16] present a general model involving mixture distributions in a chosen n-space, leading to a representation that can be validated statistically. Cohen[17] described a *job catalog* that can be used to describe a benchmark set of programs.

The concept of workload representation in the form of trace data for trace-driven simulation models was proposed by Cheng[18] in 1969. Sherman[19] and Sherman et al.[20] successfully used a trace-driven model to investigate deadlock algorithms and CPU scheduling strategies. A forerunner to the job script was presented by Keim and Schwetman,[21] and was used to produce statistical descriptions of CPU and system routine usage intervals.

THE JOB SCRIPT AS A WORKLOAD REPRESENTATION

The basic concept underlying the job script is that of a *CPU—I/O cycle.* As a job executes, it typically uses the

CPU for a period of time and then requests an I/O operation. At the completion of the I/O operation, or immediately after the issuance of the I/O request in the case of overlapped I/O activity, the CPU is again used until a subsequent I/O request. This pattern of behavior continues until the job completes.

A job script represents this behavior in terms of an extended sequence of alternating CPU intervals and I/O sequences. CPU intervals represent the total amount of CPU time actually consumed between successive I/O requests and the I/O sequences consist of the resource usage intervals involved in I/O operations: I/O processor intervals and data transfer intervals. The total resource usage of a job is thus represented by CPU, I/O processor, and data channel usage intervals. It is important to note that we are *not* dealing with a virtual memory system. The job script representation assumes that all of the memory a job will need at a given time is allocated to the job in a contiguous block. It is possible however, for an executing job to request additional memory, or to release memory (at the end of the block) that is no longer needed.

Additional detail concerning the execution time characteristics of jobs is also included by the insertion of information entries in the script. These entries provide information about the type of I/O operation requested and the associated file name, the number of characters transferred during an I/O operation, the name of the I/O processor routine used, the current amount of memory being held by a job, and the name of the current job step (control card). This combination of resource usage intervals and information entries provides a complete and detailed description of the demands placed on the system by an individual job.

Ideally, the job scripts form a load independent representation, since the time a job spends waiting for resources is eliminated. In practice however, the processing load does affect the length of some resource usage intervals to a small degree, due to such things as varying seek times and rotational delays for disk accesses, and varying amounts of system overhead. The effect of the load on the script, along with the issues of accuracy, reproducibility, and usefulness of job scripts are discussed in subsequent sections of this paper.

The job script approach differs from the synthetic job approach on one key point. The script technique is essentially a bottom-up approach, where every system event of interest is examined in order to create the scripts. This differs from the formation of synthetic jobs where information with little detail (e.g., accounting data) is used as a starting point, and the detail required to make the job realistic is introduced. It is important to note that the data from which the scripts are generated is gathered at the level at which a job interacts with the system. This implies that, as long as we restrict ourselves to monitoring techniques that are external to the job itself, we cannot increase the level of detail included in the representation.

JOB SCRIPT GENERATION

The generation of the job scripts involves the use of a software monitor and two analysis programs. A software system monitor first collects event data while the system is in operation. The event data is processed to produce a temporary file consisting of all requests, assignments, and releases of system resources for each job, plus all of the additional information to be included in the job script. The temporary file is processed to eliminate all queueing delays experienced by each job and to remove any activity solely concerned with load dependent activities. In the system being studied, it is possible for a job to be preempted from memory prior to completion and then to be returned to memory at a later time. Since we are not dealing with a virtual memory system, when a job is to be preempted from memory, it is necessary to save the contents of the job's entire memory allocation, plus the contents of all hardware registers associated with the job. Thus both the preemption and subsequent resumption require I/O processors and data channels to copy the contents of memory to and from a disk. The number of preemptions incurred by a job depends on the system load, and as such they are not included in the job script. These preemptions and resumptions represent the majority of the load dependent activity eliminated from the job scripts.

It should be noted that the removal of this load dependent behavior does not imply that this activity is ignored in the simulation model driven by the scripts. The activity associated with job preemption and resumption is included in the trace-driven simulation model but is generated from probability distributions when the simulation model decides a job preemption or resumption should take place. The elimination of this load dependent behavior from the script representation thus allows for greater flexibility in the simulation model.

The details of the software monitor can be found in References 22 and 23, and a modified version of the data analyzer described in References 23 and 24 is used to generate the temporary file. The basic problem involved in the reduction of the data on the temporary file is the recognition of the resource usage intervals. This problem is complicated by the presence of overlap between CPU and I/O activity and by the fact that several distinct I/O sequences may be in progress simultaneously. As will be seen in the example below, this implies that the order of the intervals in the job script is not necessarily the order of occurrence during ex-

Event Number	Time	Event	Resource	Event Number	Time	Event	Resource

ecution. Figure 1 contains an example of the event records that might appear in the temporary file for a portion of a job. The job script entries subsequently generated appear in Figure 2. Note that the intervals corresponding to script entries 5, 6, 7, and 8 all occur before the interval corresponding to entry 4. The order in the script does, however, correspond to the sequence that would result if overlap of I/O processors did not take place.

ACCURACY AND REPRODUCIBILITY OF JOB SCRIPTS

In order to be of benefit, the scripts must be shown to be both an accurate and reproducible representation of a job's behavior. The correctness of the script was determined by listing the event records from which the scripts are produced and verifying that the resultant script accurately interprets the event records. Reproducibility is more difficult to verify, mainly because of variation in resource usage that is not under the control of the script generation process. Two major reasons for variations of this nature are varying seek times and rotational delays in data channel intervals and varying amounts of system overhead included in CPU usage.

As the monitor is unable to measure the seek time for disk accesses, the placement of files on the system disks and the load on the system can cause access times to vary greatly for different executions of the same job. This leads to fluctuations in the scripts. Rotational delay times also vary, but over time (assuming we are observing a lengthy job) these variations should tend to average out. In addition, the monitor does not record all CPU changes to supervisor mode, so the length of recorded CPU intervals can vary depending on the amount of system overhead occurring while a job is using the CPU.

To ascertain the degree of variation in the job scripts, four jobs of differing characteristics were each executed four times in a monoprogrammed environment. Scripts were generated for each of these jobs and analyzed using a statistics gathering program. For each job script the following quantities were determined:

(1) memory residency time
(2) adjusted memory residency time (memory residency time minus the time during which only load dependent activity occurred)
(3) total work of the job (CPU, I/O processor, and data channel time)
(4) total CPU time
(5) total I/O processor time
(6) total data channel time
(7) total number of I/O transfer units (1 transfer unit = 640 characters)
(8) total number of I/O sequences

Table I contains the statistics compiled for one copy of each of the four jobs. A maximum relative error for each quantity for each job was determined by using the smallest observed value of each quantity as the correct value. As can be seen from the summary of results in Table II, all of the measured quantities are reasonably consistent, with the exception of the data channel times. This is not surprising, however, due to the problems of seek times and rotational delay discussed above. We have attempted to determine the reason for the rather high degree of variation in the data channel time for job 2 (20.6%), but the difference seems to be caused only by the inherent variation within the system.

It is not usually possible to execute jobs in a monoprogrammed environment, however, so the script must be able to eliminate variation caused by the load in a multiprogrammed environment. To determine the effects of multiprogramming, the same four jobs were executed four times in a multiprogrammed environment. Job scripts were again generated, and the same set of statistics collected. The maximum relative errors determined for the multiprogrammed jobs appear in Table III. Once again most of the measurements are consistent. Memory residency times fluctuate to a greater extent, but the fact that the total work of each job

exhibits a smaller variation (relative to the memory residency times) indicates that a majority of the effects of multiprogramming have been eliminated.

Finally, the job scripts generated in the monoprogrammed and multiprogrammed environments were compared. The average value of each measure for each job was determined in both environments, and the percentage increase caused by the multiprogramming, relative to the monoprogrammed value, was computed (i.e., (multi-mono)/mono). The results of these comparisons appear in Table IV. In addition, the sum of each quantity over all 16 jobs was determined for each environment, and the increase in the multiprogrammed environment determined. These results appear in Table V. It seems reasonable to expect a slight increase in observed resource usage due to increased overhead and seek times in a multiprogrammed environment, and the data confirms this expectation.

Based on the data in Tables II-V, the job scripts appear to be reproducible and relatively insensitive to the load on the system. Those variations that are present seem to be inherent to the system itself, and as such, any workload characterization effort would be unable to prevent such variations from being included in the workload description.

ADVANTAGES AND USES OF THE JOB SCRIPT

The primary advantage of the job script as a workload representation lies with its completeness. The scripts contain a wealth of detail, and they can be analyzed in a number of different ways. File usage patterns can be studied, including the types of operations and the number of characters transferred in each operation. The characteristics of each job step can be investigated by using the job step name entries. Since each resource usage interval is included, the distribution of device service time intervals can be displayed in addition to the determination of the mean and standard deviation of the distributions.

TABLE IV.—Average Percentage Increase Multiprogrammed over Monoprogrammed

	Job 1	Job 2	Job 3	Job 4

Total Transfer Counts	-0.2	0.3	-0.0	-0.0

One such use of the job scripts has been the generation of *activity plots,* indicating the patterns of file and device usage. Activity plots are similar in nature to page reference maps that depict a job's memory demands.[5,25,26] Virtual time is displayed along the horizontal axis, and the various files and devices used by the job appear on the vertical axis. The time axis is divided into time intervals, and a vertical line is drawn in the interval for each file or device in use during the interval. Figures 3, 4, and 5 are examples of activity plots generated from the job scripts. The three entries labeled "IOP ROU" are used for I/O sequences that do not contain file name entries and usually represent some supervisory function. The entry labeled "1AJ/1CJ" represents the I/O processor routines that advance a job to the next job step and handle job completion. The entry labeled "PFILES" is marked for any I/O sequence that uses a file associated with the permanent file system. The remaining names appearing on the Y axis are either system files or user files used by the job. The plots in Figures 3 and 4 are of the same job, executed in monoprogrammed and multiprogrammed environments respectively. These activity plots offer visual evidence of the reproducibility of job scripts, as the two plots appear to be nearly identical. The activity plot in Figure 5 indicates that jobs may pass through several *phases*, with cyclic behavior within phases. This type of behavior appears to be analogous to the phase/transition behavior of several memory reference models being proposed.[26] Additional work is planned to investigate in more detail this phase behavior with respect to file and device usage.

In addition to providing a means for investigating a job's execution characteristics, the job scripts are also suitable for use in trace-driven simulation models.[19,20] A fairly detailed model of our system has been implemented using the scripts as trace data to drive the model. In order to validate the simulation model and the use of the job script representation, a test workload of 16 jobs was selected. This workload was executed on the CDC6500 system at Purdue, and job scripts were generated. Measurements of system performance were also taken using the software monitor and compared with the results from the simulator. Three quantities were chosen for validation: completion time of the entire workload, mean adjusted memory residency time, and

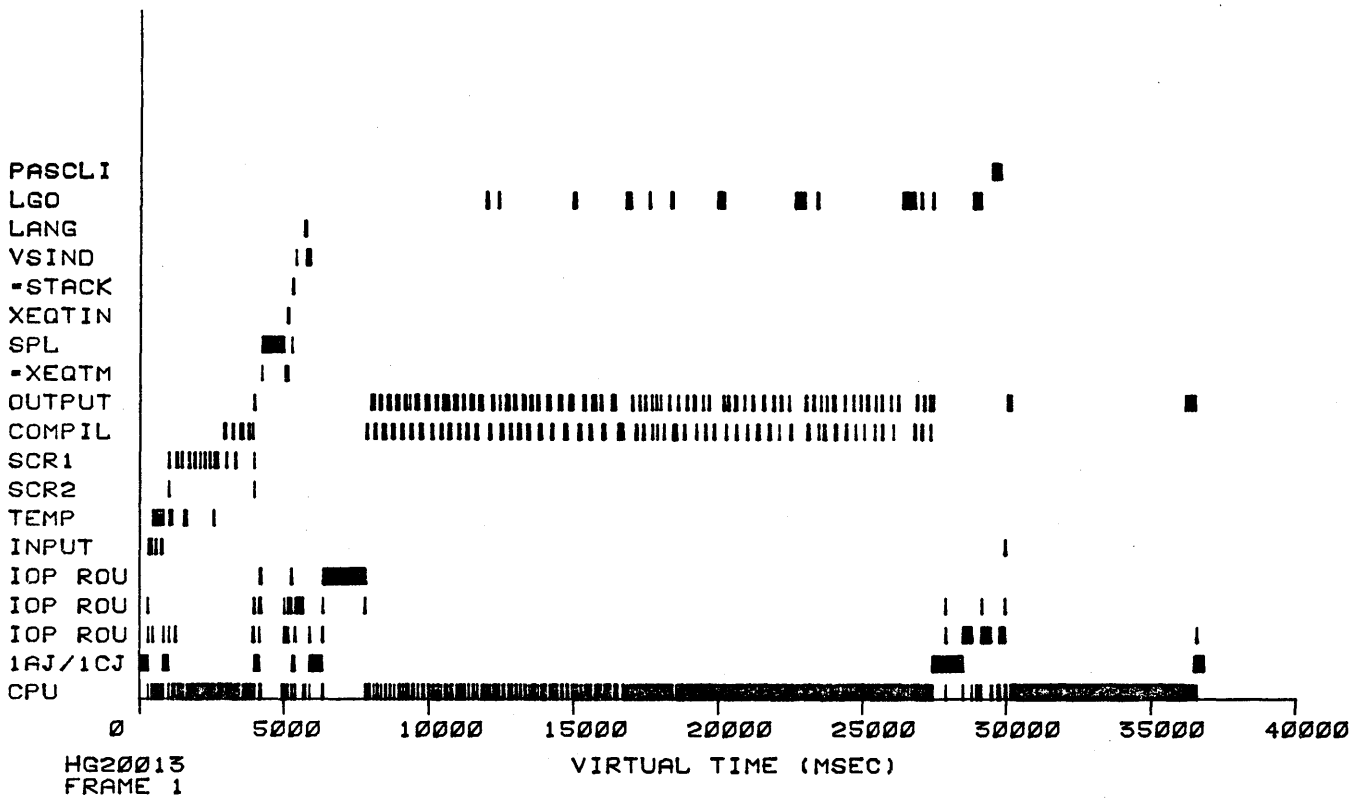

Figure 3—Activity plot of monoprogrammed job

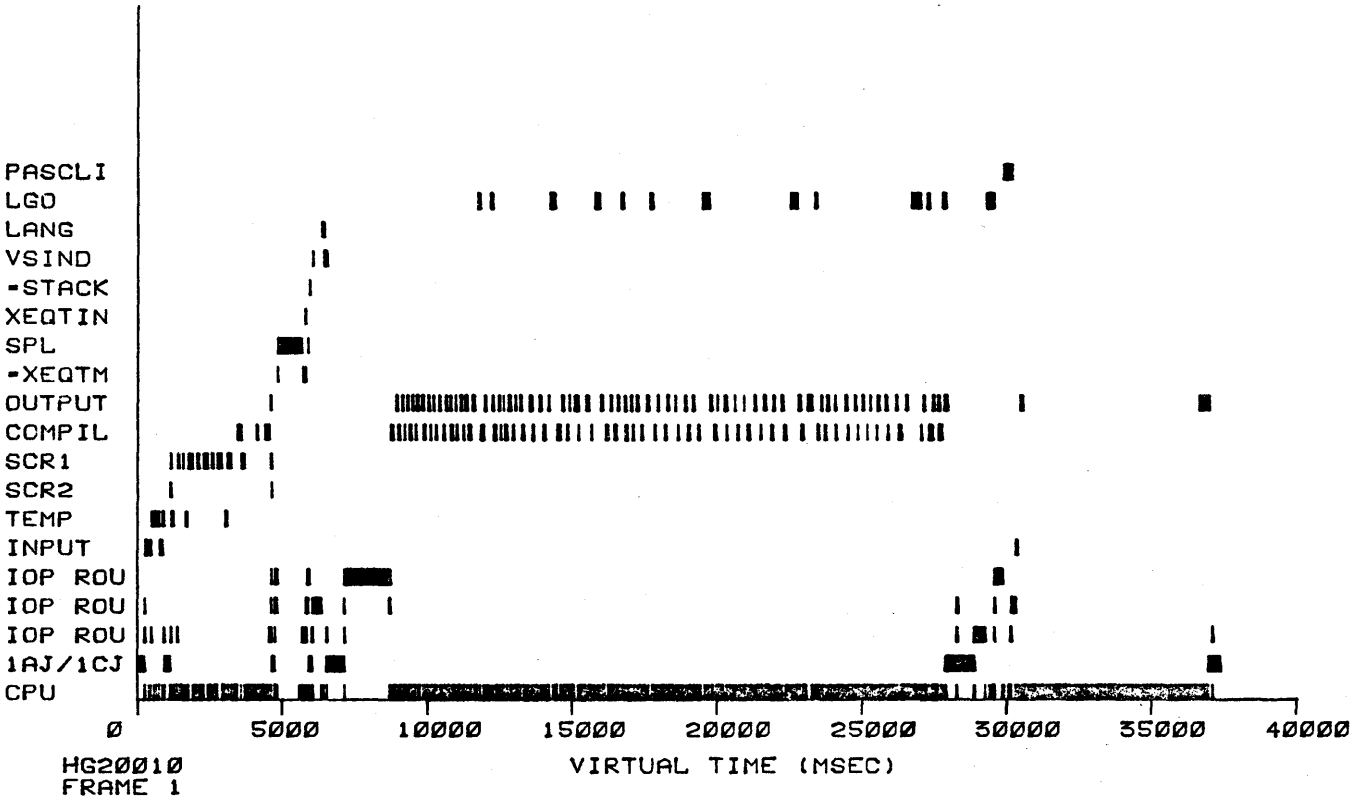

Figure 4—Activity plot of multiprogrammed job

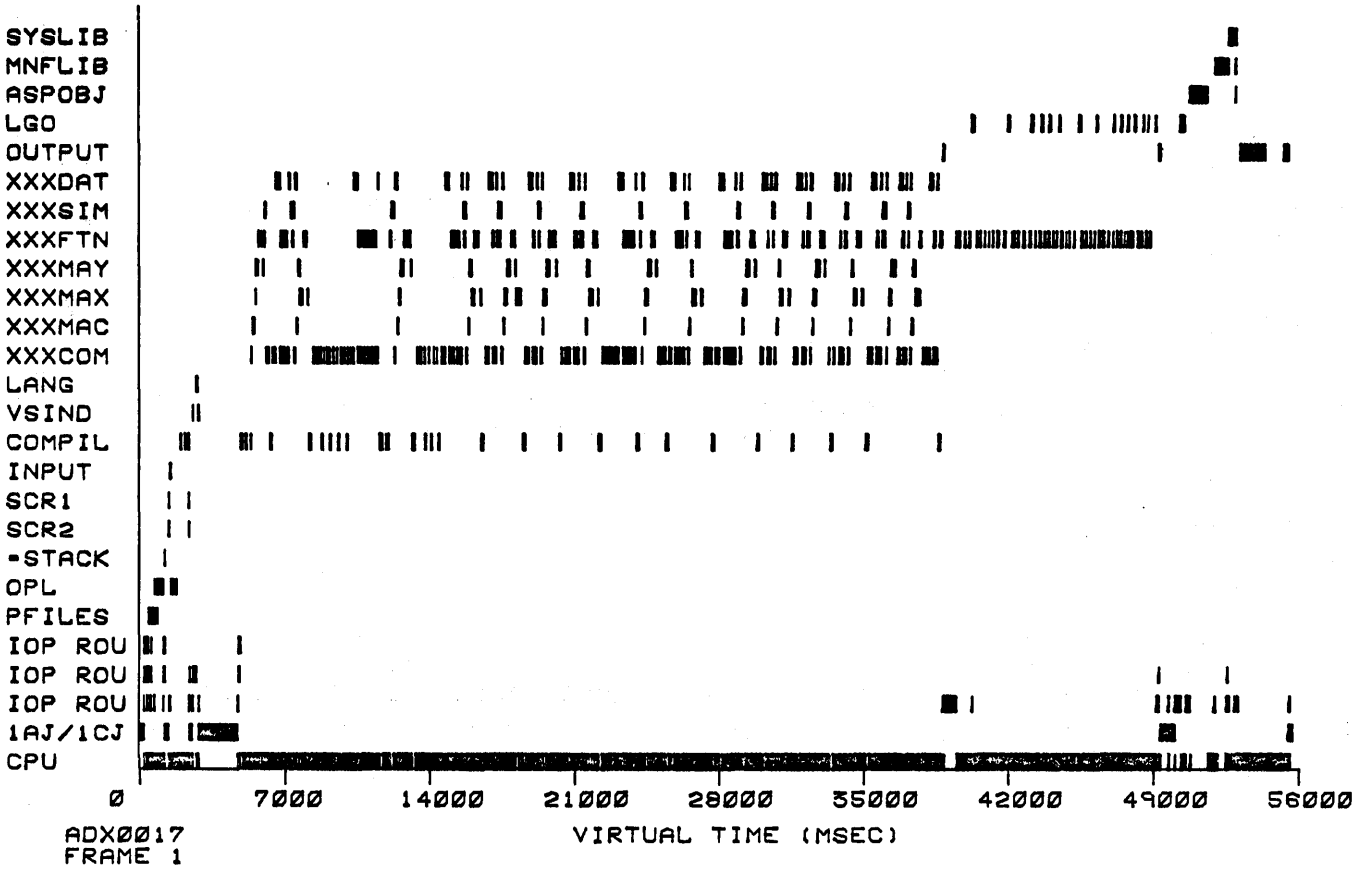

Figure 5—Activity plot showing phase behavior

mean response time. Since all of the jobs were available for execution at the start of the experiment, the mean response time is just the average of the individual job completion times. It was not possible to duplicate in the simulator the exact scheduling algorithm used by the real system, so each job in the model was given an arrival time that corresponded to the time the job first started execution in the real system. The job script accurately reflects the resource demand for each device in the system, so device utilizations were not used for validation, since accurate modeling of the completion time implies accurate modeling of the device utilizations.

In the initial test of the model, relative errors of 4.3 percent, 6.4 percent, and 10.6 percent were observed for the completion time, mean residency, and mean response times respectively. Subsequently the model was modified to use the file name and I/O operation entries to allow for CPU-I/O overlap on WRITE operations. After the modification was complete, the relative errors were 1.0 percent, 3.1 percent, and 6.7 percent. A summary of these results appears in Table VI. The number of job preemptions in each case is also included in the table, and it appears that the model does well in this respect also. Thus the job script representation can be used in a simulation model to approximate relatively closely the overlapped behavior in the real system. Further work is also planned on the use of the job script with trace-driven simulation models.

Finally, the job scripts can also be used to determine the parameters for a central server model.[27] This is possible due to the basic structure of the job script, the CPU-I/O cycle. The transition probabilities are easily determined from a count of the number of intervals for each device, and the mean service times are easily obtained. We plan to produce a sequence of central server model parameters for a job, each set of parameters corresponding to a phase of the job. In combination with the memory requirement entries in the job script, it is hoped that these parameters can be used in hybrid simulation models[28] as well.

TABLE VI.—Validation of Simulation Model

	Actual System	Simulation Model	
		Without Overlap	With Overlap

LIMITATIONS OF THE JOB SCRIPT

The use of job scripts as a workload representation has some drawbacks. The major disadvantages are the need of a software monitor, the expense of producing the job scripts, and the lack of compactness in the representation.

The use of a software monitor to gather the initial event data is an obvious limitation. The usual disadvantages associated with the use of a software monitor are also implicitly involved. Detailed knowledge of the operating system is required for the correct installation, operation, and maintenance of the monitor. The monitor must also be modified whenever changes are made to the operating system. A program is required to analyze the event data produced by the monitor, and in the case of script generation, it must also produce the input required by the script generation program.

The generation of the job script is also a somewhat expensive process in terms of the computer time involved. Table VII lists the cost of each step in the script generation process for the 16 jobs executed in a monoprogrammed environment. Step 4, script analysis, is not part of the script generation process per se, but does provide detailed statistics about the scripts generated. The costs involved are higher when scripts are generated from data collected from the production system over a 20 minute period (in excess of $75.00 and over 1300 CPU seconds). Fortunately, the script generation process is a one time cost, and the scripts produced can be used in a variety of ways.

Another potential limitation of the job script representation is that it is essentially just a record of job activity as observed by the system. For example, the job script's perception of the I/O behavior of a program is obscured by the buffering of logical I/O activity (i.e., the software monitor detects I/O activity only when the buffer of the associated file is either empty or full). It is the authors' contention however, that unless we are willing to instrument each program individually (or instrument the system I/O routines), we must be content with this "distorted" view of job behavior. We also feel that since the job script is produced from information gathered at the point where a program interacts with the system, it should be a sufficient representation for most applications. The job script representation as described appears to be suitable for use only with non-virtual memory systems. It is possible however that it could be adopted for use with a paged virtual system. At the very minimum, additional information concerning the page referencing behavior of a job, along with how it relates to CPU usage would be needed. This is one possible avenue for future research.

Finally, the inclusion of every resource interval in the job script leads to a lengthy representation of a job. Table VII also includes the size of the file generated by each step in the process. Although the script generator reduces the size of the initial event data file, the script file is still sizable (in excess of 36,000 words to represent approximately 500 seconds of job activity). Work is currently under way to find smaller representations using the job script as a starting point. This involves the determination of the "important" characteristics of a job, and the elimination of unneeded information.

TABLE VII.—Cost of Producing Job Scripts

Job Step	Time[1]	I/O Units[2]	Cost[3]	Size of File Created[4]
Software Monitor	13.019	3660	$1.22	112,501
Data Analyzer	101.952	5788	$5.22	139,756
Script Generator	35.168	2255	$1.84	36,480
Script Analysis	8.019	648	$0.54	-------

Observation interval covered 449.371 seconds
Scripts for 16 jobs were produced

[1]CPU seconds used (including time to load the program)
[2]one I/O unit = 1000 characters of data transferred
[3]as computed by the Purdue University Computing Center
[4]number of 60-bit words

CONCLUDING REMARKS

A job script, defined in this paper to be a detailed list of a job's demands for system resources, does form an accurate, reproducible, and useful workload description at the job level. In turn, collections of scripts can be used to completely describe the workload for a system. The level of detail present in these scripts is both a strength and a weakness of this descriptive form; on the plus side, the detail present means that few assumptions are required when using job scripts (all relevant information is present); on the minus side, the volume of information makes it difficult to form overall conclusions and generalizations from the scripts. In a very real sense, you cannot see the forest for the trees.

At Purdue, we have an ongoing project into the development and validation of computer system models. A critical facet of this project is the formulation of techniques which can be used to describe a system workload. Job scripts have emerged as one such technique. Future work will focus on further reduction in the scripts, perhaps along the lines suggested by the phase-cyclic behavior patterns noted above. The goal would be the automatic generation of job descriptions and then system workload descriptions which are not only accurate, reproducible, and useful, but also compact.

Another line of investigation which could be pursued is the reduction of job scripts so that the resulting information could be used to accurately and succinctly characterize a system workload in a form that would assist computer system managers. For example, such descriptions could be essential factors in upgrading existing systems and procurement of new systems. While using job scripts in this fashion can only be conjectured presently, it can be stated that the scripts in their present form do contain the necessary information. The problems lie in the reductions and final form that would be required.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Steven C. Bruell, Purdue University, for his assistance in obtaining the results given in this paper.

Predicting the workload of a computer system*

by A. K. AGRAWALA and J. M. MOHR
Performance Sciences Inc.

INTRODUCTION

It is a commonly observed phenomenon that the workload on a computer system has a tendency to increase, resulting in poorer service or the aquisition of new, more powerful computers. Since the procurement of a large scale computer is a very lengthy process, it becomes crucial to predict the workload a system is likely to have several years into the future.

Most of today's general purpose third generation computers are used in a multiuser, multiapplication environment. The workload handled by a computer is a composite of the computing needs of all of the users; each putting different resource demands on the systems. Frequently, the load increases as new applications are put on the system, or as users find new ways of making use of the facilities of the system. A commonly used practice is to describe the composite workload in terms of measures such as total CPU hours used, the number of terminal connect hours, or the number of transactions handled. While such measures give an idea as to the load a system handles, they are rarely adequate for prediction purposes.

The major, if not the only, purpose of a computer installation is to meet the computing needs of its user population. A computer system is used for different applications, the nature, volume, and characteristics of which change with time. It is these changes that result in a change in the workload on a computer system. But as the changes in different applications may be different, such changes may not be visible from the composite measures. Therefore, the workload prediction techniques have to take into account each of the components of the workload. In this paper we discuss some techniques which are applicable to the workload prediction problem.

Before we can consider the techniques for predicting the workload of a computer, we need techniques for characterizing the current workload of a system. In the second section we review a workload characterization technique which uses clustering to uncover the natural groupings in the workload. In the third section we discuss the applicability of some of the statistical forecasting techniques to the workload prediction problem. In the fourth section, we discuss the ways in which the cluster description of the system's workload may change and the ways in which such a description may be used to predict future workloads on the system. The fifth section of this paper presents an example of a workload prediction study that was carried out using the techniques discussed in the fourth section. The system described in the fifth section is currently being used for both program development and production work.

THE CLUSTERING APPROACH TO WORKLOAD MODELLING

If a computer system were to be used to carry out a small number of tasks repeatedly, then it would be a rather straightforward task to create an accurate, validated model of the workload. But, for a general purpose computer system that is shared by a large user population creating an accurate workload model is not easy.

In a multiuser environment each user makes a sequence of computational requests to the system. While the request patterns of one user are likely to be independent of the other users present on the system, the time instants at which the requests are made may depend on the system response characteristics, which in turn, depend upon the actions of all of the other users. No reliable models to date have been formulated for the behavior of a user. One often has to infer the behavior of the user based upon the data collected by the system on logs.[1] In its raw form, this information tends to be so voluminous that it can hardly be used directly as a workload model. Therefore, a simplified model has to be created. The problem of formulating accurate workload models then reduces to the problem of finding natural patterns or structures in the huge amount of data available from a system log.

The problem of finding structures in large volumes of data has often been addressed in the field of pattern recognition.[2,3] As was noted in Reference 4, however, there are some very basic differences between the pattern recognition problem and the workload characterization problem. Primarily, the pattern recognition problem assumes the existence of well defined classes, or groupings, in the observed data. The groupings we are attempting to find in the work-

load are strictly for the purposes of modelling the workload and no a priori groupings can be inferred. Several of the pattern analysis techniques can, however, be used for workload modelling. In particular clustering has been used successfully for creating workload models.[4-9]

In using clustering to model the workload, first we select the degree of aggregation by defining the lowest level of detail that we plan to model as a "workstep." Next we describe a workstep as a point in an appropriately defined multi-dimensional space whose axes represent resource usage levels, or other features of a workstep. Next, a set of worksteps is observed on the system and clustered to uncover their natural groupings.

While the validity of cluster based workload models has been well established in several studies cited above, the groupings are shown to change by changing the feature set.[4,6] This is quite natural because no a priori groupings exist and thus changing the feature set changes the perspective of the problem. This gives the analyst some flexibility in producing good models by choosing appropriate feature sets.

As noted in the first section, a problem with workload prediction arises from the fact that different groups of applications are likely to change in different ways. By using a cluster based workload model we take into account the characteristics of such individual groups. Before discussing how we can use such models in prediction let us discuss some of the statistical forecasting techniques in terms of their relationship to the workload prediction problem.

TYPES OF CHANGES OF THE WORKLOAD

Frequently the statistical forecasting techniques[10] reported in the literature address themselves to the forecasting of a single variable. The workload of a computer system can hardly be considered univariate. However, for the purposes of discussion we are going to assume that a single unit of work can be defined and that we can talk about such things as the load on a system doubling, or varying in some way, and that we can plot the workload vs time on a graph.

The statistical forecasting literature discusses four basic types of changes that may occur and methods by which they may be predicted. Let us now examine these four types of changes and discuss them in terms of the workload prediction problem.

First, there may be a random stochastic variation in the amount of work performed over a period of time. Second, the amount of work may be a monotonically increasing or decreasing function of time. Third, the amount of work performed may show an oscillatory nature, that is there may be some type of periodic behavior. Finally, there may be abrupt discontinuities in the workload. Of course combinations of these may also occur. Let us consider each of these changes briefly.

Random variations

As we noted above, on a system which supports a large user community the workload observed on the system is the composite of the workload generated by individual users. As the independent users may not follow any particular patterns in submitting their processing requests, a sequence of requests from a user may be treated as a stochastic point process.[11] The system workload may, therefore, be obtained as a superposition of the individual point processes and may be modelled as a random point process. The exact nature of the point process depends on the size of the user population as well as the characteristics of the individual users.

In addition to the point process type of characteristics of the workload, the amount of work to be performed in response to each request may also show a random variation. If we take, for instance, the case where the machine is used primarily for program development, we would typically expect to be able to describe the load supplied by an individual by a pair of random variables drawn from two, possibly different, distributions. First, there is the random factor determining how often the user submits a job. This will depend upon, among other things, how long it takes him to fix any bug found in his previous run. There will also be a random factor in the amount of work that the next job will perform, which will depend upon the program being developed and the type of bug that next appears. Therefore, some random variations in the load on the system seem quite reasonable.

Due to the randomness of such variations they can only be characterized by describing their probabilistic properties. Very little can be done with respect to forecasting them except to forecast the parameters of their probabilistic descriptions. The distributions of the loads may be useful in determining peak loading conditions.

Monotonic changes

By a monotomic change in the workload we mean that the amount of work performed by the computer system shows a steady change over time. This change may be observed as a trend and may reflect an increasing or a decreasing workload. In practice, however, the workloads of computer systems have a tendency to increase rather than decrease. The trend shown by such changes may follow any pattern e.g., straight line, quadratic, exponential.

There are several physical justifications for the fact that loads on computer systems tend to increase with time. First many programs that have been in use for a long period of time tend to grow larger and slower as changes are made or new features are added. Second, many programs that have running times proportional to the number of records processed tend to grow longer becasue each subsequent run is required to process a larger number of records. Third, many installations that perform program development or program maintenance seem to enlarge their staffs and thus present a larger processing load to the central computer system.

As the monotonic changes are likely to follow well defined trend lines they lend themselves well to forecasting. Under the assumption that the trends do not change, a prediction of the workload can easily be made by following the trends.

Oscillatory loads

The workload on a system may show a periodic behavior, increasing and decreasing in an oscillatory manner. We may argue that this is the most frequently observed behavior of computer system workloads. While a computer system may run 24 hours a day, the loads go up and down depending on the hour of the day. This variation may be connected with the user work hours and work habits. Similar types of oscillatory behavior with different periods may have a number of causes. Many installations have tasks which are performed daily, weekly, biweekly, monthly, quarterly, or yearly.

Another example of this phenomenon can be observed at a typical university computer center where the period of the oscillation is one semester. At the beginning of the semester, the load is comprised of the research users running relatively large jobs. As the semester continues the load gradually changes until by the end of the semester the load is comprised of a large number of students running small jobs. Also, as more projects are due at the end of a semester the load increases significantly at that time.

As the system workload is a composite, it may contain components with different periodic behaviors. For predicting the workload at some future time we need to identify each oscillatory component and its period. Spectral decomposition techniques may be used for this purpose.

Discontinuities

When one plots a graph of the amount of work submitted versus time one may find points of discontinuity in the curve or its derivative. These discontinuities correspond to sudden changes in the load on the system. Such abrupt changes may occur for any one of several reasons.

A frequently observed cause of sudden changes in the load on a computer system are changes in its normal operating procedures. Examples of such changes in operating procedures would include switching major files from tape to disk, or switching major applications from batch to time sharing. Both of these changes are likely to introduce rather large changes in the system's load. In an environment in which separate systems are used for development and production, the changes in the production machines's load will tend to be very abrupt as applications make the transition from the test phase to the production phase.

If a new application is decided upon and a significant number of new programmers are hired to perform the implementation, then one would expect to see the derivative of the graph of load change abruptly and expect to see the load increase rather quickly there after.

Note that abrupt changes causing the discontinuities are a result of external factors and, therefore, cannot be predicted on the basis of information available from within a system. For the models created on the basis of system measurements such changes have to be treated as random phenomenon. Since these changes may affect the loads drastically they have to be taken into account in any workload prediction. However, since these abrupt changes are due to external factors it may be possible to predict them by examining the external factors. The quantitative impact of these abrupt changes may be less precisely known due to the fact that they will occur in the future and thus cannot be measured.

Composite changes in the load

In the discussion above we observed that all four types of changes are likely to occur in a computer system workload. Examining the causes of such changes we note that they are not mutually exclusive and that the workload changes observed on real systems can only be explained in terms of two or more of these. For workload prediction we have to identify these component change behaviors first.

As the system workload may consist of several segments it is not necessary that all segments of the workload will exhibit similar changes in behavior. In fact, we expect that the change in the behavior of individual components of the workload will be much simpler than changes in the behavior of the overall workload. A way of identifying the segments of the workloads is to use the cluster based characterization.

THE CLUSTER DESCRIPTION OF THE WORKLOAD

In this section we consider the ways in which the cluster description of a computer's workload may possibly change with time and how the different types of changes in the workload will be reflected in its cluster description.

Predicting changes in the cluster description

If one is using the clustering approach to describe the system workload, the problem of predicting a future workload on the system corresponds to the problem of finding the cluster description for what the workload will be at some point in the future. As stated earlier, the purpose of clustering the workstep population is to obtain a homogeneous group of worksteps that behave in the same manner. Since the total system workload would be composed of the sum of the work supplied by each cluster one would expect to find the future system workload to be composed of the sum of the work supplied by each cluster after the appropriate modifications have been made to the cluster. Therefore, to find the predicted load on the system we must examine each of the clusters that are present in the system workload and determine how each of these clusters will change. We then make the appropriate modifications to the cluster descriptions and from these descriptions find the description for the entire system load. This operation is likely to be easier and more accurate than trying to deal with the entire workstep population at one time. These operations do of course require a reather detailed knowledge of the membership of each cluster as well as knowledge of how these worksteps have been varying in the past and the types of variation that

these worksteps are likely to exhibit in the future. Basically, all cluster analysis allows us to do is to model small segments of the load independently and gives us ways of combining these models into a model of the total system workload. The prediction of these changes may be accomplished using some of the techniques described earlier.

Changes in the cluster description of the load

A cluster taken as an abstract entity only has a limited number of properties that may vary. A cluster can be thought of as having a location in an appropriate n-dimensional space and can move or drift in this space. A cluster has members, that is, it is composed of some worksteps from the total workstep population and therefore some things can be said about the distribution of points in the cluster. Finally, a cluster can be used to describe some segment of the total system workload. In addition to the information available about the cluster itself we can analyze the members of the cluster and determine any additional information that we need to know such as their arrival rates or what types of work they performed.

The cluster description of the total system workload is composed of a group of clusters obtained from clustering the workstep population. In addition to the description of the individual clusters as described above we also know the proportion of the total system load attributable to each cluster.

Before discussing the ways in which the cluster description of the workload may change, let us consider what it means for a given cluster to appear in two different cluster runs. If the system is running in a production environment in which the same programs are run repeatedly then two clusters obtained by the analysis of data from two different times are considered to represent the same cluster if the cluster obtained from the second run contains most of the members of the cluster obtained from the first run. In a nonproduction environment, where different programs are run each day, this method of identifying clusters cannot be applied. Here we have to ascertain what type of job constitutes the cluster in question and to find the similar type of cluster in the output of the later cluster run. For example, in a university workload one would expect the amount of resources used by small student programs to grow with time. Therefore, if one found a cluster both from the beginning of the semester and a cluster from the end of the semester which contained most of the jobs from the introductory programming class then one would say the two clusters correspond even though no single job appears in both clusters.

Since a cluster has a position or location in an n-dimensional space its location may change with time. This would occur if most of the worksteps which made up the cluster changed their feature values in approximately the same way. If this were the case, and some of the worksteps did not change in the same manner as the rest of the worksteps then those worksteps would move with respect to the cluster mean. They may in fact move far enough away from the cluster mean so as to be eliminated from the cluster entirely. When the mean of a cluster moves it is quite likely that some points not previously in the cluster would become close enough to the cluster mean to be absorbed into the cluster. Thus, when a cluster drifts it is not unusual to find that some old members leave the cluster and some new members are added to the cluster. This type of change in the cluster description would of course correspond to the case where there was some monotonic change in the amount of system load, that is whether some or all of the worksteps originally contained in this cluster increased in size.

If a cluster contains worksteps which change in different ways over a period of time, the cluster may fall apart. If this happens the worksteps which were in this cluster may drift close enough to other clusters and join them. As a result the percentage of the total system workload attributable to each cluster may change also.

Another type of change in the workload that may change the cluster description of the workload is the introduction of new applications to the system, or changes in the operating mode of existing applications. In many cases the easiest way to handle such predicted changes is to treat the new or changed application as if it were a cluster by itself. This may be necessary since one might have to estimate the resource requirements of the new application as no measued data may be available. Therefore, one might want to handle this cluster in a different manner than the clusters that were obtained by observing the load on the system.

The applications that already exist but are having their operating mode changed, such as being changed from batch to timesharing or from tape to disk, could be treated the same as entirely new applications except that somewhat better estimates may be made for their resource requirements. These worksteps can be handled by removing them from the cluster to which they belonged and treating them as if they were a separate cluster by themselves.

An oscillatory change in the amount of work performed by the system, or a random variation in the amount of work performed by the system, would typically not involve a real change in the description of the clusters themselves, but rather would involve a change in the number of points assigned to each cluster. Therefore, the variation in the load would be primarily attributable to changes in the arrival rates for the worksteps belonging to the various clusters.

It should be noted that the above techniques need only be applied if a substantial portion of the load is expected to change. If only a few small worksteps are expected to change then the effect on the total system load may be extremely small and can be isolated to one or two clusters.

Predicting changes in applications

An application which continues to be processed over a period of time is often used to process transactions or records of some type. While the computer resources that will be required may not be easily predicted, in many cases an accurate prediction can be made of the number of transactions, or the number or records that will be processed as

these numbers are tied to external factors that may be precisely known or easily predicted. For example, the rate of increase of a payroll processing program depends on the rate of increase in the size of the employee records file, which in turn depends on the rate at which the employment in the company is going to change. Changes in employment levels are usually controlled by the management and can be used to project the resource requirements of the payroll program.

In cases such as this, a far more accurate prediction of the future systems load may be made by first forecasting the changes that will occur at the applications level and then mapping these changes into changes at the resource usage level. In some cases this method will be the only way in which reasonable estimates may be made of the future systems workload.

When an abrupt change occurs in the load the changes are almost always attributable to external factors such as changes in budget levels, the introduction of new applications, or other factors that are clearly known in advance. In these cases the changes in the computer load must also be predicted at the applications level and then the expected computer load must be determined based on these predictions.

Clearly the accuracy of the predictions of the applications workload will depend on the accuracy with which the influences of the external factors can be determined.

AN EXAMPLE

In this section we present an example of how the techniques described in the preceding section can be used to predict the load on a real system. One of the difficulties in describing the results of a prediction study is that the accuracy of the prediction may not be determined for several years. Therefore, the importance of this example is not that it purports to be a complete prediction of the load on a given system, which it is not, but rather that it serves to illustrate the techniques that were described in the preceding sections.

The data used in this example was drawn from work done predicting the load for an installation that operates two IBM 370/158 computers. These machines, which are used for program development and the execution of several production systems, process approximately 20,000 job steps per month. This workload prediction study was performed because a need for a replacement for the two 370/158's had been identified and it was necessary to produce a benchmark to aid in the procurement of this replacement system. The new system was to be sized such that it would satisfy the needs of the installation for a five to eight year period. Therefore, a benchmark had to be produced to represent the load five years in the future.

This installation was chosen as the example for this paper because the load shows many of the types of variations discussed above. First, the basic data set that is used by some of the production systems will be moved from tape to disk in the near future. In addition, one of the production

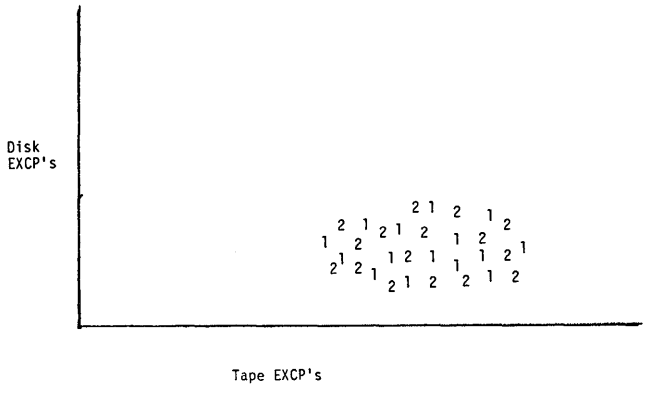

Figure 1a—Present cluster

systems will soon have its operating mode changed from batch to timesharing. The program development portion of the workload can be expected to increase due to the modifications and enhancements being made to the production systems.

Seven features were extracted for each of the job steps and the job steps were clustered using the techniques in References 4-6. This clustering produced twenty clusters, ranging from a cluster of thirty executions of the same workstep to a cluster of over 10,000 relatively small worksteps.

Rather than presenting data on the twenty clusters and over 20,000 data points in a seven dimensional space, the discussion below will deal with only a few of the clusters and some representative data points. In addition, the data presented in the example is presented in terms of only two features rather than the original seven features. We feel that by presenting the data in this manner we will be better able to illustrate the techniques involved than if we had attempted to give a detailed description of all of the data.

The scatter plot of Figure 1a represents a cluster of worksteps from two distinct classes of production systems. For the purposes of this discussion only two features, tape EXCP's and disk EXCP's are shown. The worksteps in the two classes perform essentially the same task, that is editing input data and processing updates to a large master file. There is no way, based upon their resource requirements, that the worksteps from these two classes can be distinguished. Therefore, all of the worksteps are placed into one cluster. The worksteps are described as coming from two distinct classes because the worksteps in class 1 are from a production system that will have its master file moved from tape to disk, while the master file used by the worksteps in class 2 will remain on tape. Therefore, the types of resources required by the worksteps from this class will change rather abruptly. Figure 1b shows a scatter plot of the clusters after predicting the future resource requirements of these worksteps. Since the resource requirements of the worksteps in class 2 are expected to remain essentially constant they are plotted in the same position. The worksteps in class 1 are presented as a new cluster with a significantly lower number of tape EXCP's and a correspondingly higher number of disk EXCP's. These plots are not meant to imply that there

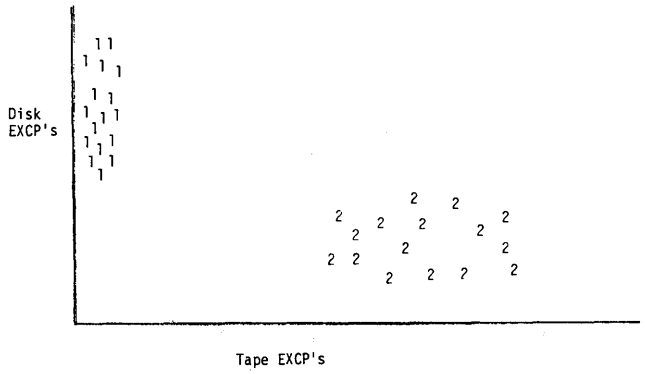

Figure 1b—Predicted clusters after splitting of single cluster

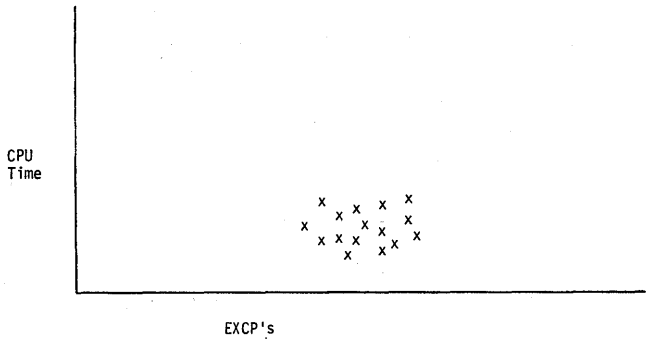

Figure 2a—Present program development cluster

will be a one for one conversion of tape EXCP's to disk EXCP's, but rather that most of the I/O that these worksteps perform will be performed to disk. The exact number of disk EXCP's executed will depend upon a number of factors such as the buffer size that is used, the disk access method that is used, expected changes in the size of the master file, and changes in the number of records to be processed by each workstep. Each of these factors will influence the number of disk EXCP's that a workstep will perform. The number of records to be processed by each workstep may change for several reasons. First, the system will become more heavily used due to increases in the application load. This would increase the amount of I/O performed per day. On the other hand, once the data file is placed on disk, and is thus more accessible, one might decide to run a larger number of worksteps each of which processes a smaller number of records, thereby decreasing the number of disk EXCP's per workstep. Each of these factors depends upon factors to be decided upon before the system conversion can be made and thus can be used in predicting the system load.

The processing load at this installation is subject to a variety of external influences. The processing carried on at this installation is used to support the activities of a large number of divisions throughout the parent organization. Therefore, the processing load on the computer will be effected by management decisions on the initiation or curtailment of activities throughout the organization. In fact, a recent decision by management to reduce a specific activity of one of the divisions will have the effect of reducing the number of records processed by one of the application programs by approximately one third. There is no way that such a change in the processing requirements of the production system could be predicted from data observed on the machine. However, the external factors influencing this change are well understood and their effects can be very accurately determined well in advance. Use of this external information is in fact the only way in which the load on the system due to this application can be accurately predicted.

Figures 2a and 2b represent a cluster that contains many of the program development worksteps. This cluster is composed of a large number of worksteps drawn from a number of sources. Based on observations carried out over a period of time it has been observed that the amount of load attributable to the program development cluster has been increasing. This increase in load is due to an increase in the number and size of the program development worksteps.

This cluster's size and position can be predicted using trend analysis. This is a case in which the position of the cluster drifts due to the movement of most of the data points in the cluster. This movement can be seen when the clusters in Figures 2a and 2b are compared. The cluster in Figure 2b contains more points that the cluster in Figure 2a. This is due to the expected increase in the number of program development worksteps that will be executed by the system.

It should be noted that as the cluster mean drifts and the size of the cluster increases the variance of the data points in the cluster increases as well. This occurs because not all of the worksteps are expected to change in precisely the same manner causing the data points to become more spread out in the seven dimensional space.

When observing this cluster over a long period of time, it becomes clear that the trend is definitely one of constant growth in terms of both the number of worksteps and the size of the worksteps. This is not meant to imply that the rate of increase is absolutely constant. There is some random variation in the number of program development worksteps executed in a given time period. However, this type of random variation is commonly encountered in trend analysis studies and is easily handled.

There is also a rather strong oscillatory component to the workload. While some of the production systems are run on

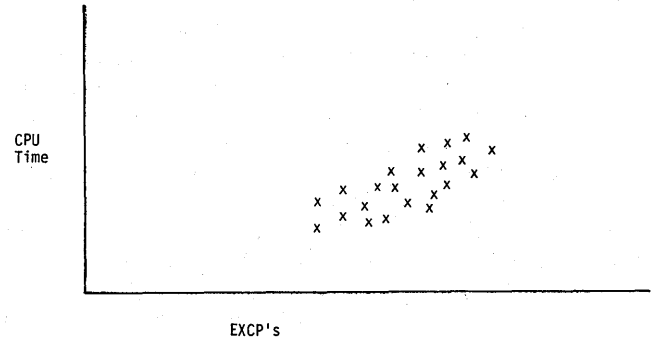

Figure 2b—Predicted program development cluster

TABLE I.—Amount of Load Attributable to Various Clusters

Cluster	Percent of workload normal environment	Percent of workload periodic environment
1	51	10
2	10	2
3	15	1
4	1	84

a daily basis, others are run only once every two weeks. The worksteps from these systems tend to be clustered together due to their rather peculiar I/O requirements. Since the work that these periodic production systems perform is quite time critical they are typically run in stand alone mode so as to insure their timely completion. Therefore, there is a cluster that contributes virtually none of the load most of the time, but every two weeks contributes essentially all of the load. The amount of time required to complete these worksteps is somewhat variable due to such factors as system crashes. Table I contains the percentage of the load contributed by some of the clusters. The two sets of data are for two separate time periods, one which contains the time period in which these periodic systems are running, and the other when the system was running what might be considered its "normal load." The percentage of the load contributed by the non-periodic worksteps is non-zero in the column for the periodic work as the period for which the data was collected overlaps the execution of the periodic systems.

When the set of benchmark programs and the system's requirements are released to the vendors there will be two benchmark experiments to be run. First, a set of benchmark programs representing the normal processing load on the system will be run and the results compared. Second, there will be a requirement that the system to be purchased must be able to execute a representative portion of one of the periodic worksteps in less than a specified amount of time. This has to be done because the system has two operating modes and a new system must be able to handle two very distinct types of loads. It is quite likely that if the worksteps from the periodic systems were combined with the rest of the worksteps into one benchmark then the results that would be obtained from such a benchmark would most likely be rather inaccurate.

CONCLUDING REMARKS

In this paper we consider the problem of workload prediction and note that an accurate prediction can only be made by considering the changes in the individual segments of the workload. For this purpose the segments, or natural groupings, of the workload may be identified using clustering, and then the way components, or clusters, are going to change can be taken into account in the prediction.

The future workload is often affected to a significant degree by external factors. It is crucial that such external factors be taken into account when making the workload predictions by considering the new applications or changes to the modes of operation as well as the effects of external factors on the applications.

Performance evaluation of nonpreemptive response-ratio schedulers*

by MANFRED RUSCHITZKA
Rutgers University
New Brunswick, New Jersey

INTRODUCTION

The schedulers of nonpreemptive batch processing systems are often based on the first-come first-serve (FCFS) or shortest-job-first (SJF) algorithms. The former is least discriminating in the sense that it does not base its scheduling decisions on the service requirements of jobs. In the SJF scheme, the service requirement of a job (or at least an estimate for it) must be known at the time of arrival. It is used to assure good response for short jobs by discriminating against long ones. Overall, the system response for SJF is better than that for FCFS, but the penalty imposed on long jobs is excessive. Brinch Hansen[1] suggested an alternate scheme which improves the overall response characteristics of FCFS without excessively delaying long jobs. In this scheme, the *highest response-ratio next* (HRN) scheme, the priority of an arriving job is set to zero. It then increases linearly in time at a rate inversely proportional to the service requirement of the particular job. When a job departs, the priorities of all jobs in the queue are evaluated and the one with the highest priority starts to execute.

The expected waiting time (the time between arrival and start of execution, also called the *delay*) of a job conditioned on its service requirement is a common measure for the performance of a scheduling algorithm. We call this conditional expectation the *delay function* $W(x)$, where the parameter x denotes the service requirement. The response time of a job is the sum of its delay in the queue and its service requirement, and the response-ratio is defined as the response time divided by the service requirement. Note that the response-ratio is equal to one plus the delay divided by the service requirement. Overall, the rate at which a job attains service is equal to its service requirement divided by the response time. Thus, its processing rate is equal to the inverse of the response-ratio. By selecting the job with the highest response-ratio for service, the HRN discipline attempts to service competing jobs at equal rates. To quantify the behavior of the HRN scheme, Brinch Hansen derived an approximate expression for its delay function which is valid for a system with Poisson job arrivals and hyperexponentially distributed service times.[1] A comparison of this approximation with the delay functions of FCFS and SJF demonstrates how HRN strikes a balance between these two extremes. In this paper, we derive the exact HRN delay function for M/G/1 systems, i.e., single-server systems with Poisson job arrivals and arbitrarily distributed service times. The derivation amounts to solving an integro-differential equation which was first developed in Reference 1. Making explicit use of random variables, we proceed to formulate this integro-differential equation via a slightly different method.

* The research reported in this paper was supported in part by the Advanced Research Projects Agency of the Office of the Secretary of Defense under grant DAHCIS-73-G6.

FORMULATION OF THE INTEGRO-DIFFERENTIAL EQUATION

According to the classification scheme of Ruschitzka and Fabry,[7] a scheduling algorithm is specified in terms of a priority function, a decision mode, and an arbitration rule. The priority function of the HRN scheme is

$$P(r,x)=r/x \tag{1}$$

where the job parameters r and x are the time a job has spent in the system and its service requirement respectively. The decision mode is nonpreemptive, i.e. scheduling decisions are only made when a job departs or when an arriving job finds the system empty. A first-come first-serve arbitration rule will be used to resolve conflicts among jobs with equal highest priority.

Jobs arrive at the M/G/1 system at a rate λ. Their service times S are assumed to be mutually independent and identically distributed. $g(s)$, ES, and ES will denote the probability density function, the expectation, and the second moment of S respectively. The first two moments are assumed to be finite. A job with a service requirement of $S=s$ will be called an *s-job*. $\rho=\lambda ES$ stands for the system load which must be less than one. We express the delay and other random variables of interest for a particular, but arbitrary, job which we call the *test job*. Its service requirement will be denoted by x. For the averages of waiting times we shall use time averages which, due to the assumption of Poisson arrivals, are identical to job averages.

The delay of the test job can be equated with the amount of service performed on other jobs. Using this approach (cf. Reference 6), we distinguish between two groups of jobs: the *early arrivals* which arrive before the test job and the *late arrivals* which arrive after it. Similarly, we define the average *early work* $W_E(x)$ (*late work* $W_L(x)$) as the total amount of service performed on all early (late) arrivals during the test job's lifetime in the system. With these definitions, the average delay of the test job is given by

$$W(x)=W_E(x)+W_L(x). \tag{2}$$

We proceed to further decompose the term for the early work.

When the test job arrives, the system is either empty (idle) or servicing an early arrival. We denote the average remaining service of this early arrival by W_0. More early arrivals may be waiting in the queue. An s-job in the queue with $s\leq x$ will be serviced before the test job since its priority grows faster according to equation (1). The average cumulative service of all these early s-jobs with $s\leq x$ will be denoted by $W_1(x)$. An s-job with $s>x$ will only be serviced before the test job if it has been in the system sufficiently long such that its priority exceeds the faster growing priority of the test job. We call the average cumulative service of these jobs the work $W_2(x)$, i.e., the work associated with those early arrivals that get serviced before the test job although their service requirement is higher. In sum, the average early work encountered by the test job is comprised of three different types:

$$W_E(x)=W_0+W_1(x)+W_2(x). \tag{3}$$

The average time which the test job must wait until the job (if any) which it finds in service completes its remaining service is well-known (c.f. Reference 2, p. 16):

$$W_0=\lambda ES^2/2. \tag{4}$$

In order to obtain expressions for $W_1(x)$ and $W_2(x)$, we first establish an expression for the average number of s-jobs in the queue. Applying Little's theorem[3] to s-jobs in the queue, the average number $n(s)ds$ of s-jobs which the arriving test job finds in the queue is simply

$$n(s)ds=\lambda W(s)g(s)ds. \tag{5}$$

Furthermore, the average cumulative service requirement of all s-jobs in the queue is $sn(s)ds$. Since s-jobs with $s\leq x$ will be serviced before the test job, their contribution to the early work is

$$W_1(x)=\int_0^x sn(s)ds=\lambda\int_0^x sW(s)g(s)ds. \tag{6}$$

Depending on the time it spent in the queue, an s-job with $s>x$ may or may not be serviced prior to the test job. Consider the limiting case in which the priorities of an early arrival and the test job are equal at the instant at which the server begins to work on the *early arrival*. Assuming that the s-job arrived T seconds before the test job and that it has waited V seconds, the test job will have spent $V-T$ seconds in the system. We now equate their priorities according to equation (1) to get

$$V/s=(V-T)/x.$$

Solving for T, we obtain

$$T=V(1-x/s) \tag{7}$$

as the minimum time between the arrivals of the s-job and the test job if the s-job is to be serviced before the test job. Conversely, all s-jobs with $s<x$ that arrive within T seconds prior to the test job's arrival will be serviced after the test job. Due to the assumption of Poisson arrivals, the average number $l(s)ds$ of these latter s-jobs is equal to the rate $\lambda g(s)ds$ of their arrival multiplied by the expected length of T:

$$l(s)ds=\lambda g(s)E[T]ds.$$

After substituting T from equation (7) and using the equality $E[V]=W(s)$ which follows from the definition of the delay function we get

$$l(s)ds=\lambda(1-x/s)W(s)g(s)ds. \tag{8}$$

The average number $n(s)ds$ of s-jobs in the queue is, of course, the sum of the average number $l(s)ds$ of those which get serviced after the test job and some average number $e(s)ds$ of those which are serviced prior to the test job. Thus, we have $e(s)ds=n(s)ds-1(s)ds$, and substituting from equations (5) and (8) yields

$$e(s)ds=\lambda(x/s)W(s)g(s)ds.$$

The average service required by all s-jobs is s times their number, and the average cumulative service of all early arrivals which require $s>x$ seconds of service and get serviced before the test job is therefore

$$W_2(x)=\lambda\int_x^\infty se(s)ds=\lambda x\int_x^\infty W(s)g(s)ds. \tag{9}$$

The early work $W_E(x)$ in equation (3) is now completely determined by equations (4), (6), and (9).

We now proceed to evaluate the late work. Recall that the priority of a late arrival requiring $s>x$ seconds of service grows slower than that of the test job. Such a late arrival will always be serviced after the test job. On the other hand, the priority of a late s-job with $s<x$ may outgrow that of the test job. Assume that a late arrival arrives i seconds after the test job. In order to determine how large the service requirement s of a late arrival may be if it is to be serviced before the test job, we consider the case where the priorities of the late arrival and the test job are equal at the instant at which the *test job's* service commences. Equating their priorities according to equation (1) we get

$$(V-i)/s=V/x$$

where V now denotes the delay of the test job. Solving for s,

$$s=x(1-i/V),$$

yields the maximum service requirement of a job arriving i seconds after the test job if it is to be serviced before the

test job. Holding V constant, we first obtain the average late work conditioned on x and V, i.e., the average cumulative service of all jobs which both arrive and depart during the test job's lifetime in the queue. Making use of Poisson arrivals, the average sum of the individual job's service times may be replaced by an integral over the expected service of a job arriving at time i (time being measured from the arrival of the test job) multiplied by the probability $\lambda\,di$ of its arrival at time i:

$$W_L(x,V)=\int_0^V \int_o^{x(1-i/V)} sg(s)ds\lambda di.$$

Substituting $y=x(1-i/V)$, exchanging the order of integration, and evaluating the inner integral yields

$$W_L(x,V)=\lambda V\int_0^x s(1-s/x)g(s)ds.$$

The average late work can now be obtained by unconditioning this expression with respect to V. With $E[V]=W(x)$, we have

$$W_L(x)=\lambda W(x)\int_0^x s(1-s/x)g(s)ds \tag{10}$$

which is the final expression for the late work.

The average delay $W(x)$ was defined in equation (2). Substituting the early work according to equations (3), (4), (6), and (9) and the late work from equation (10), we get

$$W(x)=W_0+\lambda\int_0^x sW(s)g(s)ds+\lambda x\int_x^\infty W(s)g(s)ds + \lambda W(x)\int_0^x s(1-s/x)g(s)ds.$$

Solving for $W(x)$ yields the final integro-differential equation for the average delay of a job under HRN conditioned on its service requirement x:

$$W(x)=\frac{W_0+\lambda\int_0^x sW(s)g(s)ds+\lambda x\int_x^\infty W(s)g(s)ds}{1-\lambda\int_0^x s(1-s/x)g(s)ds}. \tag{11}$$

This equation describes the HRN delay function in an M/G/1 system. It was first derived by Brinch Hansen[1] in a slightly different manner based on a geometric argument. He then developed an approximate solution for the special case of hyperexponentially distributed service times. We proceed to generalize his results by deriving the exact solution for arbitrary service time distributions.

DERIVATION OF THE DELAY FUNCTION

The integro-differential equation for the delay function $W(x)$ in equation (11) can be reduced to a homogeneous linear differential equation of the second order. We define two auxiliary functions to aid in this reduction process. The first function, $h(x)$, equals the denominator of equation (11).

For $h(x)$ and its derivative we have

$$h(x)=1-\lambda\int_0^x sg(s)ds + (\lambda/x)\int_0^x s^2g(s)ds, \quad h(0)=1, \tag{12}$$

$$h'(x)=-(\lambda/x^2)\int_0^x s^2g(s)ds, \; h'(0)=0. \tag{13}$$

Note for later reference that $h(\infty)=1-\rho$. The second function is defined as $p(x)=xh(x)$. For this auxiliary function and its first two derivatives we have

$$p(x)=x-\lambda x\int_0^x sg(s)ds + \lambda\int_0^x s^2g(s)ds, \qquad p(0)=0, \tag{14}$$

$$p'(x)=1-\lambda\int_0^x sg(s)ds, \qquad p'(0)=1, \tag{15}$$

$$p''(x)=-\lambda xg(x), \qquad p''(0)=0. \tag{16}$$

Note that the functions $h(x)$ and $p(x)$ depend only on λ, x, and g; they are not functions of the HRN discipline. We also define

$$V(x)=W(x)h(x)=W(x)p(x)/x \tag{17}$$

as a more suitable function for the reduction of the integro-differential equation.

With the definitions of $h(x)$ and $V(x)$ in equations (12) and (17), equation (11) becomes

$$V(x)=W_0+\lambda\int_0^x sW(s)g(s)ds+\lambda x\int_x^\infty W(s)g(s)ds,$$

and the first two derivatives of this equation are:

$$V'(x)=\lambda\int_x^\infty W(s)g(s)ds, \tag{18}$$

$$V''(x)=-\lambda W(x)g(x). \tag{19}$$

Using the identities in equations (16) and (17), equation (19) can be rewritten:

$$p(x)V''(x)-p''(x)V(x)=0. \tag{20}$$

Thus, the problem of solving the integro-differential equation (11) for $W(x)$ has been reduced to solving this second-order differential equation for $V(x)$.

We now assume that $V(x)$ has the form

$$V(x)=q(x)p(x) \tag{21}$$

where $q(x)$ is an unknown function to be determined. Substituting equation (21) and its second derivative

$$V''(x)=q''(x)p(x)+2q'(x)p'(x)+q(x)p''(x)$$

in equation (20) yields

$$q''(x)/q'(x)+2p'(x)/p(x)=0.$$

The integral of this equation is

$$\log q'(x)+2\log p(x)=\log C$$

where $\log C$ is an integration constant. Equivalently, $q'(x)=C/p^2(x)$, and a further integration yields the unknown function $q(x)$:

$$q(x)=\int_x^\infty C(1/p^2(y))dy+D \tag{22}$$

where D is a second integration constant. From equations (17) and (21) we have $W(x)=xq(x)$, and with this equality equation (22) becomes

$$W(x)=x\int_x^\infty C(1/p^2(y))dy+Dx. \tag{23}$$

Equation (23) is the desired solution for the HRN delay function, but it remains to determine the integration constants C and D.

Equation (1) states that the priority of a job with a zero service requirement increases at an infinite rate. Such a job will be serviced as soon as the job it finds in service departs. Thus, we have the boundary condition $W(0)=W_0$ which we use to determine the integration constant C. Note that this boundary condition is consistent with our expressions for the early work in equations (3), (4), (6), and (9). Evaluating equation (23) for $x=0$ results in an indeterminate expression (zero times infinity) which can be resolved by L'Hospital's rule

$$W(0)=W_0=C\lim_{x\to 0}\frac{\int_x^\infty (1/p^2(y))dy}{1/x}$$

$$=C\lim_{x\to 0}\frac{-(1/p^2(x))}{-1/x^2}.$$

With $p(x)=xh(x)$ and $h(0)=1$ from equation (12), the value of the integration constant C follows:

$$C=W_0h^2(0)=W_0.$$

The second integration constant, D, may be obtained by using the fact that the average unfinished work U in an M/G/1 system (as seen by a Poisson arrival) is invariant to the scheduling scheme (Reference 2, p. 115):

$$U=W_0/(1-\rho).$$

Expressing U as the average remaining service time of the currently serviced job plus all the work represented by jobs in the queue we have

$$W_0+\int_0^\infty sn(s)ds=W_0/(1-\rho).$$

Substituting the expression for $n(s)ds$ from equation (5) yields

$$W_0+\lambda\int_0^\infty sW(s)g(s)ds=W_0/(1-\rho).$$

We now evaluate this invariance for the HRN discipline by substituting the delay function in equation (23) with $C=W_0$:

$$W_0+\lambda W_0\int_0^\infty s^2\int_s^\infty (1/p^2(y))dyg(s)ds$$

$$+\lambda D\int_0^\infty s^2g(s)ds=W_0/(1-\rho)$$

where the term containing D evaluates as λDES^2 or $2DW_0$. After canceling W_0 and exchanging the order of integration in the double integral, we get

$$1+\lambda\int_0^\infty (1/p^2(y))\int_0^y s^2g(s)dsdy+2D=1/(1-\rho).$$

According to equation (13), the inner integral is equal to $-h'(y)y^2/\lambda$. After evaluating the outer integral by making use of the equalities $p(y)=yh(y)$, $h(0)=1$, and $h(\infty)=1-\rho$ we have

$$1+[1/(1-\rho)-1]+2D=1/(1-\rho).$$

It follows that $D=0$. With the integration constants determined, the delay function in equation (23) becomes

$$W(x)=x\int_x^\infty (W_0/p^2(y))dy. \tag{24}$$

Equivalently, after substituting the auxiliary function p by the defining expression in equation (14) we have

$$W(x)=x\int_x^\infty \frac{W_0}{\left[y-\lambda y\int_0^y sg(s)ds+\lambda\int_0^y s^2g(s)ds\right]^2}dy. \tag{25}$$

The delay functions in equations (24) and (25) are two equivalent forms of the exact solution of the integro-differential equation (11). They specify the average delay of a job, conditioned on its service requirement x, in an M/G/1 system under the HRN discipline.

PROPERTIES OF DELAY FUNCTIONS

The HRN discipline strikes a balance between the extreme scheduling algorithms of FCFS and SJF. It still favors short jobs, but the delay of long jobs is much less excessive than under SJF. Figure 1 illustrates the typical forms of the delay functions of the three scheduling disciplines. The average delay under FCFS is, of course, equal to the unfinished work U:

$$W_{\text{FCFS}}(x)=U=W_0/(1-\rho).$$

It is also independent of the service requirement x. The delay function for SJF was first obtained by Phipps:[4]

$$W_{\text{SJF}}(x)=\frac{W_0}{\left[1-\lambda\int_0^x yg(y)dy\right]^2}.$$

Note that the bracketed term in the denominator is equal to the auxiliary function $p'(x)$ defined in equation (15); it equals one minus the load contribution of all s-jobs with $s<x$. The SJF delay function starts with a value of W_0 and a zero

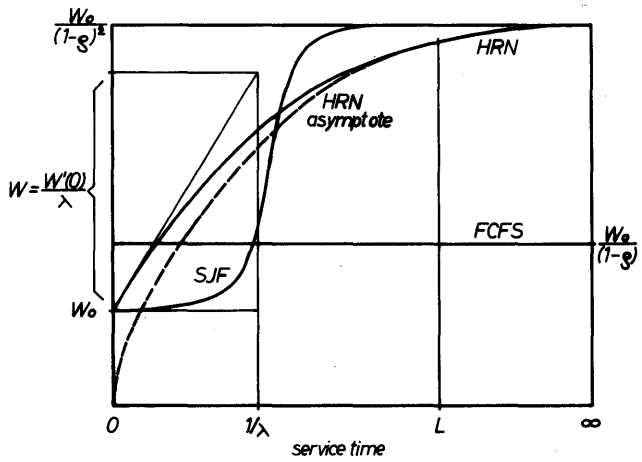

Figure 1—Properties of the delay functions for HRN, SJF, and FCFS

slope at the origin, but rises quite rapidly to its maximum value $W(\infty)=W_0/(1-\rho)^2$. The delay function for HRN covers the same range, but its form is quite different.

The upper integration limits of the two integrals in the definition of $p(x)$ in equation (14) may be replaced by infinity to yield a function which $p(x)$ will asymptotically approach. For very large values of x, say $x \geq L$, we shall use this asymptote as an approximation for the auxiliary function $p(x)$:

$$p(x)=x-\lambda x E S+\lambda E S^2, \qquad x \geq L.$$

The value of L will vary with the given distribution g and the desired accuracy. With this approximation, the delay function in equation (24) can be evaluated analytically,

$$W(x)=W_0/[(1-\rho)(1-\rho+\lambda E S^2/x)], \quad x \geq L, \quad (26)$$

to provide an asymptote for the delay function. This asymptote is depicted in Figure 1. Note that the value of $W(\infty)=W_0/(1-\rho)^2$ can be obtained from this asymptote. The slope of the delay function at the origin may be used to graphically determine the overall average delay W. By definition,

$$W=\int_0^\infty W(s)g(s)ds, \quad (27)$$

and according to equation (18) this expression is equal to $V'(0)/\lambda$. From the definition of $V(x)$ in equation (17) and with $h(0)=1$ and $h'(0)=0$ from equations (12) and (13) we get $V'(0)=W'(0)$ and therefore

$$W=W'(0)/\lambda. \quad (28)$$

Figure 1 illustrates how this equality may be used to obtain the overall average delay W from a plot of the HRN delay function.

So far, we have obtained elementary expressions for $W(0)$, $W(\infty)$, and the asymptote for large service times in equation (26). For intermediate service time values of the delay function, the integral in equation (24) can be evaluated analytically for simple service time distributions only. In general, we will depend on numerical methods for their evaluation. In order to deal with the upper (infinite) integration limit, we split the integration interval into two partitions, $[x,L)$ and $[L,\infty)$. The integral over the latter can then be obtained analytically by making use of the approximation in equation (26). For the integral over $[x,L)$ we use the trapezoidal integration technique with subinterval size d such that $x=md$ and $L=nd$. Thus, equation (24) becomes

$$W(x)=x\sum_{j=m}^{n-1}\left[\frac{W_0}{p^2(jd)}+\frac{W_0}{p^2((j+1)d)}\right]d/2+xW(L)/L \quad (29)$$

where $W(L)$ is given by equation (26). Since $1/p^2$ decreases monotonically, roundoff errors are reduced by summing in decreasing order of j; this corresponds to an integration from L to the left. When many values of the delay function are needed, an iterative method may be used to increase the efficiency of the computation. This iterative method is based on the relation

$$W(md)=W((m+1)d)\frac{m}{m+1}+dm\left[\frac{W_0}{p^2(md)}+\frac{W_0}{p^2((m+1)d)}\right] \quad (30)$$

which follows from equation (29). The initial value $W(L)=W(nd)$ is again given by equation (26), and the iteration proceeds from $m=n-1$ to $m=1$. For $m=0$, we already obtained $W(0)=W_0$ analytically.

The overall average delay W is an important performance measure. Analogous to the delay function, we use a combination of analytical and numerical methods for its evaluation. Starting from equation (27), we again divide the integration interval into two partitions: $[0,L)$ and $[L,\infty)$. The contribution of the integral over the interval $[L,\infty)$ can be approximated analytically by making use of equation (26). Choosing the simple trapezoidal integration method for the interval $[0,L)$, we get

$$W=\sum_{j=0}^{n-1}[W(jd)g(jd)+W((j+1)d)g((j+1)d)]d/2+W(L)G^c(L) \quad (31)$$

where $L=nd$ and G^c is the complementary cumulative distribution function,

$$G^c(x)=1-G(x)=\int_x^\infty g(s)ds. \quad (32)$$

with $G(x)$ denoting the cumulative distribution function of the service time S. Equation (28) shows the relation between the overall average delay W and the slope of the delay function at the origin. Thus, in addition to its importance as a performance measure, the value of W also aids in verifying the accuracy of the numerical integration underlying equation (30).

THE HRN DELAY FUNCTIONS OF SPECIFIC SYSTEMS

Our result for the HRN delay function in equations (24) or (25) is valid for M/G/1 systems. To illustrate the behavior of the HRN discipline for a representative set of specific

distributions, we present four examples with widely varying coefficients of variation C_V, where C_V is defined as

$$C_V=\sqrt{ES^2-(ES)^2}/ES.$$

In the M/D/1 system, service times are constant and $C_V=0$. Erlangian (hypoexponential, Gamma) distributions are characterized by $C_V<1$; we shall deal with a 2-stage distribution or an $M/E_2/1$ system. With the exponential distribution in an M/M/1 system we cover the case $C_V=1$. Finally, the 2-stage hyperexponential distribution of the $M/H_2/1$ system will represent distributions with $C_V>1$.

The program for the evaluation of delay functions and overall delays was written in SIMULA on a PDP-10. We reduced the subinterval size d until we obtained an accuracy of at least 3 digits; $d=1/100$ was sufficient in all cases. For a given distribution and load, the delay function was evaluated at multiples of the subinterval size according to equation (30), and these values were subsequently used to obtain the overall average delay as indicated by equation (31). The SIMULA EXP-function on the PDP-10 has a minimum (most negative) permissible parameter value which is around -89 [EXP$(-89)=2.23\ 10^{-39}$]. We used this constraint to determine the value of L for the various distributions. We shall list these values of L for the Erlangian, exponential, and hyperexponential distributions. For constant service times, the delay function can be obtained analytically, thus avoiding the use of numerical methods.

The M/D/1 system

For constant service times, the distribution function is given by

$$g(x)=\delta(ES)$$

where δ is Dirac's delta function. For this distribution function, the auxiliary function defined in equation (14) evaluates as

$$p(y)=\begin{cases} y, & y<ES; \\ y-\rho y+\rho ES, & y\geq ES. \end{cases}$$

Due to the simple form of $p(y)$, the delay function can be obtained analytically. Evaluating equation (24) for this distribution, we get

$$W(x)=\begin{cases} W_0(1-\rho+\lambda x)/(1-\rho), & x<ES; \\ W_0 x/[(1-\rho)(x-\rho x+\rho ES)], & x\geq ES. \end{cases}$$

Of course, the probability of any job requiring more or less than exactly ES seconds of service is equal to zero. The average delay of a job is therefore

$$W(ES)=W=W_0/(1-\rho).$$

Note that this expression is equal to $W'(0)/\lambda$. As one should expect in an M/D/1 system, the average delay under HRN is equal to the delays under FCFS or SJF.

The $M/E_2/1$ system

The distribution function of the 2-stage Erlangian distribution is given by

$$g(x)=(2\mu)^2 x\exp(-2\mu x)$$

where $\mu=1/ES$. The second moment is $ES^2=3/(2\mu^2)$. For the complementary distribution function we have

$$G^c(x)=1-(1+2\mu x)\exp(-2\mu x).$$

Evaluating equation (14) for this distribution, we get

$$p(y)=y(1-\rho)+3\rho/(2\mu)-\rho y(\mu y+2+3/(2\mu y))\exp(-2\mu y).$$

For the numerical evaluation of the delay function with $ES=1$, we set $L=44$. Figure 2 depicts the HRN delay function together with those of FCFS and SJF for a load of 75 percent. The average overall delays for FCFS, HRN, and SJF are 2.25, 1.74, and 1.37 respectively.

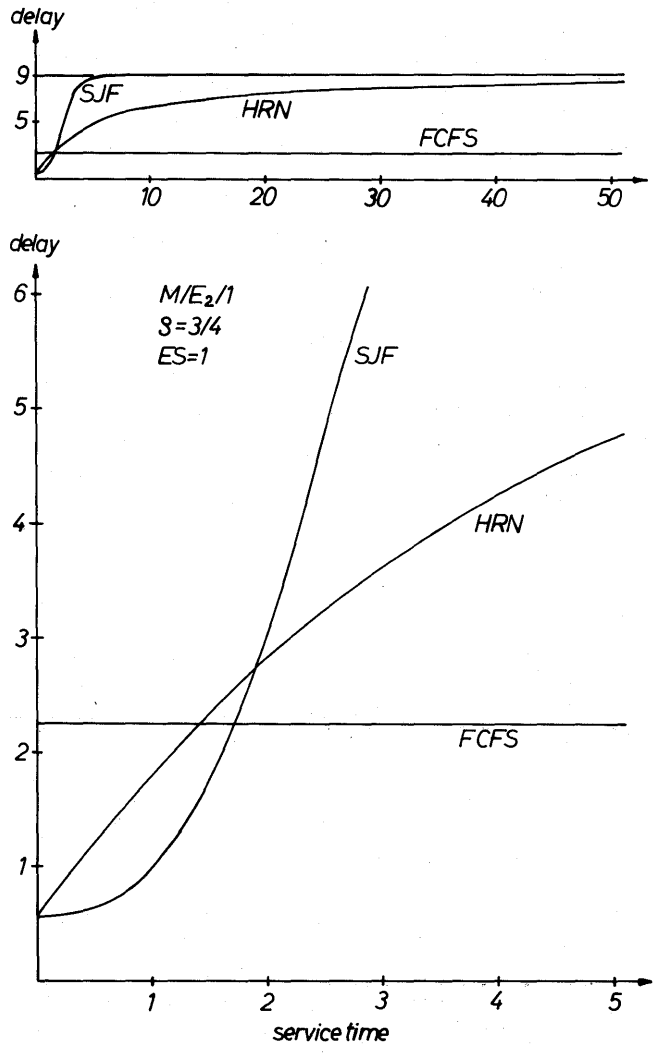

Figure 2—Delay functions for hypoexponentially distributed service times

The M/M/1 system

For the exponential distribution function,

$$g(x)=\mu \exp(-\mu x), \qquad G^c(x)=\exp(-\mu x),$$

the first two moments are given by $ES=1/\mu$ and $ES^2=2/\mu^2$. The auxiliary function in equation (14) specializes to

$$p(y)=y(1-2\rho)+\rho(y+2/\mu)(1-\exp(-\mu y)).$$

Choosing $ES=1$, we set $L=89$ for the evaluation of the delay function based on equation (30). For a load of 75 percent, the delay function of HRN is plotted in Figure 3. For comparison, the delay functions of FCFS and SJF are also illustrated. The average overall delays for FCFS, HRN, and SJF are 3.00, 1.98, and 1.56 respectively.

The M/H$_2$/1 system

The 2-stage hyperexponential distribution function is given by

$$g(x)=ab\mu \exp(-b\mu x)+(1-a)c\mu \exp(-c\mu x)$$

where $\mu=1/ES$, a is an arbitrary probability, and b and c are positive parameters satisfying $a/b+(1-a)/c=1$. The second moment is $ES^2=2[a/(b\mu)^2+(1-a)/(c\mu)^2]$. The complementary distribution function may be obtained from equation (32):

$$G^c(x)=a \exp(-b\mu x)+(1-a) \exp(-c\mu x).$$

The auxiliary function $p(y)$ to be used in the numerical integration specializes to

$$p(y)=y-a\rho y[2-(1+2/(b\mu y))(1-\exp(-b\mu y))]/b$$
$$-(1-a)\rho y[2-(1+2/(c\mu y))(1-\exp(-c\mu y))]/c.$$

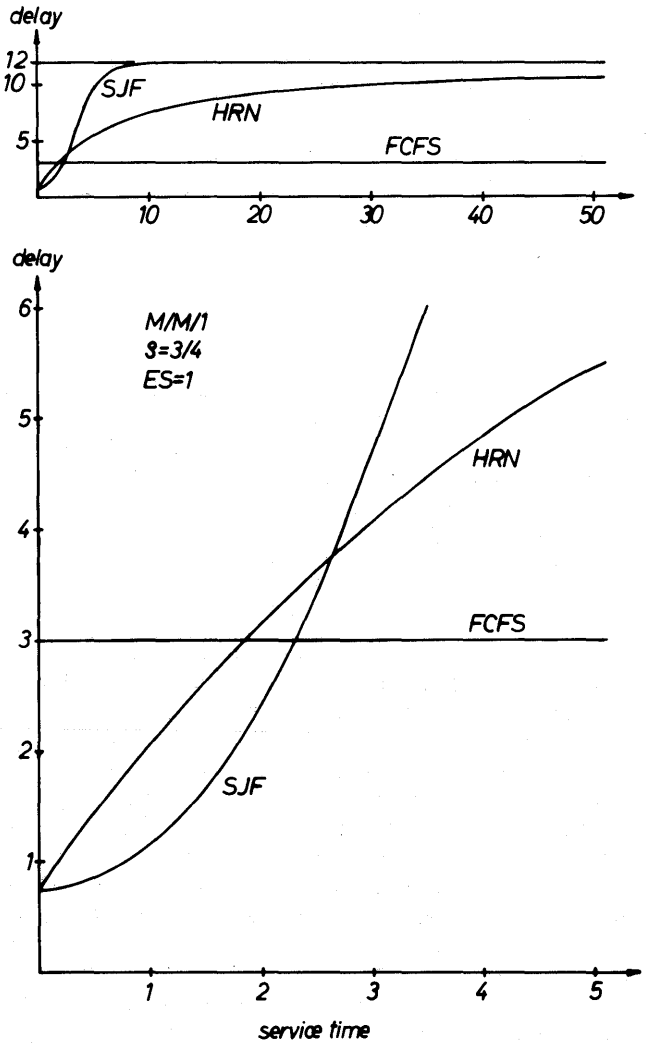

Figure 3—Delay functions for exponentially distributed service times

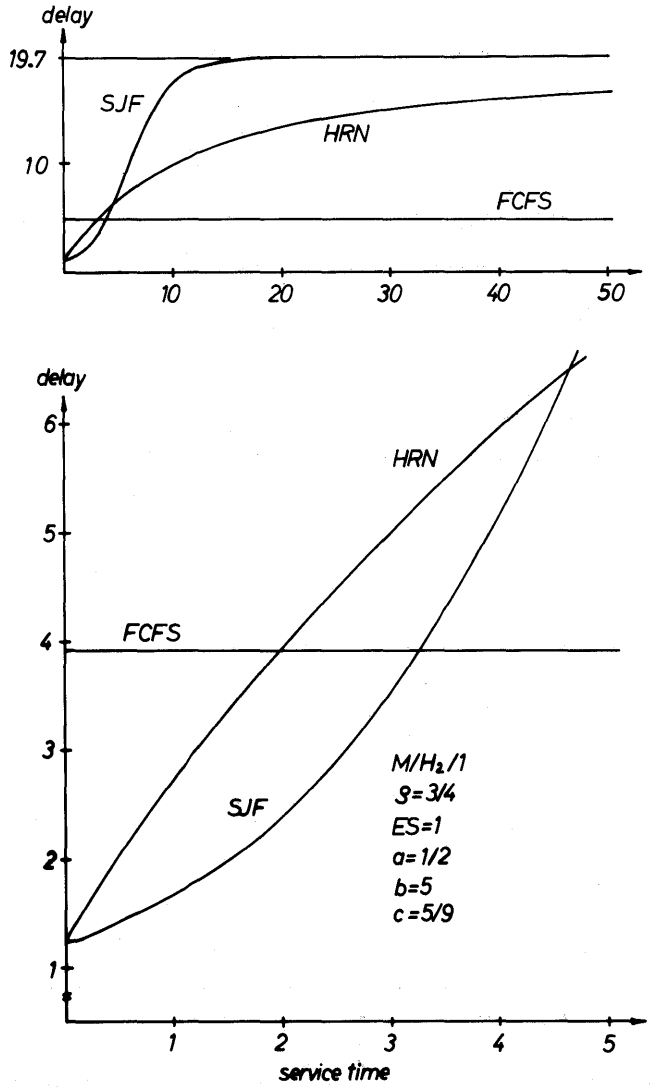

Figure 4—Delay functions for hyperexponentially distributed service times

For the plots in Figure 4 we used the parameters $\mu=1$, $a=\frac{1}{2}$, $b=5$, $c=\frac{5}{9}$, and $\rho=\frac{3}{4}$; L was set to 17. Again, the delay functions of FCFS and SJF are also plotted. The average overall delay of HRN is 2.53 as opposed to 4.92 for FCFS and 2.06 for SJF.

In his paper defining the HRN scheduling scheme,[1] Brinch Hansen also developed an appealingly simple approximation for the delay in an M/H_2/1 system:

$$W(x)=\begin{cases} W_0+x\rho^2/(2(1-\rho)), & x\leq 2W_0/\rho; \\ W_0/[(1-\rho)(1-\rho+2W_0/x)], & x>2W_0/\rho. \end{cases}$$

This approximation was plotted for a load of $\rho=0.71$ and the parameters $a=0.11$, $b=0.21$, and $c=1.88$ which roughly describe a service time distribution which was observed at the University of Michigan.[5] For comparison, we plot the exact solution for this distribution and load in Figure 5 (we set $ES=1$ which determined $L=47$). Again, we also plot the delays for FCFS and SJF. The average overall delay for

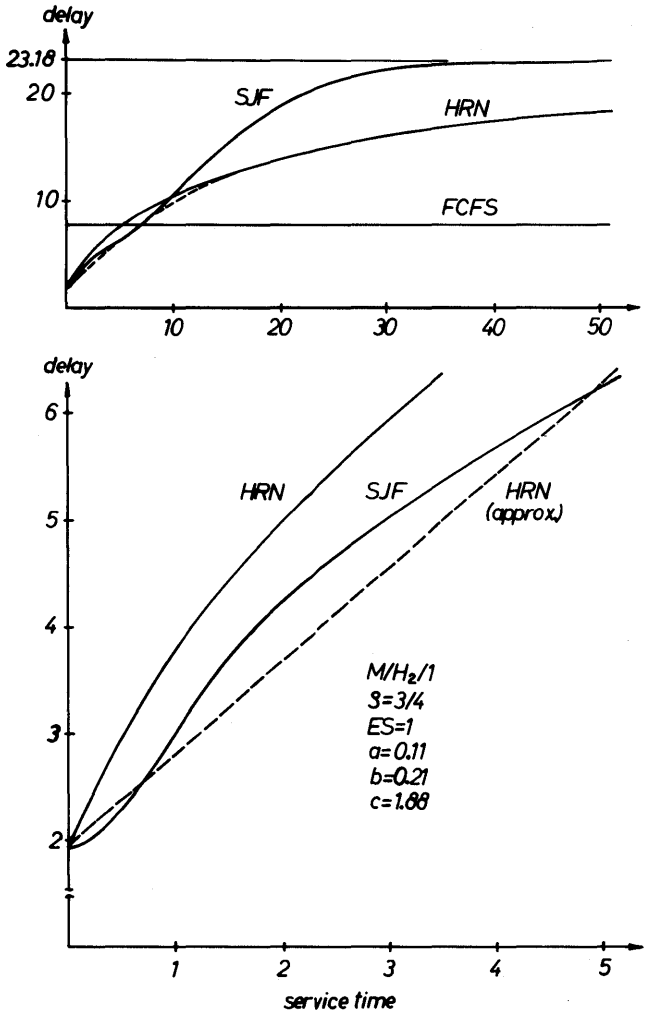

Figure 5—Delay functions for a service time distribution observed at the University of Michigan

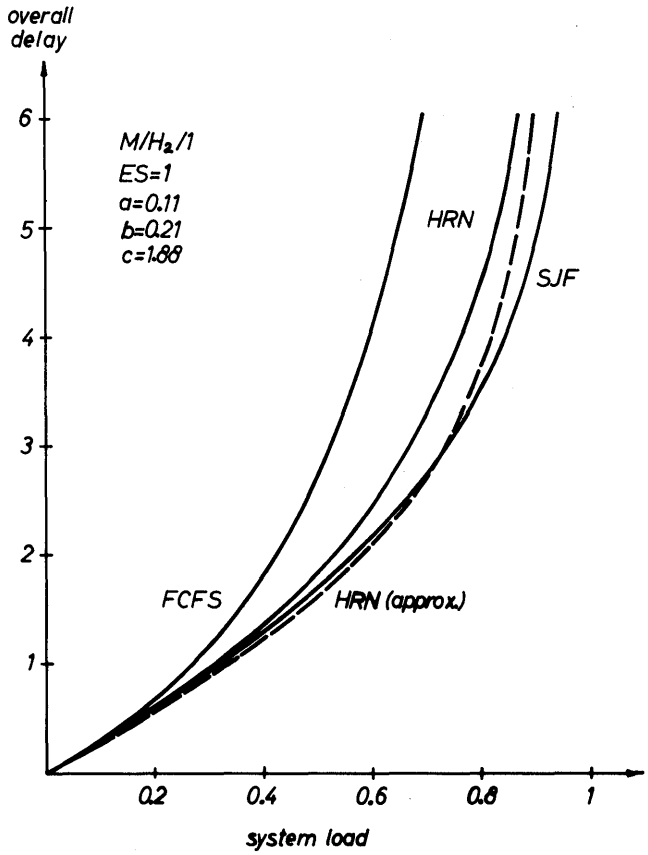

Figure 6—Load-dependency of the overall delay under HRN, SJF, and FCFS

HRN is 3.34 compared to 5.80 for FCFS and 2.84 for SJF. Figure 5 demonstrates the usefulness of the approximate HRN delay function as a rough design tool. Note however, that this function approximates SJF more closely than HRN for service times of up to several times their mean value of one unit of time. This explains why the approximation for the overall average delay W as derived in Reference 1,

$$W=W_0+\rho^2/[2\mu(1-\rho)], \tag{33}$$

evaluates to 2.82, a value which is actually smaller than the overall average delay of 2.84 in the SJF discipline. Figure 6 depicts overall average delays for the University of Michigan distribution as a function of the system load. The broken curve corresponds to equation (33). The solid curves illustrate the load dependencies of the FCFS, the HRN, and the SJF disciplines. While the average overall delay under HRN is necessarily longer than that under SJF, it is still considerably shorter than the overall delay under FCFS. In addition to the preferential treatment of long jobs under HRN as compared to the SJF scheme (which is illustrated by their respective delay functions), the load dependency of the overall delay is a further indication of the superior characteristics of the HRN discipline in a batch-processing environment.

CONCLUSION

The highest response-ratio next (HRN) discipline was first suggested by Brinch Hansen[1] as an attractive alternative to the first-come first-serve (FCFS) and shortest-job-first (SJF) disciplines on which the most common batch-processing algorithms are based. He also formulated an integro-differential equation for the delay function and derived an approximate solution for systems with Poisson job arrivals and hyperexponentially distributed service times.

We redeveloped this integro-differential equation in order to both keep this article self-contained and to present our slightly different derivation technique. We then derived an exact solution for this equation by reducing it to a linear differential equation of the second order. This solution, the delay function for the HRN scheme in equation (25), is valid for Poisson arrivals and arbitrary service time distributions. For general service time distributions, the delay function cannot be expressed in terms of elementary functions. For some simple distributions, however, the integral in the delay function yields to an analytic treatment. As an example of such a simple distribution for which the delay function can be expressed by elementary functions, we presented the case of constant service times. In general, a combination of numerical and analytical methods must be employed to evaluate the delay function. We discussed these hybrid methods and plotted the delay functions for hypoexponentially, exponentially, and hyperexponentially distributed service times. Brinch Hansen's approximation for hyperexponentially distributed service times[1] was compared with our exact result and its accuracy was discussed.

The predominant advantage of the HRN scheme is that it resembles the SJF scheme with respect to the preferential treatment of short jobs without causing the latter's excessive delays for longer jobs. While the average overall delay under HRN is slightly longer than that under SJF, it is still considerably shorter than that under FCFS. Intuitively, these characteristics should be expected as a consequence of the definition of the HRN scheme, but there have been no quantitative measures with the exception of Brinch Hansen's approximate results which are limited to hyperexponential distributions. Our analysis provides the designer with such a quantitative measure which can readily be used to evaluate the performance characteristics of a system under HRN for a given (or anticipated) distribution and load.

ACKNOWLEDGMENT

The author would like to thank his colleagues Bob Vichnevetsky and Jerry Richter for many stimulating discussions concerning the evaluation of delay functions for general service time distributions.

Derivation of equilibrium and time-dependent solutions to M/M/∞//N and M/M/∞ queueing systems using entropy maximization*

by JOHN E. SHORE
Naval Research Laboratory
Washington, DC

INTRODUCTION

Queueing theory has provided the basis for remarkable successes in the performance modeling and analysis of computer systems.[6,19,21] Because it is clear that computer systems do not satisfy assumptions made by the stochastic process models that are used, this success has been somewhat puzzling; it appears that queueing theory equations have wider applicability than is suggested by their classical derivations. Buzen has offered one possible explanation in terms of "operational analysis."[4] In this paper we point out that certain results in elementary queueing theory can be derived simply and with relatively few assumptions by means of entropy maximization. This entropy maximization viewpoint provides the basis of another possible explanation for the widespread applicability of queueing theory formulas.

Analysis by means of entropy maximization has been of interest since Shannon[24] showed, for discrete noiseless systems, that the best encoding of an information source, in the sense of enabling the highest information rate over a fixed capacity channel, is the one that maximizes the source entropy. In addition to continuing applications in communication theory, there has been a growing interest in the use of entropy maximization techniques for probabilistic analysis and problem solving in other fields. Much of this work has been stimulated by that of E. T. Jaynes. Detailed discussions concerning the motivation, justification, and validity of various entropy maximization techniques are available elsewhere.[3,9,12–15,17,26,27] There have been applications in statistical mechanics,[10,11,16] traffic networks,[3,8] reliability estimation,[27] production line decision making,[13,29] system simulation,[5] statistics,[9,20,22] spectral analysis,[1] image reconstruction,[30] and general probabilistic problem solving.[12–15,17,28]

After summarizing the entropy maximization technique in the second section, we obtain in the third section the maximum entropy solution for the state probabilities of an abstract, general system. All of our results are obtained by specializing this general solution. We make some general remarks about applications in the fourth section, and in the fifth section we apply the model to M/M/∞//N and M/M/∞ queueing systems and show how the classical equilibrium distributions result. In the sixth section we discuss how maximum entropy techniques can be used in deriving time-dependent results. After a preliminary application in which we consider a pure birth process, we derive time-dependent distributions for the M/M/∞//N and M/M/∞ queues. Discussion follows in the last section.

ENTROPY MAXIMIZATION

Given a set of independent propositions $\{S_i\}$ that enumerate all of the possibilities in some situation or problem, and given relevant information that is not expressed directly as probabilities, one frequently wishes to convert this information into suitable probability assignments $p(S_i)$ for each of the propositions. Entropy maximization is a means for doing so. In the usual case, known information is expressed as expectations of suitable functions $f_l(S_i)$ defined on the set of propositions. The entropy

$$H=-\sum_i p(S_i)\log p(S_i) \tag{1}$$

is then maximized subject to the constraints

$$\sum_i p(S_i)=1 \tag{2}$$

$$\sum_i f_l(S_i)p(S_i)=\langle f_l\rangle \qquad (l=1,2,\ldots). \tag{3}$$

The well-known solution is

$$p(S_i)=\exp\left[-\beta_0-\sum_l f_l(S_i)\beta_l\right], \tag{4}$$

where β_0 is a Lagrangian multiplier determined by the normalization constraint (2), and where each β_l is a Lagrangian multiplier determined by a known expectation $\langle f_l\rangle$. If the "partition function"

$$Z=\exp(\beta_0)=\sum_i \exp\left[-\sum_l f_l(S_i)\beta_l\right] \tag{5}$$

* The results in this paper were presented orally at the 1976 IEEE International Symposium on Information Theory.

can be evaluated, then the relationship between each Lagrangian multiplier β_l and its associated constraint $\langle f_l \rangle$ is determined by the equation

$$\langle f_l \rangle = -\frac{\partial \beta_0}{\partial \beta_l} = -\frac{1}{Z}\frac{\partial Z}{\partial \beta_l}. \tag{6}$$

For continuous functions, the appropriate generalization appears to be the maximization of "cross-entropy"

$$H = -\int dx\, p(x) \log [p(x)/q(x)] \tag{7}$$

where $q(x)$ is some "prior" distribution. Like (1), (7) originated with Shannon[25] (Shannon's results for continuous channels and for source rates relative to fidelity evaluations are based on expectations of (7)). Maximization of (7) and related functions is discussed by Good,[9] Kullback,[20] and Kashyap.[17] The term cross-entropy is due to Good.[9] Equation (7) has a discrete analog in cases where a prior distribution is known in addition to the expectations (3) (i.e., given no information about the prior, (1) assumes a uniform prior).

As an example, consider the following problem: It is known that a series of events occurs and that the time between successive events can range between 0 and ∞. It is also known that the average time between successive events is $\langle t \rangle$, i.e., that events occur at the average rate $\lambda = 1/\langle t \rangle$. A function $p(t)$ giving the probability density of the time between events is needed. The result of maximizing entropy subject to the constraint $\int t p(t) dt = \langle t \rangle$ is $p(t) = \lambda e^{-\lambda t}$.[5,28] Thus, when a finite mean is specified, the distribution of inter-arrival times that maximizes entropy is exponential. From the maximum-entropy viewpoint, the term "exponential arrivals" describes processes about which one knows only the average arrival rate. If it is further required that the inter-arrival times are independent, then we are assured of a Poisson process. Derivation by maximum entropy of the full exponential family is discussed by Noonan, et al.[22] and, in a somewhat different form, by Kullback.[20]

MAXIMUM ENTROPY SOLUTION FOR A MODEL SYSTEM

In this section, we will obtain the maximum entropy solution for the state probabilities of an abstract system. All of our later results will be obtained by specializing this general solution. The results presented in this section are similar to those in Reference 14. We consider a system composed of N components, each of which can be in one of two "microstates." A system state S_i is defined as an enumeration of which components are in which microstates. Hence, there are 2^N such system states S_i. If one of the two microstates is specified as the "microstate of interest" (it doesn't matter which one), then we may define the function $n(S_i)$ as

$n(S_i) \equiv$ the number of components that are in the microstate of interest, given that the system is in the system state $S_i (0 \leq n(S_i) \leq N)$.

Let $p(S_i)$ be the probability that the system is in the state S_I. We shall now assume that the expectation of $n(S_i)$ is known, and proceed to maximize the entropy of the distribution $p(S_i)$ given this constraint. Specifically, we shall maximize

$$H = -\sum_{i=1}^{2^N} p(S_i) \log p(S_i)$$

subject to the constraints

$$1 = \sum_{i=1}^{2^N} p(S_i)$$

and

$$\langle n \rangle = \sum_{i=1}^{2^N} n(S_i) p(S_i). \tag{8}$$

In this case, the partition function (5) can be evaluated exactly as follows:

$$\begin{aligned} Z = \sum_{i=1}^{2^N} e^{-\beta_1 n(S_i)} &= \sum_{k=0}^{N} g(k) e^{-\beta_1 k} \\ &= \sum_{k=0}^{N} \binom{N}{k} e^{-\beta_1 k} \\ &= (1 + e^{-\beta_1})^N \end{aligned} \tag{9}$$

In (9), β_1 is a Lagrangian multiplier determined by the constraint (8) and $g(k)$ is the number of system states S_i such that $n(S_i) = k$. The relationship between the multiplier β_1 and the constraint $\langle n \rangle$ can be expressed explicitly by applying (6) to (9). The result is

$$e^{-\beta_1} = \frac{\langle n \rangle / N}{1 - \langle n \rangle / N} \tag{10}$$

Using (9) and (10), one can express the maximum entropy solution (4) for $p(S_i)$ as follows:

$$\begin{aligned} p(S_i) &= (1 + e^{-\beta_1})^{-N} e^{-\beta_1 n(S_i)} \\ &= \left(\frac{\langle n \rangle}{N}\right)^{n(S_i)} \left(1 - \frac{\langle n \rangle}{N}\right)^{N - n(S_i)}. \end{aligned} \tag{11}$$

In deriving (11), we began by maximizing entropy subject to the constraint that the expectation of a function $n(S_i)$ is known. Equation (11) expresses the result explicitly in terms of the function $n(S_i)$ and its known expectation $\langle n \rangle$.

In applying the result (11), we shall be particularly interested in the quantity

$p(k) \equiv$ probability that the system is in any state S_i such that $n(S_i) = k$,

which is obtained easily from (11):

$$\begin{aligned} p(k) &= g(k)(1 + e^{-\beta_1})^{-N} e^{-\beta_1 k} \\ &= \binom{N}{k} (1 + e^{-\beta_1})^{-N} e^{-\beta_1 k} \\ &= \binom{N}{k} \left(\frac{\langle n \rangle}{N}\right)^k \left(1 - \frac{\langle n \rangle}{N}\right)^{N-k} \end{aligned} \tag{12}$$

Thus, given the model system and its constraints, the max-

imum entropy distribution for $p(k)$ is a binomial. This derivation of the binomial distribution was first obtained, in a slightly different form, by Jaynes.[14]

In certain applications, one is interested in the limit $N\to\infty$ while $\langle n\rangle$ remains finite. The result for $p(k)$ in this case is obtained by using standard methods (e.g., see Reference 7, p. 142) to derive an approximation to (12) given $\langle n\rangle \ll N$, yielding

$$p(k)=e^{-\langle n\rangle}\frac{\langle n\rangle^k}{k!}. \tag{13}$$

Another probability of interest is

$p_I \equiv$ probability that any given system component is in the "microstate of interest."

Since there are 2^{N-1} system states that meet the requirement that the given component be in the "microstate of interest," p_I is the sum of $p(S_i)$ over these 2^{N-1} states. The function $n(S_i)$ is restricted to the values $n(S_i)=1,2,\ldots,N$. For a particular value $n(S_i)=k$, there are $\binom{N-1}{k-1}$ system states that contribute to the sum of $p(S_i)$. Thus, using (11), we obtain

$$\begin{aligned} p_I &= \sum_{k=1}^{N}\binom{N-1}{k-1}\left(\frac{\langle n\rangle}{N}\right)^k\left(1-\frac{\langle n\rangle}{N}\right)^{N-k} \\ &= \frac{\langle n\rangle}{N}\sum_{l=0}^{N-1}\binom{N-1}{l}\left(\frac{\langle n\rangle}{N}\right)^l\left(1-\frac{\langle n\rangle}{N}\right)^{N-1-l} \\ &= \frac{\langle n\rangle}{N}. \end{aligned} \tag{14}$$

An equivalent form, in terms of the Lagrangian multiplier β_1, is

$$p_I=(1+e^{\beta_1})^{-1}.$$

GENERAL REMARKS ON APPLICATIONS

In general, application of the foregoing results to a given problem requires two steps: First, one must verify that the abstract system on which our results were based is an accurate representation of what is known about the given problem. Specifically, one must make sure that the set $\{S_i\}$ describes completely the set of possibilities implied by the given problem, and that the extent of additional knowledge is limited to the expectation $\langle n\rangle$ of the function $n(S_i)$. If more is known, then our solutions will be incorrect in the sense that additional information is available but not considered, although the solutions may be useful approximations.[14]

The second step is to identify the relationship between $\langle n\rangle$ (or β_1) and parameters contained in the problem statement so that our results for $p(S_i)$ or $p(k)$ can be expressed in terms of these relevant parameters.

As an example, consider the problem of computing the probability of obtaining k heads in N flips of a coin whose single-toss probability of obtaining a head is p_H. In applying out model system, we identify the jth system component as being in the microstate (heads or tails) that records the outcome of the jth coin toss ($1\leq j\leq N$). Thus, a system state represents a record of the results of each toss and the 2^N-element set $\{S_i\}$ is a complete enumeration of the results obtainable by tossing the coin N times. Since p_H is the same as p_I, the combination of (12) and (14) yields the standard result

$$p(k)=\binom{N}{k}p_H{}^k(1-p_H)^{N-k}.$$

APPLICATION TO THE EQUILIBRIUM SOLUTION OF M/M/∞//N AND M/M/∞ QUEUES

In the notation of queueing theory (Reference 18, p. viii), M/M/∞//N refers to a system of N customers and an "infinite" number of servers (effectively equal to N). Both the interarrival times for each customer and the service times for each server are exponentially distributed. Customers arrive for service at an average rate λ per customer and are served at the average rate μ per server ($1/\mu$ is the average time it takes to complete the service of a customer, after which the customer returns to the state "not being served;" $1/\lambda$ is the average time it then takes for that customer to return to the state "being served"). A server is always available to begin service immediately on any customer who needs it. Recall that the specification of only λ and μ is equivalent, from the maximum entropy viewpoint, to the statement that the interarrival and service time distributions are exponential.

In order to apply our model system, we let each system component represent one of the N customers, each of which can be in the microstate of interest "being served" or in the other microstate "not being served." Thus, the 2^N element set $\{S_i\}$ represents all possible states of the M/M/∞//N queueing system. The function $n(S_i)$ is then the number of customers being served given that the system is in state S_i and the expectation $\langle n\rangle$ may be interpreted as a time average. Conventionally (Reference 18, p. 90), $p(k)$ is defined to be the $t\to\infty$ equilibrium limit of a time dependent probability $p(k,t)$. In this context, the probability p_I is the fraction of time that a given customer spends "being served" in a system that has reached equilibrium. The relationship between $\langle n\rangle$ and the parameters of interest (λ,μ,N) is obtained by noting that the following equality must hold at equilibrium:

$$p_I\mu=(1-p_I)\lambda. \tag{15}$$

Hence, using (14) and (10), we have

$$\frac{\lambda}{\mu}=\frac{\langle n\rangle/N}{1-\langle n\rangle/N}=e^{-\beta_1}. \tag{16}$$

Substitution of (16) into (12) yields the following result for the probability that k customers are being served:

$$p(k)=\binom{N}{k}\left(1+\frac{\lambda}{\mu}\right)^{-N}\left(\frac{\lambda}{\mu}\right)^k. \tag{17}$$

This is the classical answer (Reference 18, pp. 107-108).

For the M/M/∞ system, the situation is the same except that the limit $N\to\infty$ is taken and the arrival rate λ is a total

arrival rate (as opposed to an arrival rate per customer) independent of the number of customers in service. In this case, the equilibrium condition is

$$\mu\langle n\rangle=\lambda, \tag{18}$$

which, when combined with (13), yields the classical M/M/∞ result (Reference 18, p. 101):

$$p(k)=e^{-\lambda/\mu}\frac{(\lambda/\mu)^k}{k!}. \tag{19}$$

Based on work by Beneš,[3] a maximum entropy analysis somewhat similar to the foregoing was made by Ferdinand[8] for the machine servicing problem (M/M/1//N) at equilibrium. In that derivation, however, the relationship between the Lagrangian multiplier and the parameters of interest was obtained by assumption and analogy, rather than by derivation. Specifically, for a system in a state S_i with $n(S_i)=k$, Ferdinand assumed a state "energy" $E(k)=-k\log(\lambda/\mu)$ and was thereby able to eliminate the Lagrangian multiplier by analogy with statistical mechanics. In obtaining (17) and (19), on the other, we eliminated the Lagrangian multiplier by means of (10) and the equilibrium conditions (15) and (18).

TIME DEPENDENT SOLUTIONS

The $\langle n\rangle$-constraint equation (8) can represent knowledge of $\langle n\rangle$ at any particular time; the maximum entropy solutions $p(S_i)$ or $p(k)$ then apply to that time. It was only in the last section that we chose a time ($t\to\infty$) that corresponded, in the queueing systems, to equilibrium values of $\langle n\rangle$. Time-dependent knowledge $\langle n;t\rangle$ of the constraint (8) can therefore be substituted meaningfully into (12) or (13) in order to obtain time-dependent probabilities $p(k,t)$. For example, consider a pure birth process in which customers arrive at a constant, total rate λ from an infinite ($N\to\infty$) customer population. Once having arrived, a customer stays forever. The expected number of customers having arrived therefore grows constantly at the rate λ:

$$\frac{d\langle n\rangle}{dt}=\lambda. \tag{20}$$

By substituting the solution of (20) into Eq. (13), and assuming that no customers have yet arrived at $t=0$, we obtain

$$p(k,t)=e^{-\lambda t}\frac{(\lambda t)^k}{k!},$$

which is the classical result (Reference 18, p. 60).

In the last section, we transformed the general solution (12) for $p(k)$ into specific solutions by relating $\langle n\rangle$ or the Lagrangian multiplier β_1 to the physical constraints λ, μ, and N. We did so by writing down the equilibrium conditions (15) and (18), which we repeat here in more explicit form:

$$\frac{d\langle n\rangle}{dt}=-\mu\langle n\rangle+\lambda(N-\langle n\rangle)=0 \quad \text{(M/M/∞//N)} \tag{21}$$

$$\frac{d\langle n\rangle}{dt}=-\mu\langle n\rangle+\lambda=0 \quad \text{(M/M/∞)} \tag{22}$$

Solving these equations for $d\langle n\rangle/dt\neq 0$ would yield time-dependent functions for the expectation $\langle n;t\rangle$. Both (21) and (22) have the form

$$\frac{d\langle n\rangle}{dt}=\alpha-\varphi\langle n\rangle,$$

which has the general solution

$$\langle n;t\rangle=(\alpha/\varphi)(1-e^{-\varphi t})+\langle n;0\rangle e^{-\varphi t}.$$

For the M/M/∞//N case (21), one has $\alpha=\lambda N$ and $\varphi=\mu+\lambda$ so that

$$\langle n;t\rangle=\frac{\lambda N}{\lambda+\mu}(1-e^{-(\lambda+\mu)t})+\langle n;0\rangle e^{-(\lambda+\mu)t}. \tag{23}$$

By assuming that $\langle n;0\rangle=0$ and substituting (23) into (12), we obtain the following time-dependent solution for the M/M/∞//N queue:

$$p(k,t)=\binom{N}{k}\left(\frac{\lambda}{\lambda+\mu}\right)^k[1-e^{-(\lambda+\mu)t}]^k \times\left[1-\frac{\lambda}{\lambda+\mu}(1-e^{-(\lambda+\mu)t})\right]^{N-k}.$$

This result appears not to be well-known among queueing theorists, although it can be derived from a well-known result in reliability theory (Reference 2, p. 78).

For the M/M/∞ case (22), one has $\alpha=\lambda$ and $\varphi=\mu$, so that

$$\langle n;t\rangle=(\lambda/\mu)(1-e^{-\mu t})+\langle n;0\rangle e^{-\mu t}. \tag{24}$$

By assuming that $\langle n;0\rangle=0$ and substituting Eq. (25) into (13), we obtain the following time-dependent solution for the M/M/∞ queue:

$$p(k,t)=\frac{1}{k!}\left(\frac{\lambda}{\mu}\right)^k(1-e^{-\mu t})^k\exp\left[-\frac{\lambda}{\mu}(1-e^{-\mu t})\right].$$

This is the classical solution, which can be derived from a slightly more general result given by Saaty (Reference 23, pp. 99-100).

DISCUSSION

In what sense does the maximum entropy distribution for our model system relate to observations made on corresponding real systems? Jaynes[14] has shown that the maximum entropy distribution is related to observed frequencies in the following sense: Given the imposed constraints, the maximum entropy distribution can be realized experimentally in overwhelmingly more ways than any other distribution. Thus, if the analysis includes all of the experimentally operative constraints, then the maximum entropy distribution is overwhelmingly the most likely distribution to be observed experimentally.

In general, one can consider experimental confirmation of a maximum entropy distribution as evidence that the operative physical constraints have been accounted for properly in the maximum entropy analysis. Conversely, major discrepancies between an experimentally observed distribution

and a corresponding maximum entropy distribution is evidence that important physical constraints have been overlooked.[14] When a maximum entropy analysis does not include all of the operative physical constraints, the maximum entropy distribution may still be a useful approximation. The accuracy of the approximation will depend on the importance of the ignored constraints.

In the case of the queueing formulas derived in this paper, we should expect them to apply when a real system's states correspond to those of the model ($\{S_i\}$) and when the system's dynamics are most strongly dependent on the constrained mean value $\langle n \rangle$ determined by the stated equilibrium conditions. If these criteria are satisfied, then the system need not satisfy other assumptions that may be made in classical derivations of the queueing formulas. The maximum entropy viewpoint may therefore explain the surprisingly widespread applicability of queueing theory results.

The cycle time of a class of closed queueing network models

by WE-MIN CHOW
IBM Thomas J. Watson Research Center
Yorktown Heights, New York

INTRODUCTION

Computer system performance is usually evaluated by its degree of congestion. Hence analysis of queueing network plays an important role in this area. Since in a computer system there are two types of participants—processors and jobs—degree of congestion is usually studied from two different aspects accordingly. In addition to system throughput, processor utilization and queue size, system users would particularly be concerned with their own response times. Many fruitful results in network queues have been presented in previous works,[1-4] where queue size distributions were derived. Based upon these distributions, one can easily calculate throughput, utilization and even average response time. However, little knowledge about response time distribution is available. In this paper, we consider a central server type of queueing system and investigate equilibrium behavior of job's cycle time under certain simplified assumptions. Derivations of equations and theorem proofs can be found in References 5-10, and hence are omitted here.

A central server queueing system is a closed network consisting of a single central server and k parallel servers. A job starts his cycle at the time that he enters the queue of the central server (central queue). After having received service from the central server, the job will join one of queues in front of parallel servers (parallel queues) according to a probability distribution. When the job leaves the parallel server, he will re-enter the central queue and at this moment a cycle has just been completed. Considered in the following is a simple central server queueing system serving N identical jobs. Servers are assumed to have independent exponential service time with FIFO queueing discipline. All parallel servers are identical. Without losing generality, it is further assumed that at time $t=0$ a tagged job is about to join the central queue and the system is in equilibrium.

Define

λ=service rate of the central server
μ=service rate of parallel servers
C=cycle time

$$N_i(t)=\begin{cases}\text{number of jobs in the central server at time } t, & i=0,\\ \text{number of jobs in the } i\text{th parallel server at } t, & i=1,\ldots,k.\end{cases}$$

$\bar{N}(t)=(N_0(t),\ldots,N_k(t))$, system state at time t
$p_m{}^i(t;\bar{n})=P[N_i(t)=m \mid \bar{N}(0^+)=\bar{n}]$
$q(\bar{n})=P[\bar{N}(0^+)=\bar{n}]$
$f(t,k)$=cycle time density with k parallel servers.
$\{U_j\}$=exponential random variables with a rate λ
$\{V_j\}$=exponential random variables with a rate μ

$$T(m)=\sum_{j=1}^{m} U_j$$

$$H=\{\bar{n} \mid \sum_{i=0}^{k} n_i=N,\ n_i\geq 0,\ \forall i=0,\ldots,k\}$$

$$H_1=\{\bar{n} \mid \sum_{i=0}^{k} n_i=N,\ n_0\geq 1,\ n_i\geq 0,\ \forall i=1,\ldots,k\}$$

Given that $\bar{N}(0^+)=\bar{n}$ and the system enters state $\bar{m}=(m_0,\ldots,m_k)$ after a random time $T(n_0)$, with probability $1/k$ the tagged job would join the i parallel queue and then his conditional cycle time is defined by

$$C=T(n_0)+\sum_{j=1}^{m_i} V_j \tag{1}$$

In order to find the distribution of C, it suffices to evaluate $q(\bar{n})$ and $P_m{}^i(t;\bar{n})=P[N_i(t)=m \mid \bar{N}(0^+)=\bar{n}]$.

QUEUE SIZE DISTRIBUTION

By using Gordon and Newell's formula,[2]

$$P[\bar{N}(0^+)=\bar{n}]\propto\left(\frac{1}{\lambda}\right)^{n_0}\prod_{j=1}^{k}\left(\frac{1}{k\mu}\right)^{n_j},\ \forall \bar{n}\epsilon H$$

where $\propto$ is read as "is proportional to" it then can be shown[9]

that

$$q(\bar{n}) \propto \left(\frac{1}{\lambda}\right)^{n_0-1} \prod_{j=1}^{k} \left(\frac{1}{k\mu}\right)^{n_j}$$

or

$$q(\bar{n}) = G^{-1} \left(\frac{1}{\lambda}\right)^{n_0-1} \left(\frac{1}{k\mu}\right)^{N-n_0}, \quad \forall \bar{n} \in H_1, \tag{2}$$

where

$$G = \sum_{\bar{n} \in H_1} \left(\frac{1}{\lambda}\right)^{n_0-1} \left(\frac{1}{k\mu}\right)^{N-n_0}.$$

Note that $q(\bar{n}) = q(\bar{m})$ if $n_0 = m_0$. The state space H_1 may be reduced to one dimension by considering $N_0(t)$ only. (This will be discussed later).

To evaluate the conditional probability

$$p_m{}^i(t;\bar{n}) = P[N_{i(t)} = m \mid \bar{N}(0^+) = \bar{n}]$$

we look into the arrival process to a parallel server. The following lemma are due to the fact of exponential service distribution.

Lemma 1[8,9]

Given that $T(n) = \sum_{j=1}^{n} U_j = s$, where U's are *iid* exponential random variables, then the conditional joint distribution of partial sums $\{T(m) \mid m = 1, \ldots, n-1\}$ are uniform over $(0,s)$.

The above statement asserts that conditioning on $\{N_0(0^+) = n$ and $T(n) = s\}$, the first $(n-1)$ departures epochs from the central server (hence the arrival epochs to parallel servers) form a uniform order statistics ranged over $(0,s)$. Since each departure randomly selects his own parallel server, one would expect that the arrival epochs as seen by each parallel server would also be a set of uniform order statistics.

Lemma 2[10]

Given that in the central server queueing system

(i) $N_0(0^+) = n_0$,
(ii) $T(n_0) = s$ and
(iii) during the period $(0,s)$, $w_i (< n_0)$ jobs enter the i parallel server,

then these w_i arrival epochs form a uniform order statistics ranged over $(0,s)$.

The probability distribution of condition (i) is given by (2). Due to exponential assumption, $T(n)$ has an Erlanigian distribution, i.e.,

$$P[T(n) \le t] = \Gamma(t \mid n,\lambda) = \int_0^t \frac{(\lambda u)^{n-1}}{(n-1)!} e^{-\lambda u} \lambda \, du \tag{3}$$

Furthermore, since parallel servers are identical, condition (iii) is subject to a binomial distribution, i.e.,

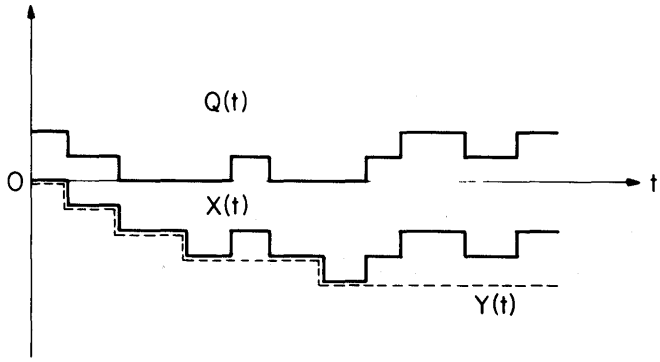

Figure 1—Queue size is characterized by $X(t)$

$$P[W_i(n,s) = w \mid N_0(0^+) = n, T(n) = s] = B(w_i \mid n-1,k) = \binom{n-1}{w_i} \left(\frac{1}{k}\right)^{w_i} \left(1 - \frac{1}{k}\right)^{n-w_i-1}, \quad w_i = 0, 1, \ldots, n-1, \tag{4}$$

where $W_i(n,s)$=number of jobs entered the ith parallel server during $(0,s)$.

By virtue of (2), (3), (4) and Lemma 2, the arrival process to each individual parallel server during the random interval $T(N_0(0^+))$, can be characterized.

Now we investigate transient queueing behavior of parallel servers from which the conditional queue size distribution $P_m{}^i(t;\bar{n})$ is derived.

Consider a single exponential server. Let $A(t)$ be the arrival process and $D(t)$ be the "potential departure process" (departure process when the server is never empty). Hence, $D(t)$ is a counting process such that the interval between successive events is exactly a service time. For a given initial condition the queue size can be characterized by $A(t)$ and $D(t)-$ (see Figure 1).

Lemma 3[5,6,9]

Let $X(t) = A(t) - D(t)$ and $Y(t) = \inf_{0 \le u \le t} X(u)$. Then the queue size $Q(t)$ is given by

$$Q(t) = X(t) + \text{Max}\{Q(0), -Y(t)\} \tag{5}$$

Lemma 4[9]

Let $0 \le S_1 \le \ldots \le S_v \le s$, and $0 \le T_1 \le \ldots \le T_w \le s$ are two independent sets of uniform order statistics over $(0,s)$. Define $Z(t)$ as a one dimension random walk such that (see Figure 2).

$$Z(0) = 0,$$
$$Z(S_i{}^+) = Z(S_i{}^-) - 1,$$
$$Z(T_i{}^+) = Z(T_i{}^-) + 1 \text{ and}$$
$$Z(s) = w - v.$$

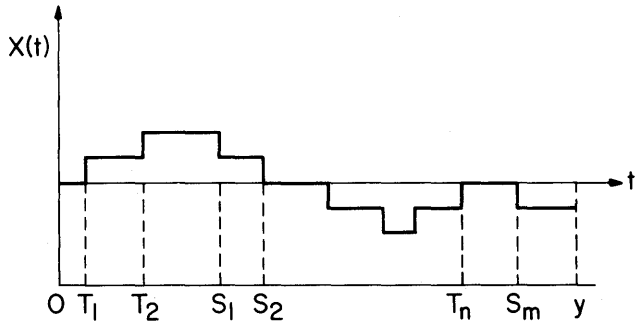

Figure 2—A realization of $X(t)$

Then every realization of the imbedded chain defined by $Z(t)$ at $t=S_i$ or T_i has the same probability $\binom{w+v}{w}^{-1}$.

As far as a parallel server is concerned, $D(t)$ is a Poisson process with a rate μ. It is well-known that the conditional potential departure epochs $\{S_i=\sum_{j=1}^{i} V_j,\ i=1, \ldots, v-1\}$ are uniform order statistics between 0 and s, given that $D(s)=v$. On the other hand, Lemma 2 showed that given (i), (ii) and (iii), the conditional arrival epochs $\{T_1, \ldots, T_w\}$ are also uniform order statistics. In view of Lemmas 3 and 4, we conclude that given $\{N_0(0)=n_0,\ T(n_0)=s,\ A(s)=w,\ D(s)=v\}$, every path defined by $X(t)$ as an imbedded chain for $0\leq t\leq s$ has the same probability.

The reflection principle[7] allows us to verify that the number of paths of a random walk $X(t)$ from (0,0) to (y,u) which cross or touch the line $X(t)=-r$ is equal to the number of paths from $(0,-2r)$ to (y,u) (see Figure 3). Let w (or v) be the number of increments (or decrements) in $X(t)$ by time $t=s$. The total number of possible paths is equal to $\binom{w+v}{w}$ and the number of paths cross or touch the line $X(t)=-r$ is then $\binom{w+v}{w+r}$. Since each path can be realized with an equal chance, the probability

$$P[X(y)\leq -r, \text{ some } y\epsilon(0,s)]=\frac{\binom{w+v}{w+r}}{\binom{w+v}{w}}$$

By definition $Y(t)=\inf_{0\leq y\leq t} X(y)$, it follows that

$$P[Y(s)>-r]=P[X(y)>-r, \text{ for all } y\epsilon(0,s)]$$

$$=1-\frac{\binom{w+v}{w+r}}{\binom{w+v}{w}} \tag{6}$$

By using Lemma 3 and equation (6), it is not difficult to show the following theorem:

Theorem 1[9]

$$P[N_i(s^-)=m_i \mid \bar{N}(0^+)=\bar{n},\ T(n_0)=s,\ W_i(n_0,s)=w_i]$$
$$=r(\mu s, n_i-m_i+w_i)$$
$$-\frac{R(\mu s, n_i+w_i+1)(w_i-m_i-\mu s)w_i!}{(\mu s)^{m_i+1}(w_i-m_i)!}$$
$$=A(m_i \mid n_i, w_i, s, \mu)$$

where

$$r(u,n)=e^{-u}\frac{u^n}{n!}$$

and

$$R(u,n)=\sum_{v=n}^{\infty} e^{-u}\frac{u^v}{v!}.$$

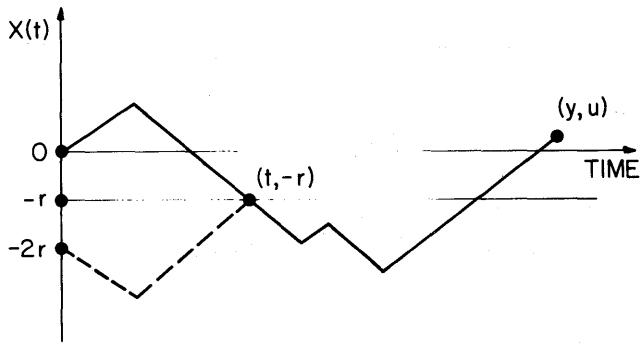

Figure 3—Reflection of $X(t)$

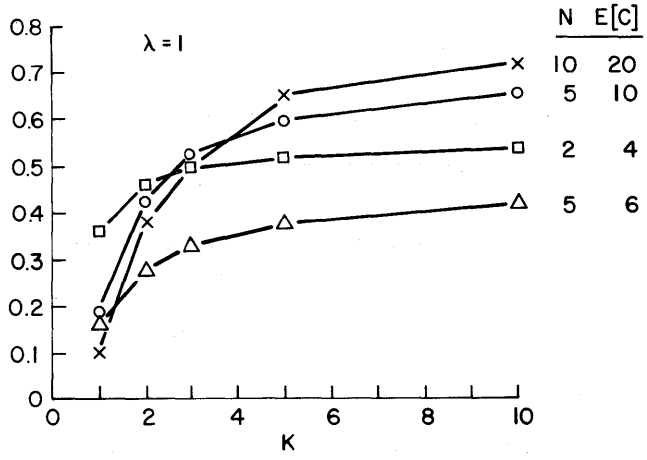

Figure 4—VAR[C]/($E[C]$)^2 when $\lambda=1$

CYCLE TIME

According to equation (1), the conditional cycle time distribution is given by

$$P[C \le t \mid \bar{N}(0)=n,\ T(n_0)=s,\ W(n_0,s)=\bar{w}]$$

$$=\sum_{i=1}^{k}\sum_{m_i=0}^{n_i+w_i}\Gamma(t-s \mid m_i,\mu)\cdot A(m_i, \mid n_i w_i,s,\mu)\cdot\frac{1}{k} \quad (7)$$

Note that since parallel servers are identical, this equation can be simplified. By symmetry the first summation and the factor $1/k$ can be deleted. From this equation, together with (2), (3), (4), and Theorem 1, we can show the following:

Theorem 2[10]

The cycle time density

$$f(t;k)=V^{-1}\sum_{n=0}^{N-1}\sum_{m=0}^{n}\sum_{i=0}^{N-n-1}(k-1)^{n-m}U(k,n,i)$$

$$\left(\frac{\mu}{\lambda}\right)^{n}\Bigg\{r(\mu t,i+m)R(\lambda t,n+1)\binom{n}{m}$$

$$-[r(\mu t,m-1)-r(\mu t,m)]$$

$$[R((\lambda-\mu)t,n-m+1)\lambda^{n+1}(\lambda-\mu)^{m-n-1}\mu^{-m}$$

$$-\sum_{j=0}^{i+m}\left(\frac{\lambda}{\mu}\right)^{m-j}\binom{n+j-m}{j}R(\lambda t,n+j-m+1)]\Bigg\} \quad (8)$$

where

$$V=\frac{1}{\mu}\sum_{j=0}^{N-1}\binom{k+n-i-2}{N-i-1}\left(\frac{\mu}{\lambda}\right)^{i}$$

$$U(k,n,i)=\begin{cases}1, & \text{if } k-1\\ \binom{N-n-i-3+k}{N-n-i-1}, & \text{otherwise}\end{cases}$$

The expected cycle time is

$$E[C]=\frac{N}{\lambda}\left\{1-\frac{\binom{N+k-1}{N}}{\sum_{i=0}^{N}\binom{N+k-1-i}{N-i}\left(\frac{k\mu}{\lambda}\right)^{i}}\right\}^{-1} \quad (9)$$

LIMITING CASES

As mentioned earlier, the state space

$$H_1=[\bar{n} \mid n_0\ge 1,\ n_i\ge 0\ i=1,\ldots,k,\ \sum_{i=0}^{k} n_i=N\}$$

may be reduced to one dimension. Equation (2) implies that

$$P[N_0(0^+)=m]=q(m)$$

$$=\sum_{\bar{n}\ni n_0=m} q(\bar{n}).$$

Hence,

$$q(m)\propto\binom{N-m+k-1}{N-m}\left(\frac{1}{\lambda}\right)^{m-1}\left(\frac{1}{k\mu}\right)^{N-m},\ m=1,2,\ldots,N.$$

Machine Repairman Model, $K=\infty$

If $K=\infty$, it can be shown that

$$q(m)\propto\left(\frac{1}{\lambda}\right)^{m-1}\left(\frac{1}{\mu}\right)^{N-m}\frac{1}{(N-m)!},\ m=1,\ldots,N.$$

and $B(w_i \mid n,\infty)=1$, iff $w_i=0$, for all $i=1,2,\ldots$

The cycle time density becomes

$$f(t;\infty)=\left(\frac{\rho}{\rho-1}\right)^{N}\left(\sum_{i=0}^{N-1}\frac{\rho}{i!}\right)^{-1}$$

$$\mu e^{-\mu t}\left\{\sum_{i=0}^{N-1}\frac{(\rho-1)^i}{i!}[i-(1-\mu t)^i e^{-(\lambda-\mu)t}]\right\} \quad (10)$$

where $\rho=\lambda/\mu$.

Cyclic Queueing Mode, $k=1$

For $k=1$,

$$q(m)\propto\left(\frac{1}{\lambda}\right)^{m-1}\left(\frac{1}{\mu}\right)^{N-m},\ m=1,\ldots N,$$

$$B(w \mid n,1)=1, \text{ iff } w=n-1.$$

The cycle time density becomes

$$f(t;1)=\frac{\mu^N}{\mu^N-\lambda^N}\lambda e^{-\lambda t}\frac{(\lambda t)^{N-1}}{(N-1!)}$$

$$+\frac{\lambda^N}{\lambda^N-\mu^N}\mu e^{-\mu t}\frac{(\mu t)^{N-1}}{(N-1!)} \quad (11)$$

DISCUSSION

In a computer model the central server and parallel servers are usually interpreted as a CPU and k I/O processors, respectively. Therefore, a job's cycle time is equivalent to the interval between his two successive I/O completions. When the number of I/O processors is increased, the system becomes less congested. If the multiprogramming level, the CPU rate and the mean cycle time are fixed, it can be seen from Figure 4 that the ratio of variance to squared mean (V/E)

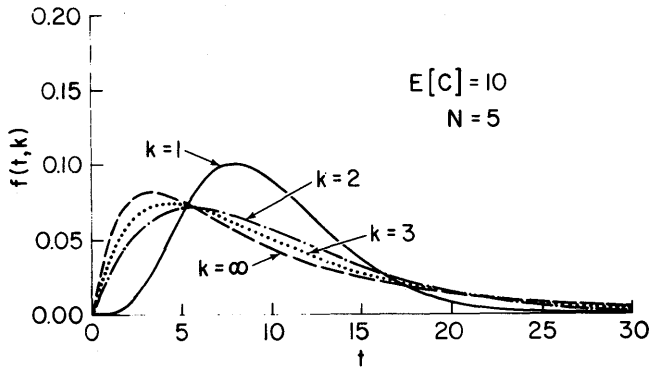

Figure 5—Cycle time densities for different K

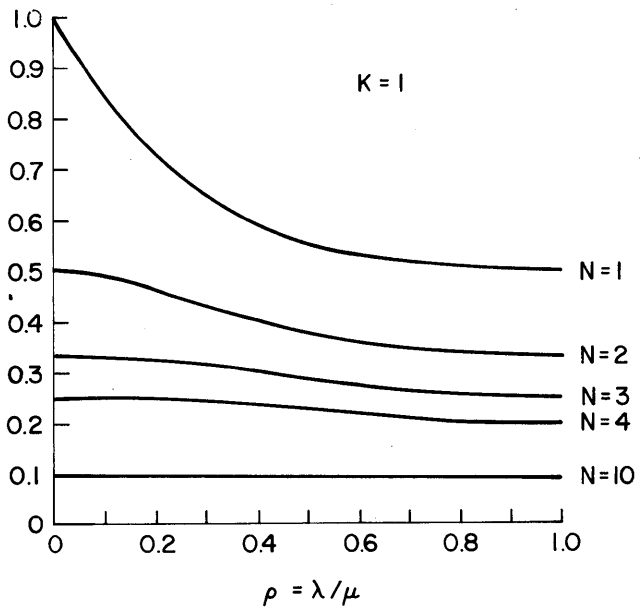

Figure 6—VAR[C]/| $E[C]$ |^2 when k=1 (cyclic queueing model)

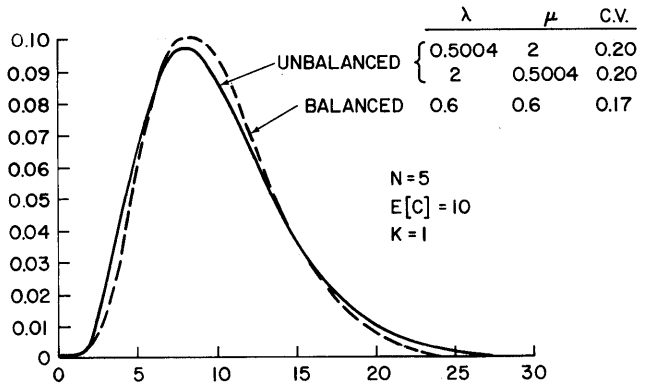

Figure 7—Cycle time densities of cyclic queueing model

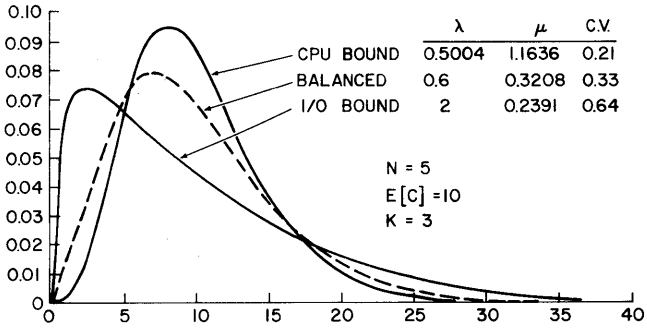

Figure 8—Cycle time densities of central server model

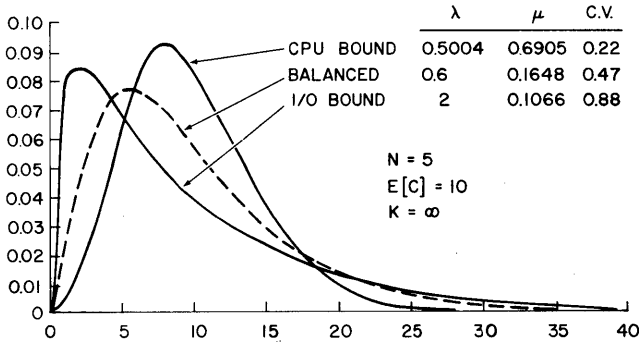

Figure 9—Cycle time densities of machine repairman model

of cycle time is increasing in k. Also, illustrated in Figure 5 is the fact that degree of skewness of cycle time density is reduced if the parameter k is.

When k=1, the cycle time behavior would remain the same if and are interchanged. It can be shown that

$$V/E=\frac{N+1}{N}\cdot\frac{(1-\rho^{N+2})(1-\rho^{N})}{(1-\rho^{N+1})^2}-1, \tag{12}$$

where $\rho=\lambda/\mu$.

This ratio takes its minimum at ρ=1, and is monotonically increasing in ρ for $\rho>1$ (hence decreasing in ρ for $\rho<1$). In other words, the cycle time is more regular in a balance system (i.e., CPU and I/O have compatible processing speeds). However, in a congested system random fluctuation of the cycle time is reduced and its regularity becomes insensitive when ρ changes. As shown by (12), for any positive ρ, $V/E\to 0$ as $N\to\infty$. (See also Figure 6). In fact it is easy to show that

$$f(t;1)=\lambda e^{-\lambda t}\frac{(\lambda t)^N}{N!}, \text{ if } \lambda=\mu \text{ and}$$

$$f(t;1)\to\theta e^{-\theta t}\frac{(\theta t)^{N-1}}{(N-1)!}, \text{ as } N\to\infty$$

where $\theta=\min(\gamma,\mu)$.

TABLE I.—V/E Ratio When N=5 and $E[C]$=10

k		CPU BOUND 0.5004	BALANCED 0.6	I/O BOUND 2
1	μ	2	0.6	0.5004
	V/E	0.20	0.17	0.20
2	μ	1.399	0.393	0.305
	V/E	0.203	0.28	0.51
3	μ	1.164	0.321	0.239
	V/E	0.206	0.33	0.64
5	μ	1.002	0.261	0.186
	V/E	0.21	0.38	0.76
∞	μ	0.691	0.165	0.107
	V/E	0.22	0.47	0.88

For $k>1$, analysis of cycle time is very much complicated. We turn to look at numerical results. Considered are three cases: CPU bound, balanced and I/O bound. For $N=5$ and $E[C]=10$, it is found that V/E ratio decreases as CPU becomes busy. (See Table I. Note that in cyclic queueing model balanced system has the smallest V/E ratio). Figures 7, 8 and 9 present cycle time densities when $k=1$, 3, and ∞, respectively. When CPU is congested, both the machine repairman model and the central server model have less skew densities.

Network access technology—A perspective*

by SHIRLEY WARD WATKINS and STEPHEN R. KIMBLETON
National Bureau of Standards
Washington, DC

INTRODUCTION

The utility of computer networking is widely accepted, as is the complexity of accessing network resources and services. This complexity must be reduced to support more effective user access to and utilization of these resources as discussed in References 1 through 3. Accomplishing this reduction across heterogeneous systems is a primary objective of network access support. Specific capabilities which have currently been shown to be feasible include: "macros" which permit the user to invoke via a single directive a complex of individual system and/or communications subnetwork commands which collectively accomplish a specific and common function such as "login;"[4,5] common command languages for file manipulation and network job execution across a heterogeneous collection of systems;[6] "soft" user interfaces providing command completion, spelling correction, and, potentially, correction of minor syntactic errors;[4,7,8] uniform interfaces to similar services existing on diverse systems such as bibliographic retrieval services;[9,10] and the emergent area of "intelligent assistance."[5]

Currently, there are several ongoing projects providing varying degrees and types of network access support for the interactive user—the population of interest in this paper. Appreciating the functions provided by these efforts and determining additional functions necessary to maximize access support requires establishment of a basic perspective on network access. The global objective of this paper is to provide such a perspective. This will be accomplished through: (i) identifying related research efforts; (ii) identifying problems inhibiting network access support development for the appropriate user categories; and (iii) structuring and discussing the major components of such support. One of the key components of this structure, expert assistance, shields the user from the requirement of learning yet another language—that of the access system. Expert assistance eliminates the requirement that the user become an 'expert' on the access system in order to obtain simplified access to the target system. The sixth section of this paper provides insight into how this goal may be achieved.

Rand Intelligent Terminal Agent (RITA)

The Rand Intelligent Terminal Agent (RITA) has initially been implemented on a shared minicomputer. This implementation is based on production systems (sets of condition-action rules) to encode complex sets of heuristics for handling interactions with users and with external systems.[5,11,12] RITA performs complex time-dependent tasks over extended periods of time with minimal intermediate user input. This is accomplished through user agents (processes operating in behalf of the user). Since the productions systems can modify themselves, RITA agents can learn in the sense of dynamically modifying their behavior.

Two considerations reflected in the design of RITA are that the agents maintain knowledge bases containing heuristic assertions, data reflecting system behavior, and user preferences, and that these knowledge bases must be modifiable by the user. The adaptive behavior of RITA agents represents a sophisticated approach to the area of access assistance.

NBS Network Access Machine (NAM)

The Network Access Machine (NAM) at the National Bureau of Standards is implemented on a PDP 11/45 running the UNIX operating system and represents another shared minicomputer based approach to aiding the network user.[1,3,13,14] Such support is provided through three primary mechanisms: macros which support expansion of simple user-entered commands into the command sequences executable on specific networks and host computers connected to the network; a response analyzer allowing alternative responses (typically the expected response plus error conditions which could occur) during the expansion of a macro; and control mechanisms (case statements, if-then- else, . . .). Collectively, these mechanisms constitute a command language level programming language.

The NAM design is based on the concept of presenting one uniform set of user commands which are executable

Partial funding for the preparation of this paper was provided by the U.S. Air Force Rome Air Development Center (RADC) under Contract No. F 30602-77-F-0068. Certain commercial products are identified in this paper in order to adequately specify the procedures being described. In no case does such identification imply recommendation or endorsement by the National Bureau of Standards, nor does it imply that the material identified is necessarily the best available for the purpose.

across network boundaries and across heterogeneous host systems. In operation, user commands are first expanded into the command sequence appropriate to the system being accessed, responses are analyzed to determine if the interaction is proceeding as expected, anticipated errors are handled directly, and unanticipated errors are presented to the user for handling. These capabilities have proven sufficiently powerful to support implementation of a prototype common command language for file manipulation and network job execution.[6] In addition, a uniform interface to a collection of bibliographic data retrieval systems has also been demonstrated.[10]

Service specific access support

The use of computer networks has stimulated interest in providing a homogeneous (virtual) interface to multiple heterogeneous resources. One such effort has been pursued by Marcus at MIT in the information services community.[9,15] Access to heterogeneous bibliographic retrieval systems is provided in such a way as to make them appear similar. There are three distinguishing features of this implementation: emphasizing a particular application, providing a uniform virtual interface to heterogenous systems such that all systems appear uniform to the user, and stressing access support to the naive user.

The initial interface, called CONIT (Connector for Networked Information Transfer), is based on the MULTICS system at MIT. Support includes a master index and thesaurus to store the vocabulary of the separate data bases along with index term interrelationships. In addition, the user is provided with a common bibliographic data structure in which data elements are structured and interrelated among different data bases. Once the desired retrieval system is selected, the user enters common commands which are then translated into the specific commands required on the selected retrieval system. The approach has been demonstrated using the ARPANET for access to the National Library of Medicine MEDLINE service and the MIT Intrex retrieval system.

PROBLEMS IN AUTOMATING SERVICE ACCESS

The objective of network usage is access to computer resources or services. Service, here, refers to programs or combinations of programs provided by a computer system: for example, assemblers, compilers, data base management, report generation, and text processing.

Since users access services, the fundamental problem of network access technology is simplification of service access. Moreover, in view of the trend toward interrelated services such as that provided by the National Software Works program production service,[16–18] the problems of interfacing users to services may require consideration of both the interface to a service provided on an individual system as well as to a collection of services provided by several systems. Consequently, Common Command Languages (CCLs) across heterogeneous systems are desirable and have been shown to be feasible.[6]

Simplification of service access requires identification of service user categories and analysis of the factors impeding access simplification.

User categories

Users of a computer system can be divided into three major categories: endusers, applications programmers who construct services for endusers, and systems programmers who provide the environment in which applications programmers function. Note that a given individual may function in all three categories; the importance of the trichotomy is its implicit definition of user objectives.

The global objective of the enduser is access to services. In particular, the nuances of the capabilities provided by a computer communication system, the general characteristics of the system, the locations actually providing the services and the availability of other services not of interest to the user are of secondary interest. The user would prefer that the computer communication system be transparent so that one sees services rather than systems and is only required to provide that information necessary to utilize the service. Further, the user should be relatively unconcerned with the precise structure of system command languages, problems caused by spelling errors and other requirements to conform to the precise syntactic requirements of the system.

Applications programmers construct services. Provided the performance impact is acceptable, high level access support of computer and communication components is very useful. Such support would reduce the need for explicit concern with the vagaries of Job Control Languages, permit common naming conventions across systems, ease access to systems, and support command language level programming.

Systems programmers will often find the software support provided applications programmers of use. However, the detailed, highly system specific knowledge required for the construction of 'systems' software often precludes adoption of a high level view. Although network access support mechanisms can be used by systems programmers, performance constraints will probably limit their applicability. This observation is consistent with the evidence provided by programming language development which demonstrates that for some functions one can only program at the assembly language level.

Looking at the objectives of each user category, it appears that endusers constitute the major user group for network access support. Applications programmers are likely to find such support to be of some help, and systems programmers seem unlikely to be directly aided in the construction or modification of 'system level' functions. Even for this restricted audience, developing the required access support proves difficult.

Access support difficulties

Access support would be comparatively simple if all users had the same problems with the same services. Unfortunately, user perceptions of the difficulty of service access are influenced by:

- user skill
- rate of change
- usage intensity
- access complexity

User skill

Developing effective access support would be difficult even if user skills were uniform across services. However, skills tend to be service dependent and, for each user, span the spectrum from "novice" to "expert." We hypothesize that the desired access support level is inversely correlated with the user's skill and, as a result, there is no single "best" access support methodology.

Rate of change

Rate of change measures the rapidity with which the user changes the collection of accessed services and, thereby, the rate at which the user must learn about the new (for the user) services being accessed. Although we shall not attempt to characterize the precise metric or the difference between 'fast' and 'slow' rates, it is evident that the higher the rate, the greater the learning burden of the user. Thus, we hypothesize that the utility of network access support, as perceived by the user, is positively correlated with the rate of change of service access.

Usage intensity

Usage intensity measures the frequency of use of a given service. We hypothesize that from the viewpoint of an individual user, for services of equivalent complexity (measured in terms of some unspecified metric), the utility of network access support is positively correlated with the (average) time between invocations of the service. This seems intuitively reasonable since the longer the interval between service accesses, the greater the likelihood that required items of information will be forgotten or confused.

Access complexity

Service complexity and capability are often positively correlated. We hypothesize that the desirability of network access support correlates positively with service complexity and, thereby, capability. This seems reasonable since more complex services typically require more complex interactions for their effective utilization.

NETWORK ACCESS OBJECTIVES

Identification of a "best" access support mechanism is a reasonable initial objective for network access investigations. This objective proves unrealistic due to the four factors identified above which, individually, cannot be optimized due to user differences. Heafner found the same difficulty in dealing with user differences for a subset of access support functions, namely command languages. He concluded that there is no "best" command language.[19]

Since developing a "best" approach is infeasible, we consider an alternative—the determination of access functions which are most amenable to automation. Our alternative is based on the identification of: (i) service components appropriate for network access; (ii) support requirements appropriate to these components; and (iii) an integrated set of functions corresponding to these support requirements.

Service access taxonomy

Access to a service proceeds in four stages: acquisition, initialization, utilization and termination. Acquisition encompasses those commands required to 'run' the service together with those required to gain access to the host, if required. Similarly, termination encompasses both the process of "exiting" the service and logging off the host, if appropriate. (It would be inappropriate, or at least inefficient, to log out if the next service to be accessed is also located on the same host.) Initialization covers the setting of parameters prior to actual utilization of the service to accomplish the user's objective.

Given this taxonomy of service access, it follows that the objectives of network access support can be characterized in terms of the capabilities to be provided for each of these stages.

An assertion

We assert that service utilization is not amenable to centralized network level support. Such support can be provided for the other three stages.

Justification of this assertion is provided by both organizational and technological considerations. Organizational justification follows through consideration of the groups which could provide network access support and through analogy with the functions of a computing center counselor.

Network access support of service utilization requires explicit knowledge of the service. Since one would not expect any individual or group of individuals to be knowledgeable in all network accessible services, it follows that no single group can support service utilization. Instead, such support should be provided either by user groups for the

various services, by the service developers (as was done for MYCIN, a diagnostic support service experiment for physicians,[20] and is being done for the ACCAT Command and Control testbed,[7,21,22] or through other means as is being done in the area of providing homogeneous virtual interfaces to heterogeneous bibliographic retrieval services.[9,10,15] In this context, it should be noted that the RITA effort, described earlier is concerned with the development of "smart" user daemons to assist in the utilization of services. (Note that although RITA and MYCIN utilize a similar technology (production systems), RITA support is external to the service while MYCIN provides support as part of the service.)

The technological difficulty in supporting service utilization reflects its implicit requirement of knowledge of both the syntax and semantics of the service. As such, excluding trivial cases, it is effectively a specific instance of the artificial intelligence problem of knowledge representation which, in the general case, is unsolved and still a subject of study.

The following discussion establishes the feasibility of supporting service acquisition, initialization and termination at the network level. Although the difficulties of providing such support for service utilization have been articulated, some discussion of this topic is included for completeness.

Access support objectives

Network access support should simplify access to new (to the user) services and should minimize the need for entering relatively unchanged, previously supplied information when accessing a previously accessed service. We now discuss some of the major requirements implicit in supporting these two objectives.

Accessing new services

Access support of new services requires: (i) identifying the existence of the appropriate service; (ii) providing information about the service; and (iii) simplifying the problems of initial access. Within this paper we shall not consider item (i); however, some consideration has been given to this issue as is reflected in the existence of the ARPANET Resource Handbook[23] and the objectives of the REX system.[24]

Users require two kinds of information to access a service: global descriptive information such as is commonly found in manuals, and specific problem solving oriented information to assist them in more efficient usage of the service. Although either online or hardcopy manuals are appropriate for providing global information, a dynamic mechanism providing highly specific information is required for problem solving. Such information would be based on the individual user and system. Network level support of dynamic assistance seems feasible for the acquisition, initialization and termination stages of service access. Further, it could be provided by the service constructor to support more effective service utilization.

Dynamic service access assistance requires profiles for the acquisition, initialization and termination stages of service access. Such profiles are system dependent and user dependent because access to services is dependent upon the idiosyncracies of the system providing the service and the idiosyncracies of the user accessing the service. Their implementation requires resolution of two issues: (i) determination of the information to be provided, and (ii) development of a mechanism for inserting, storing, modifying and retrieving profiles. For the three stages of interest, handling the service dependency of the profile seems relatively straightforward. However, handling user dependencies can become quite complex if self-tailoring mechanisms are provided.[19]

Accessing previously accessed services

Given that a service has been accessed before, its subsequent access can be simplified through minimizing reentry of previously supplied information via: (i) user and system profiles automating service initialization, and (ii) expert assistance to eliminate the need for explicit user concern with service acquisition, initialization, and termination. Although this reduces the need for entering previously supplied information, it will probably not eliminate it. Consequently, a 'soft user interface' is desirable to accommodate more flexible input than is presently acceptable.

The preceding can be summarized in our assertion that the key network access support components are: (i) profiles for users and services to simplify and automate service acquisition, initialization, utilization and termination; (ii) soft user interfaces to eliminate the need for concern with syntactic 'nits'; (iii) expert assistance to reduce the need for entering repetitive information during the acquisition, initialization and termination stages of accessing previously accessed services; and (iv) dynamic tutorial assistance to provide specific, pinpointed problem solving information online.

The next four sections summarize existing information on the four support components. It should be noted that the soft user interface, expert assistance, and dynamic tutorial assistance require a knowledge base which is provided in profiles. The order in which these components are discussed corresponds to a logical progression providing increasing support to the user (see Figure 1). However, the boundaries between these support functions are not precise and often overlap.

PROFILES

The word "profile" implies an outline or representation of some entity. In access technology a profile is used to represent or characterize a user or service. Several groups have investigated the area of profiles and the information to be maintained therein.[10,19] Since this is an evolving subject area, a succinct list of profile contents is lacking. However, a minimal list of required entries can be suggested.

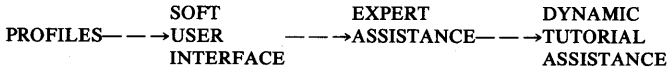

Figure 1—Spectrum for network access support levels

The information in a profile parameterizes both the system and the user for all stages of service access: acquisition, initialization, utilization, and termination. Thus, the profile provides the means to free the user from remembering and executing the mundane, trivial portions of service access. As a specific example, consider the user of multiple systems—each system requiring different connection protocols, passwords, identifications, etc. The profile can be used to store the value of these variables for each system and user, thus relieving the user from remembering these details.

The information stored in profiles is of two different types: static and dynamic. Static refers to entries that are basically unchanging or change very infrequently. The profile entries for acquisition, initialization, and termination contain static entries. Dynamic refers to information which is typified by change. Profile entries associated with service utilization are dynamic; for example, although one may use an information retrieval system daily, it would be expected that key words would not remain the same from session to session. Another example of dynamic profile entries is a function of the access system design rather than the target system. If an objective of the access system is to characterize the user (e.g., experience level) or the use of a system (e.g., certain sequences of commands are habitually repeated), these characterizations are dynamic in nature.

Static profile entries

We know that certain static entries are required for both the user and system profiles. It would appear that such entries are fairly well defined given the access system, target systems, and the communications environment.

User profiles

In the user profile the following entries are required to support the acquisition stage: passwords, user identifications, and account numbers of the user for all known target systems. For the initialization stage, the descriptors required for the target system are any default actions to perform following login to a target system (e.g., any commands which describe special characteristics of a user's terminal) or any default options to issue upon initialization of given services on a target system. If the target system is configured as part of a computer network, the requirement may exist to transfer files from another system to the target system as part of the initialization procedure. Any commands which should be issued prior to finalizing connection with a target system are within the scope of termination. Thus, the user may wish to have certain classes of files deleted prior to logout. If the target system is configured as part of a computer network, the user may wish for all files (or a subset of files) to be transferred to another system in that network prior to disconnection.

System profiles

In the system profile, there are two subcategories of profile entries associated with the acquisition stage: those relative to target systems and those relative to the communications subnetwork (if employed). For the target system, the login sequence is required; for the communications subnetwork, the connection sequence to specify the target system is required along with any required communications control commands.

The profile entries for the initialization stage reflect any requirements of the system prior to utilization. Examples are the syntax required to invoke services, and any identification procedures required prior to accessing given services. Profile entries for the termination stage are in two subcategories: the target system and the communications subnetwork. For the target system, the syntax for logout is required, and for the communications subnetwork, commands for closing a network connection are required.

Dynamic profile entries

While much is known about requirements for static entries in the user and system profiles, determination of appropriate dynamic entries is still an open subject for research. Nevertheless, two major generators of such entries can be identified. Entries corresponding to service utilization are likely to fall into the dynamic category. Further, characterizations of users and modes of access support utilization maintained by the access system require regular updating and, thereby, are likely to be dynamic. We conjecture that dynamic profile entries will be highly dependent upon specific services being accessed and the design of the access system.

SOFT USER INTERFACE

The soft user interface refers to those tasks which humanize the system or network interface to a service for the user. This section structures the functions to be provided by a soft user interface and discusses an approach developed by the Stanford Research Institute.

The functional capabilities provided by a soft user interface can be divided into three major categories: (i) assistance in entering individual commands; (ii) assistance in entering a collection of commands; and (iii) service identification as discussed above. Moreover, each of these categories can be subdivided into two major parts according to whether the actual command syntax is assumed to be fixed. If this syntax is variable, the problem of providing such an interface is closely related to the general problem of restricted natural language interfaces.

Assuming the reader knows the appropriate command,

assistance in its entry can be provided through command completion to minimize the amount of information which must be entered, spelling correction, help features to remind the user of the command syntax, and user oriented diagnostics to facilitate identification of what went wrong.

Assistance in reentering collections of commands can be achieved through allowing the user to catalog command sequences generated in previous interactions with the system. This minimizes the amount of information which must be reentered. An approach to providing such a mechanism is described in the following section.

The preceding has described means for facilitating the entry of commands having rigid syntactic specifications. We now discuss how these restrictions might be reduced through a more sophisticated interface.

Restricted natural language interfaces represent a logical means for providing syntactically and semantically flexible commands. In this context, there is a spectrum of features which can be provided. Thus, the interface may query the user concerning goals and objectives in an attempt to unravel a nebulous user request. Moreover, the interface may use a profile system to facilitate self-tailoring in terms of verbosity and user idiosyncracies. As this query facility is expanded it rapidly approaches the capabilities included in dynamic tutorial assistance discussed below.

As an example of the potential power of a restricted natural language interface, we briefly summarize some of the capabilities of a system called LIFER (Language Interface Facility with Ellipsis and Recursion),[7,8,21] which has been implemented at the Stanford Research Institute. LIFER provides an automatic facility for handling elliptical (incomplete) inputs, a spelling corrector, a grammar editor, and language extension through the use of paraphrase. LIFER is implemented in INTERLISP and consists of two major components. One component is a set of interactive language specification functions which are used to define an application language which is a supset of a natural language. The other component is a parser which interprets natural language inputs to translate them into appropriate interactions with the application software.

Production rules are at the core of the LIFER language specification functions. The production rules are advertised to be easily modified and interactively tested. The intermixing of calls to LIFER for language definition, extension or modification with calls to the parser for utilizing the developing language system serves as an aid for language development. The processing of elliptical inputs is another aid to the language builder. This elliptical handling is provided automatically by LIFER and frees the system builder from incorporating such constructions in the application language.

For spelling correction LIFER makes use of the spelling corrector in INTERLISP. In the event that LIFER does not understand an input it prints "user-oriented" error messages to indicate what it does understand and suggests correctional steps.

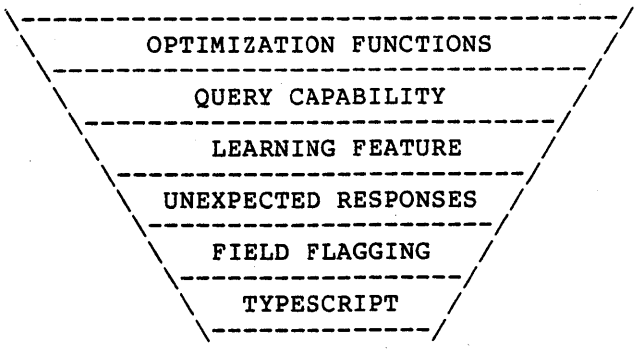

Figure 2—Levels of expert assistance

EXPERT ASSISTANCE

Using an access system often requires that the users learn a new command language—the language of the access system. Generally, system developers provide a menu of existing aids; however, in order for the users to tailor those aids to individual needs, or to create new aids, the users must deal with the language of the access system. This indeed is an ironic consequence since it is the goal of access assistance to lift users above the idiosyncracies of individual systems. Expert assistance refers to the capability of automatic generation of access system commands to achieve the desired user actions.

Levels of expert assistance

There are five increasing levels of sophistication for expert assistance; however, the underlying commonality is that the user informs the expert assistance system of the points at which observation of the user's actions is to begin and end. Figure 2 represents the hierarchy of functions which can be provided in an expert assistance system.

The minimum level of access assistance is provided through a capability to simply record interactions which actually occur between a system and user, and produce the access system command sequences required to replay the recorded interactions. This level of expert assistance is not flexible because it does not handle variations in system response or minor (parameter setting) changes in the user commands. Greater sophistication is desired.

The second level of expert assistance permits identifying certain fields of the user command or system response as variable. Such identification can either be explicitly provided by the user or by the expert assistance system based on its knowledge about commands and services. The identified fields can then be incorporated as parameters in the single command entered by the user to invoke the parameterized sequence of commands entered earlier. As an example, the expert assistance system might recognize the invocation of an editor; given that the syntax for the editor is known, the location of the expected file name would also be known and could be flagged as a parameter.

The major drawback of the second level is the frequent occurrence of unexpected responses common to a networking environment. The remedy is to incorporate handling of

unexpected responses in the assistance system—the third level. Two approaches to their handling can be identified: (i) a priori identification of all possible responses together with incorporation of appropriate actions; and (ii) notifying the user when an unexpected response occurs and permitting the user to specify the next action to be taken.

At the fourth level of sophistication, the expert assistance system draws upon its own knowledge base of services, and uses this information to enhance the generation of command sequences. For example, the expert assistance system may automatically generate appropriate responses to handle system level messages which occur during an interaction and should be ignored rather than generating an error. This level differs from the third level because the expert assistance system dynamically expands its knowledge base rather than having given situations identified at design time and programmed into the system.

At the fifth level of assistance, the user would be able to ask the assistance system to create the specific commands by indicating a general class of activity and a target system.

Currently, expert assistance is viewed as an option available to the user. There is no intent in the overall design to have the expert assistance system suggest to the user that certain activities are being repeated and could be incorporated into a command to the access system; nor is there an intent for the expert assistance system to suggest to the user that there are more efficient ways to achieve the goals being pursued. These capabilities are beyond the current scope of expert assistance. However, there is a sixth possible level, optimization, which may prove desirable as a future goal of such assistance. (Such support mechanisms have been considered for provision as part of a military message processing system.[19])

An implementation approach

The NBS Expert Assistance System (EAS) is a logical extension of the existing Network Access Machine. The implementation currently under way will accommodate field flagging (by either the user or the EAS if the information is contained in its database) and adaptive accommodation to unexpected system responses.

To accomplish these objectives, the EAS initially records all characters exchanged between a user and the system as demarcated by the user's overt initiation and termination of the recording session. A translator is then invoked to transform these character strings into proper NAM macros which may be called and expanded at any time. Variable fields are initially accommodated through flagging via a control character. Subsequently, as the NAM knowledge base is implemented, automatic recognition and flagging of variable fields (parameters) will be provided. As identified in Section 6.1, there are two approaches to handling unexpected responses. In view of the evident impossibility of foreseeing all possible system responses, the approach being adopted at NBS is the second (user intervention) coupled with preprogramming of some 'expected' unexpected responses. Thus, the EAS will have a minimal learning capability sufficient to permit incorporation of unexpected responses when they occur and, thereafter, to automatically handle such responses.

Usage of an expert assistance system by expert users constitutes an interesting, potential application. Users who are "expert" in the use of specific services on specific systems use the expert assistance system to generate the appropriate commands in the language of the access system to automate access to services for endusers. These "expert" users may be from a variety of areas—information retrieval, data base management, text processing—and are enabled by the assistance system to sit down and quickly create a library of commands to support predictable requirements of endusers. The "expert" users are shielded from learning the command language of the assistance system; they simply sit at terminals and enter the commands specific to their services. Further, the endusers are shielded from learning the command language of the services they wish to access and from learning the language of the assistance system.

A natural enhancement of an expert assistance system would be building access aids in the language of the access system interactively with the user. Thus, while the system is totally responsible for providing aids to support the inexperienced user, aids might be cooperatively generated while interacting with the more experienced user. Such a mechanism is discussed in the next section describing a highly interactive system in which the user is always being guided through the available alternatives.

DYNAMIC TUTORIAL ASSISTANCE

A dynamic tutorial system provides for user/service interactions controlled by the access system. The purpose of the tutorial system is to guide the user through all possible classes of activity offered by an access system. The tutorial system continually prompts the user and takes an appropriate course of action dependent upon the user's action. As an example of the use of the tutorial system consider the sample interaction below. (The italicized portions are generated by the user and the other portions are generated by the tutorial system.) This example terminates in the invocation of the required access system commands to login to the sending system, and transfer a file to the receiving system. The profile system contains the default values for the sending and receiving systems. If the user elects to use other than the default systems, the user may then have the profile updated with the new values at the end of the session.

File Manipulation? *yes*
Type of Activity? *transfer*
Sending Host is HOSTA? *yes*
Receiving Host is HOSTB? *yes*
Filename? *TESTER*

File transfer complete.

At this point the transfer is completed. This is of course the simplest sequence of events. Either the sending or receiving system could be other than the default ones; if so, the tu-

torial system may have to request user numbers and passwords for the new systems if they are not already known.

The essence of the dynamic tutorial assistance system is that the system is in command. It guides the user through all activities provided by an access system and executes the required commands to achieve the user goals. Additionally, the user could have the option to have the tutorial system catalog specific interactions so that the user may invoke them directly at a later time. Notice that this procedure implies a cooperative effort between a dynamic tutorial system and an expert assistance system. Using the above example, the user could invoke a "transfer" command which would result in the transfer of a file from one system to another.

SUMMARY

This paper has addressed issues relevant to implementing access support at the network level. An overview of the area of network access was presented, related research efforts were identified, factors which complicate network access support were identified, and the major components of network access support were structured. A specific implementation for one of these components, expert assistance, was described as it is being constructed at the National Bureau of Standards.

Our development of a structure for network access support began with the observation that user categories and access support difficulties preclude the existence of a single general support mechanism. Further, if the objective is provision of support via a network level group, only the acquisition, initialization and termination stages are reasonable candidates. This reflects the reality that service utilization requires intricate knowledge of the implementation of a specific service on a given system; it is unreasonable to expect one group (namely, the developers of a network wide access mechanism) to possess that level of knowledge for all systems on one network—much less across network boundaries.

Although support of service utilization cannot be provided at the network level, it is appropriate to provide general purpose support mechanisms. To accomplish this, an expert assistance system was introduced which can partially automate tailoring general purpose access mechanisms to meet individual objectives. Such a system shields users of access support systems from the command languages of those systems, while enabling them to construct procedures to access services on target systems.

ACKNOWLEDGMENT

The authors would like to express their appreciation to Rob Rosenthal and Sig Treu for their helpful comments and discussion of network access support.

Adaptive random data generation for computer software testing

by STEPHEN F. LUNDSTROM
Burroughs Corporation
Carlsbad, California

INTRODUCTION

This paper discusses computer-assisted generation of input data for program testing. The test data generation system must produce input data that is per specification, unbiased by prior analysis of the program to be tested. The test data generators evaluated use random generation techniques to produce the test data. To reduce the number of sets of test data needed to test a program, summary information about the performance of previously generated sets of input data is used to modify the probability distributions upon which the next set of test data is based. Four test data generators were evaluated and used to generate test data to exercise five testcase programs of various complexity. Observations of the results of the actual evaluation runs and of the types of structures involved led to the establishment of some guidelines for future testing operations. Program verification of any sort was not attempted. Manual checks of the normal program outputs did detect a number of software errors. No attempt was made to automatically isolate or even detect software faults. Nor was any comparison with other methods, manual or automatic, made.

The Software Testing System developed to use as a tool to evaluate the test data generators is similar to others previously reported.[1-7] These systems require repetition of steps to guide and assist test case selection, to execute the instrumented program and to analyze testing coverage until the test goals have been achieved. The system used here to evaluate the test data generators not only provided the summary reports of testing progress similar to the above systems, but also provided progress summary information to the test data generators which was then used to modify the probability distributions controlling the generation of the test data.

Most previous work relating to the generation of test data for program testing in some way base the test data on analysis of the program to be tested. R. L. Sauder[8] determined the format and description of the test data by analysis. Other systems[9-12] use analysis of the program to guide choice of test data when the main goal of testing was usually to execute all paths through a program.

Program analysis is subject to any related programming errors in the program to be tested which may, in turn, cause the generation of test data which is inconsistent with the original specification. If any paths are missing in a program to be tested, they would not normally be detected through use of test data generators which are based on program analysis.

Program test data should be based, as much as possible, on the program specifications rather than on the program implementation. Sauder's work was unique in that it required the user to specify the data relationships thus allowing the "semantics" of the test data to be derived from the specification and whatever test plan might exist. The systems reported by W. H. Burkhart,[13] and K. V. Hanford[14] are specifically concerned with testing compilers and generate test data from the formal syntax of the language to be processed. These systems are unable to take any semantic information, such as relationships or limitations between syntactic variables, into account in the generation of test data. A new program product recently introduced by Burroughs Corporation[15] does allow specification of both the desired syntax and semantics of the desired test data. Each of these three systems generate data based on a uniform random distribution generator without any concern as to the efficiency of such an approach.

The only reported work involving random test data generation where techniques were evolved to improve the efficiency of the generators was in the area of hardware test data generators used to test digital logic.[16-17] The original concepts have been further extended by K. P. Parker.[18-22] Parker's system allows the probability of a particular value of any test input to be based on the average or most probable value of previously successful sets of test data.

Although the hardware techniques were developed without regard to software problems, there are many areas in common and some of the hardware experience can be applicable.[23] Although the concept appears valid, hardware testing is the process of searching for equipment malfunction (assuming a correct design), but software testing is the process of somehow verifying the design and implementation of the software itself.

SOFTWARE TESTING SYSTEM

The software testing system used for evaluation of the test data generators is organized into two phases as shown in Figure 1. The first phase, program analysis, inserts monitors in the program to be tested. The monitors allow observation of flow through the control structure of the program, and also observation of changes in the values of variables during execution. The second phase, program test and evaluation, is the phase which generates test data, runs the instrumented program and evaluates the results of the tests. In each of the repeated cycles, a new set of input data is produced, the program (with monitors) is executed, and the results are evaluated. Three of the four test data generators evaluated were adaptive and utilized monitor-generated summary information relating to the success of previous tests in their heuristic algorithms.

The actual format and values of the input data must be as specified for the particular program under test. Special programs supported this function for each of the five test programs used. In a production environment, a special input data specification language would be developed together with a processor for that language. Even though each program to be tested has special requirements for the form and range of its input data, the procedures used for selection of the data are generalized and apply regardless of the program to be tested.

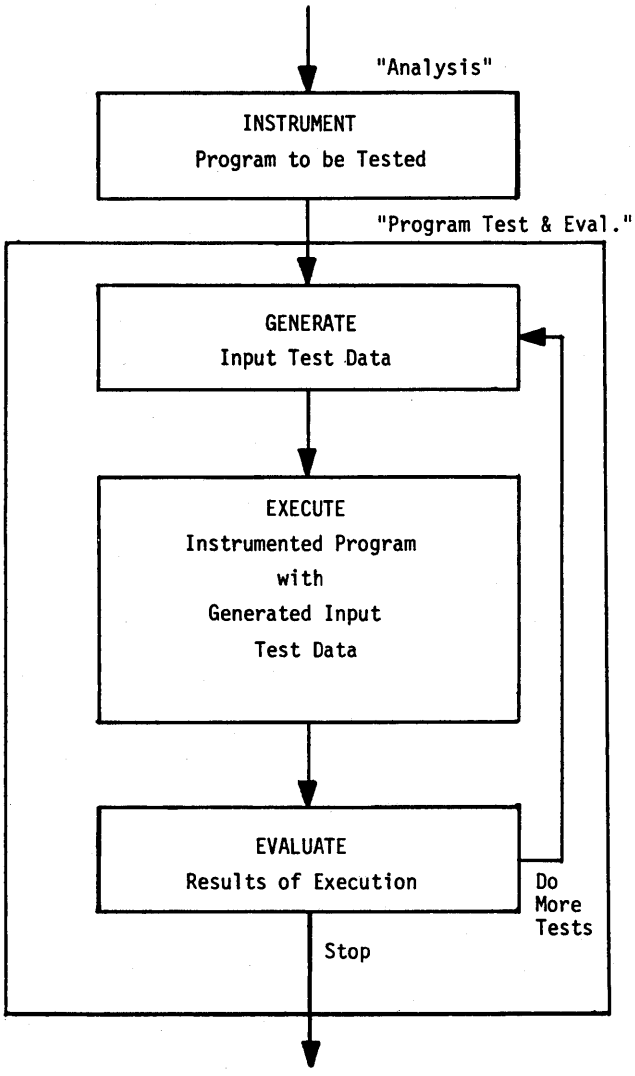

Figure 1—Software testing system

Monitoring requirements

When developing a testing system of any sort, it is important to know what the test procedure has tested and to what extent. This information is important both in determining what is faulty if a problem is found and in determining when sufficient testing has been done. The system developed monitors both the control structure and range of variables as a means of measuring the ability of the generators to "thoroughly" test the software.

Branch monitoring

All possible branches within the program graph are monitored. The obvious goal is to attempt to exercise all possible branches. Even if all possible branches are exercised, all possible paths in the program being tested may not have been exercised. In addition, there may be paths which have not yet been implemented and which cannot be monitored. The simpler measure of branch executions was chosen as one measure useful in demonstrating the viability of the proposed adaptive random data generators.

Range of value monitoring

The user may define a desired range of values to be monitored for each variable of interest. Each range is divided into "N" equal size segments (another simple measure chosen as sufficient to demonstrate the viability of the generators, in this case $N=10$). Assignments to these variables are monitored with the goal of observing data values in each of the segments of the range for each variable. The specified range of interest is not required to be the same as the observed range of values for any variable.

Termination conditions

The need for well-defined termination conditions are particularly important in a testing system where there may be no guarantee that all testing requirements can ever be met. The following conditions were adopted, any of which can force immediate termination of any testing in progress:

1. "M" test data sets have been applied to the program being tested. (M=50 was used.)
2. All possible branches have been observed to have ex-

ecuted and values have been observed in each segment of the range of values for each monitored variable.

3. The last "P" test data sets were inefficient. In this case, if P=10 successive test data sets were not productive, termination would occur. A test data set was considered not productive if the sum of "new" branch executions observed and "new" range of value segments observed is "R" or less (R=2 during testing). "New" branches are those observed which had not been executed previously; "new" segments are those in which values were observed which previously had not been.

Software test sequence

The actual procedure of software testing can start after the program analysis phase has generated the instrumented source program. The system developed (see Figure 2) consists of a central control which, after any necessary initialization, sequences through automatic test data generation, execution of the instrumented source program and test evaluation. The conditions which cause termination were defined previously. These conditions are checked during the test evaluation phase. If termination is not yet required, the central control restarts the test generate, execute and evaluate sequence. The automatic test data generators are discussed in detail below.

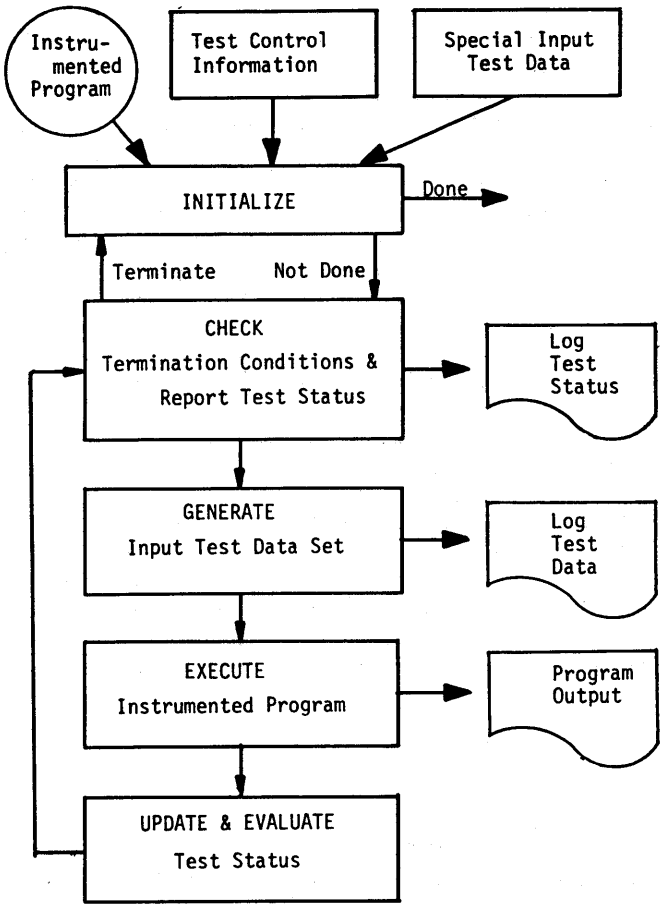

Figure 2—Software testing system—Program test and evaluation phase

Manual verification

The software testing system developed is not capable of automatic verification of the validity of the outputs of a program given the automatically generated inputs. The system produces summaries of the results of all testing (including which branches have not been executed and what range of value segments have been observed). This information together with the normal program outputs must be manually inspected as the final step of program testing.

AUTOMATIC TEST DATA GENERATION

The major problem faced in automatic test data generation is how to devise adequate tests. Program development proceeds through a sequence of four steps; specification, design, implementation, and verification. If the specification is assumed correct, then the design and implementation should be checked. The test data generation system described below generates input data based on the specification. It also allows use of manually generated or previously saved input data. By monitoring the execution of the program, the testing process covers both the design and implementation. Other systems, which generate test data based on analysis of the program being tested only have the capability of exercising the implementation. Analysis-based test data generators produce test data with implementation errors reflected in the test data. Therefore, many kinds of implementation errors are masked. Specification-based test data generation does not have this problem. Since input data is based directly on the specification, any errors due to the design or implementation procedure are vulnerable to detection. Errors such as missing control paths or incorrect handling of input data are likely to be observed using specification-based test data.

In a production-oriented software testing system, an input data definition language should be available to allow the representation of the portion of the program specification which defines expected input data in an unambiguous, machine-recognizable form. In the system implemented, that portion of each generator which would normally interpret an input data description was specialized for each of the programs tested. The specialization was based on the specification of the input data to be produced and not on analysis of the programs tested.

Recall that the software testing system monitors both the sequence of execution and range of value segments. The sum of the number of "new" branches and "new" range of value segments (where "new" indicates previously unobserved) is used as a means of comparison of the productivity of two test data sets and is used during evaluation of the termination condition.

The judicious selection of a small number of input test

data sets from an extremely large domain is another major problem when developing an automatic test data generation system. The capabilities of four input test data generators were evaluated. The four generators are called UNIFORM, GAUSS, INVERSE, and NEXT-BEST. All of these generators, except UNIFORM, are designed to adapt to the most effective areas of the input data space.

UNIFORM test data generator

The UNIFORM test data generator is the only generator evaluated which is not adaptive. Values are chosen randomly over the given legal range of the particular test data element being chosen. A uniform probability distribution guides the choice so that each value in the range is equally likely to be chosen as any other value in the range. In addition to allowing direct use of the UNIFORM generator, each of the other generators use the UNIFORM generator under circumstances explained below.

GAUSS test data generator

The development of the GAUSS test data generator was motivated by the observation that many program organizations are not symmetric. The simple example below illustrates the asymmetry. The example procedure (Figure 3) receives an input parameter X which is an integer in the range of 0 through 100. If X is less than 50, a parameter Y is incremented. If X is less than 50 and is even, then a parameter Z is multiplied by X. If input data to test the example procedure is chosen with a uniform distribution, one half of the cases, on the average, will test only the first conditional. Only one quarter of the cases, on the average,

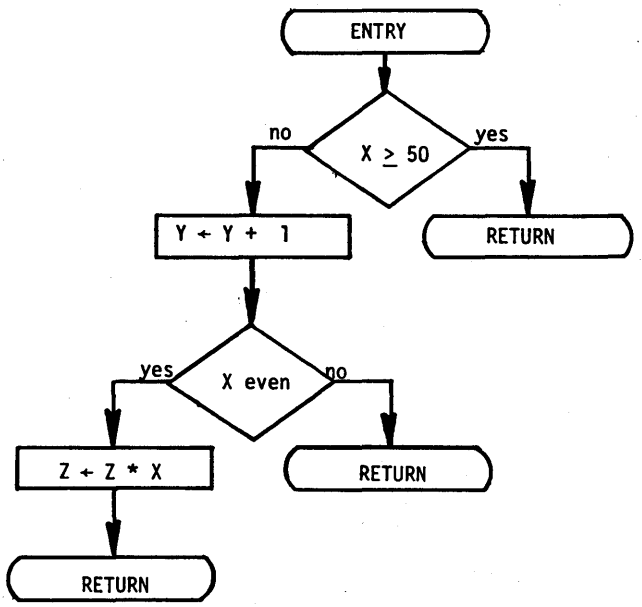

Figure 3—Flowchart of example showing control asymmetry

test both the code which increments Y and which multiplies Z by X. If those were major program blocks, it is clear that much of the work of a UNIFORM test data generator would be ineffective in testing the example program. The asymmetry also exists in computation of variable values. The GAUSS test data generator is designed to bias choice of test data by consideration of previously useful test data sets.

Test data generators are called productive if the data produced exercise portions of the program not previously tested. In terms of the productivity requirement, the program organization (or at least that part of interest) is dynamic. After each application of a set of inputs, that portion of the program which actually was exercised "disappears" and is no longer used in evaluation of the performance of the generator. The goal of the generators is to produce test data which exercises the "remaining (untested) portion" of the code.

Once the generator produces inputs which force execution of a branch of the program not previously executed, the generator becomes productive. The productivity might be maintained by choosing inputs to again enter the same branch, but perhaps test a different subbranch. One can usually assume that entry to a particular branch is controlled by some subset of the input variables. Thus, if the proper input variables are kept "the same" and others are modified, it is likely that various subbranches will be exercised. However, no analysis is performed which would determine the subset of inputs which control entry of some branch. If input values are chosen randomly under control of a Gaussian distribution, and if the standard deviation is small, and if the mean represents values needed to enter the branch, the generation of values the same as before becomes likely. The variation in values should be limited enough to continue generation of tests of a productive branch but, at the same time, be sufficient to exercise other subbranches. Eventually, as all the subbranches have been exercised, the productivity of test inputs based on that distribution will decrease. As this occurs, other successful test sets will be used to compute the distribution, and inputs will be produced to test other portions of the program.

Initial GAUSS distribution

Unless the user provides guidance, the GAUSS test data generator has no means of knowing where to set the mean and standard deviation initially. In order to provide some initial history, the GAUSS generator produces the first "C" cases with the UNIFORM generator. For purposes of evaluation, "C" was arbitrarily chosen to be four. The UNIFORM cases are not generated if any manual or previously generated cases are input initially.

GAUSS generation technique

The GAUSS generator bases the test data produced on a Gaussian probability distribution. Each variable generated with GAUSS has a corresponding mean and standard deviation which, together with the defined range of the variable,

control the values produced. The mean and standard deviation for each variable are not fixed. These parameters are adaptive. Each time the GAUSS generator is activated, the mean and standard deviation of each variable is recomputed based on the latest "successful" tests.

It remains to be determined which tests are successful. First, a test set is assumed to have certain productivity, defined for purposes of evaluation to be the sum of the number of "new" branches executed and the number of "new" variable value ranges observed. Recall that "new" simply means "not previously observed." The test data chosen to compute the means and standard deviations are those whose productivity exceeds the average productivity of the "M" most recent sets of test data.

The size of the collection of test data sets considered, "M", also is adaptive. If a number of successive data sets are not productive, the range of "M" is doubled up to an arbitrary limit. On the other hand, if a number of successive data sets are productive, the range of "M" is halved, but not less than the original value (in this case, 5). The size of the collection of data sets used to define the variable value distributions varies because of many of the arguments summarized earlier. A period of high productivity can often be maintained by basing distributions on a small number of recently successful tests. A period of low productivity is often characterized by a search for another productive area. A search of this sort is often successful when not biased by only a few sets of previously successful data, but by a broad representation of all previously successful tests.

The standard deviations of the distributions used to produce the test values vary widely. When a particular value V_0 of a variable V is useful to force control into a particularly productive set of tests, the standard deviation of V may become very small as more and more tests with values of V near V_0 are produced. If the value of a particular data element is not important in that way, the standard deviation is likely to be very large, often large enough that the Gaussian distribution over the legal range of values is essentially uniform.

INVERSE test data generator

The development of the INVERSE test data generator was motivated by impatience with the dynamics of the GAUSS generator. In particular, because of the procedures used to compute the distributions of the various input data values, a number of test sets would be produced before the deviation was large enough to allow an effective search for new productive areas. The problem appeared to be that data generated based on current distributions was often non-productive and no reliable information was available as to which part of the remaining portion of the input space would be productive.

INVERSE and GAUSS commonality

The resulting INVERSE data generator operates the same as the GAUSS generator during computation of variable value distributions, establishment of an initial history with cases produced by the UNIFORM generator, adjustment of the size of the collection of test cases used for distribution computations, and random generation of data based on a Gaussian distribution. Only after the normal GAUSS procedures become non-productive is the INVERSE generation technique activated.

INVERSE generation technique

The only difference between the GAUSS and INVERSE generators is how data values are produced after non-productive test data sets. If the previous test data set is not productive, the INVERSE search procedure is activated to attempt to find a new productive region in the input space. Successive activations of the search procedure alternate between standard generation of input data with the GAUSS generator and generation of input data with the INVERSE procedure. A true inverse distribution is not really appropriate. The inverse GAUSSIAN distribution would tend to generate probable values at the boundaries of the input data space. Rather, it is desirable to produce values not likely to be produced with the GAUSS generator, but still provide an unbiased search of the rest of the input space. The UNIFORM generator can accomplish this easily with the addition of a simple test of each of the variables generated. If a UNIFORM generated value is in the "GAUSSIAN-likely" range (MEAN−STANDARD DEVIATION through MEAN+STANDARD DEVIATION) where MEAN and STANDARD DEVIATION are as normally computed for the GAUSS generator, then another replacement value is produced (through use of the UNIFORM generator once again). When none of the generated values lie within the "GAUSSIAN-likely" range, the data values are output and applied to the program being tested. Analysis of the productivity and recomputation of the variable distributions then proceed as previously described with GAUSS. In many respects, the INVERSE test data generator can be thought of as a random data generator controlled by a UNIFORM distribution which has a hole in it, centered at the variable MEAN and with radius of the STANDARD DEVIATION. It allows a uniformly distributed random search of the area not recently productive.

NEXT-BEST test data generator

The NEXT-BEST test data generator was motivated by the observation that once a particularly productive input data set is chosen, other productive data sets can often be produced solely by changing only one of the variables in the input data set. Calculation of most variable values can be considered to be some function of the input variables. Variations of only one input variable will usually affect the computed values of some of the program values. Similarly the expressions which control branches between basic blocks in the program are also functions of the input variables. The appropriate modification of only one input variable

can cause the execution of different basic blocks. The effect of modifying only one input variable is essentially an orthogonal search of the input data space for other productive cases given a known productive case. Any arguments in favor of this technique for execution of basic blocks is equally valid for testing ranges of variables.

Initial NEXT-BEST distribution

The NEXT-BEST test data generator must have at least one set of input data values before modification of individual, randomly-chosen input values can be done. If no manual or previously specified data sets are input initially, one input data set is produced using the UNIFORM generator. If more than one manual or previously specified data set is input, the most productive will be used during the next phase of the NEXT-BEST procedure, input variable distribution initialization. The case chosen will be called the base case.

Input variable distribution initialization

The input variables which are randomly selected will not be equally productive during the use of the NEXT-BEST generator. In an attempt to further improve efficiency, the most productive variables are given a somewhat greater probability of being used to generate new data sets under the implementation of the NEXT-BEST generator. Before normal processing begins, each of the input variables is used to generate at least one input data set which is a modification of the base case chosen after the Initial Distribution phase. If the data set generated by modification of a particular input variable is productive, then the same variable will be used again. If non-productive, the next variable is used. The values generated for each of the chosen variables are produced through use of the UNIFORM generator. A record of the total productivity of each variable is kept both during this and the final phase. The productivity information is utilized during input variable selection.

NEXT-BEST generation technique

After Initial Distribution and Input Variable Distribution initializations, the major test data set generation phase begins. This phase consists of a number of subsequences of test data set generation steps. Each subsequence begins with the choice of a base case. The new base case chosen is that test data set previously generated which has the largest productivity of all those not yet used as a base case. Upon completion of a subsequence this base case is marked as used.

After a base case is chosen to start a subsequence, a new input variable is chosen. The choice is made randomly but with a preference toward previously productive variables. To make the choice, an assignment of each variable to a portion of the range of real numbers from 0 through 2 is made. Let S_i be the size of the portion of the range assigned to the ith variable. Assume there are n variables and that P_i is that fraction of the total productivity to date contributed by the ith variable. Then:

$$S_i = \frac{1}{n} + P_i .$$

A random number between 0 and 2 is then chosen under control of a uniform distribution. That number will be within the portion of the range from 0 through 2 assigned to one of the variables and will be used to select that variable. The order of the variables across the range does not vary and is the same as the order of selection during variable distribution initialization phase.

Once a variable is chosen, a new value is selected for it to replace its original value in the current base case. The selection is under control of the UNIFORM generator. If the resulting test data set is productive, the same variable is used again for production of the next data set. When a data set is not productive, the next variable in the same order as chosen during the variable distribution initialization phase is selected. By sequencing to other variables in this way, variables with poor past productivity can develop a more complete history of productivity. The subsequence ends when the end of the sequence of variables is reached. At that point, the base case is marked as used and a new subsequence is initiated.

EVALUATION AND RESULTS

The software testing system together with the automatic test data generators were evaluated through use of some programs chosen as testcases. Limitations of manpower and computer time reduced the number of programs chosen to five. They were chosen to represent a wide variety of program application and complexity. Three of the programs are student submissions from an introductory programming course and represent table lookup, search techniques, interpolation, numerical approximation, divided difference, boundary value and game playing applications. In these three cases, the general problem was chosen as representative and one of the programs submitted was arbitrarily chosen for each. The other two programs chosen are production programs written (and selected) by a staff analyst other than the author. These two programs are numerical analysis programs concerned with the analysis of stresses in turbine blades. The five programs were called:

Temperature Distribution in a Conducting Solid
The Series Magnetic Circuit with an Air Gap
Tictactoe (a tournament)
Aerospace Analysis
Turbine Blade Analysis

(See Lundstrom[24] for a more complete description of each of the five testcase programs.

Test procedures

Each of the five testcase programs was "tested" by each of the four test data generators. Four of the testcases were also "tested" with at least one prespecified set of test data values. In order to gather reasonable statistics, each of the procedures above was performed ten times.

Measurement and observation of results

Control flow and range of value monitors were chosen since they reflect, at least to some degree, the thoroughness of a collection of test data sets. In the future, other measures may prove more useful. The monitors are observed and recorded after each test data set is applied to a testcase program. This information, when averaged over the ten times each generator was used to test each testcase program, gives a good feeling for the expected performance of each generator.

Summary of results

The software test system proved to be useful in detecting errors in the programs tested. More importantly, even though the input test data generators used cannot be guaranteed to find all errors, the generators produce unbiased test data which is more likely to thoroughly exercise a program, with respect to its specification, than its creator would.

The NEXT-BEST generator, as implemented, never demonstrated productivity better than the others. The results might have been different if more initial cases were produced, if more initial variable productivity history development was performed, and if variables known to be nonproductive were used less during the main body of the procedure.

The GAUSS generator proved to be most successful in situations where a very non-uniform mapping from input data space to the program occurs such that only one productive region exists. In similar cases with more than one productive region, the INVERSE generator was most productive, since distribution repositioning can be speeded through the UNIFORM "search."

The UNIFORM generator represents the type of test data generator most used in the past and is most productive when the mapping described is uniform. If the mapping is not known, then the UNIFORM generator may be slightly more productive than the INVERSE generator, most likely due to an insufficient "UNIFORM" search for productive areas before the main INVERSE procedure begins. Although the INVERSE generator is never quite as productive as the UNIFORM generator when the mapping is uniform, it is sufficiently better when a non-uniform mapping exists (especially if a good manual case is input) that the INVERSE generator can be recommended as the generator to use in the many situations when the mapping is not known.

Recommendations

An improved generator, called COMPOSITE, has been considered, but not evaluated. It should offer better early productivity and less sensitivity to the mapping. COMPOSITE would make use of both the UNIFORM and INVERSE generators described. However, COMPOSITE would allow selection of the generator to be based on past performance. The mapping changes for each variable as more and more of the program is exercised. By allowing the data generator to reflect the current mapping, an increase in productivity should be observed. Additional suggested features of COMPOSITE are described in Lundstrom.[24]

The values of many variables cannot be monitored realistically with the fixed-size, fixed-number range of variable value divisions utilized in the system implemented. It should be possible to specify the number of range segments together with the size of each segment (without the constraint that each segment be the same size). It is more important that the possible values be distributed uniformly across the segments of the range of values of a variable than to have equal-sized segments.

CONCLUSION

The goals of the work described here were to study random test data generation techniques as applied to software testing, to develop and evaluate random data generation algorithms, and to develop a complete software testing system to support the study. The software testing system was successfully implemented. The test data generators were evaluated by using them to test each of five programs chosen as testcases; programs which represent a wide variety of applications.

The four test data generators developed and evaluated were called UNIFORM, GAUSS, INVERSE and NEXT-BEST. While each of these was observed to be productive in some situations, only INVERSE was consistently productive. It was determined that knowledge of the type of mapping from the input space to the program could allow choice of the appropriate generator for most efficient operation. Since understanding of the mapping is often difficult or time-consuming, and since the system developed did not provide tools to support identification of the mapping, the INVERSE generator was determined to be the most broadly useful over the cases studied. An improved generator, called COMPOSITE, was proposed, but not evaluated.

Although program verification was not attempted, enough program faults were manually observed in the test output to demonstrate that input test data generation can be successfully based on the specification rather than on analysis of the program.

ACKNOWLEDGMENTS

The work described in this paper contributed to the fulfillment of the requirements of the Doctor of Philosophy degree while the author was enrolled at Texas A&M University. Dr. Dick B. Simmons provided motivation to investigate the importance of range of variable value monitoring as well as much needed encouragement throughout. Dr. Richard E. Fairley was the catalyst leading to the understanding of how the relationship between the input test data set domain and the program affects the choice of the test data generator. Computer facilities were provided by Texas A&M University and Burroughs Corporation.

DP management and administration

OVERVIEW

The area of data processing management and administration covers topics related to the effective utilization of data processing personnel and technology to help achieve the objectives of the organization. Personnel costs continue to grow faster than hardware costs, and technology improvements continue to encourage more widespread uses of data processing. How our methods of data processing management and administration can help us cope with changes such as these is theme of the sessions in this area for NCC 78. The sessions can be grouped around two general issues. The first issue is the increasing influence of people management on the effectiveness of data processing. The sessions related to this theme include: time management, motivations, and why is D. P. management so difficult? The second issue is the impact of new techniques and technology on DP management and administration. Related to this general issue are sessions on: information technology and organizational response, security assessment techniques, contribution of planning to information systems productivity, DP auditing, and organizational considerations in the allocation of computer resources.

Time management for the data processing professional

by J. F. TOWSEN
Harrisburg, Pennsylvania

No longer can the Technical Professional ignore a day-to-day interface with peer groups from within the Organization.

The advent of newer—smaller and faster—operating systems have made the user a new partner in the development of the Corporate Data Processing Strategies.

But with this new role of partner came a new and different type problem for our technical professional. A new problem called TIME MANAGEMENT.

When they started to become more involved in the BIG PICTURE, they started just like their peer groups to complain about:

Meetings	Telephone
Interruptions	Postponed Decisions
Lack of Planning	Crisis Management
Visitors	No Priorities
Snap Decisions	Peer Demands on Time

The story is always the same, someone or something is WASTING my TIME. But have you noticed how most people are reluctant to admit their own faults or shortcomings as the real TIME WASTERS.

Telephones and meetings are very important tools for the D. P. Professional. Ideas need to be exchanged, questions asked or answered.

And let's not overlook the team members of this new partnership who can't COMMUNICATE. Behind most every user-D. P. problem, is a breakdown in some form of communications. When will they ever realize how much time is lost as a result of poor communications, and TIME IS MONEY.

Up to this point I have dwelt on the Data Processor. But we must understand that they are no different than other managers, most of whom don't know how to MANAGE their OWN TIME.

How many times have you seen major Data Processing projects go down to the wire or even come in late? Why does this happen? Why is all of this time and money wasted because of unnecessary reruns?

There are many reasons, but I do suggest that part of the problem comes from the D. P. Manager's inability to manage the many demands on their time. The normal management functions such as planning, delegation, follow-up and communicating get lost in the fast pace of doing business.

And we can't forget the cluttered desk and cluttered office. I believe in the saying "CLUTTERED DESK EQUALS CLUTTERED MIND." I have seen MANY D. P. centers and for the most part they are cluttered.

Along with many other Managers, the D. P. Professional must develop some of the basic techniques of good TIME MANAGEMENT.

This seminar will help the manager to develop some of these techniques. We will consider some of the following:

1. Spend more time on FIRE PREVENTION and less on FIRE FIGHTING.
2. Spend 10 or 15 minutes reflecting on the day's activity and planning for tomorrow.
3. Prepare a THINGS TO DO list detailing the major items to be accomplished tomorrow.
4. Don't become involved in areas of responsibility directly assigned to others.
5. Consider a management by exception program. Only the important exceptions reach your desk and require your time, energy and ability.
6. LEARN TO SAY NO.
7. If your job entails dealing with outsiders, learn to control these interruptions. Always be in control of the situation.
8. Don't spend all of your time "getting organized" only to find at the end of the day that nothing was accomplished.

And as part of the same seminar, we will look at how to get more out of our meetings, and how to "get an extra hour out of every day."

Organizational response and information technology*

by RICHARD L. NOLAN
Richard L. Nolan, David P. Norton, and Company, Inc.
Lexington, Massachusetts

INTRODUCTION

In one instance after another, organizations have remolded themselves, not in direct response to great ideas, but in response to the development of intervening technology that stimulates implementation of those ideas.[1] The remolding, however, does not immediately correspond with the advent of the new technology. An organizational response process is initiated with the advent of the new technology, and then evolves over time. The purpose of this paper is to render theoretical frameworks that are useful for understanding the organizational response process and then to apply the frameworks to add perspective to contemporary organizational developments in respect to information technology.

RELEVANT THEORY

There are two theoretical frameworks that are particularly relevant to the impact of information technology on organization. The first is an organizational change framework developed by Harold J. Leavitt. The second is an organizational learning framework developed by Richard L. Nolan.

Organizational change framework

Leavitt's organizational change framework views the organization as a complex system consisting of four main variables: task variables, structural variables, technological variables, and human variables. As shown in Figure 1, the variables are interrelated. A change in one results in compensatory change in the others. Usually, efforts concentrate on structure, people, or technology variables in order to effect an improvement in the task variable, but other variables also react to the change.

For example, a structural change such as decentralization may have been made with the primary intention of affecting the way in which production tasks are carried out. However, the change will most likely have an impact on the technology, such as a shift toward distributive data processing from centralized data processing. The impact on the technology variable could be consciously intended, or could be unforeseen and often a costly outcome of an intention to change only one variable.

Recognizing that a change in one variable affects the others, the remainder of this paper will concentrate on the effects of developments in information technology and the resultant impact on structure variables or, more specifically, organizational response. Information technology is defined as any technology that affects the way in which people in organizations carry out decision-making and administrative activities. The essential concept is that new information technology enables implementation of ideas about more efficient organizational structures. This flow from new information technology can be better understood by applying a second framework.

Organizational learning about information technology framework

Nolan's organizational learning framework views the assimilation of information technology as an organizational learning process involving four growth process variables: application portfolio variables, DP (data processing) organization variables, DP planning and management control system variables, and user awareness variables. The applications portfolio consists of all the automated systems of the company. It changes over time in a fairly predictable pattern. The other three growth process variables are acted on in order to develop an effective applications portfolio.

In Nolan's original work he identified four stages of maturity in the evolution of assimilating computer technology. The four stages are initiation, contagion, control, and maturity. The assimilation of data base technology requires four similar evolutionary stages. Typically, the data base initiation stage has coincided with the control stage of computer technology assimilation. The overlapping of the two four-stage evolutionary patterns produces the six stage evolution of the data resource functions illustrated in Figure 2.

* The author acknowledges helpful reviews of the ideas and concepts in this paper by William E. Bowen, David F. Dantzig, Benjamin S. Porter, Larry G. Robbins, and Gonzalo Verdugo, all of Richard L. Nolan, David P. Norton, and Company, Inc., Lexington, Massachusetts.

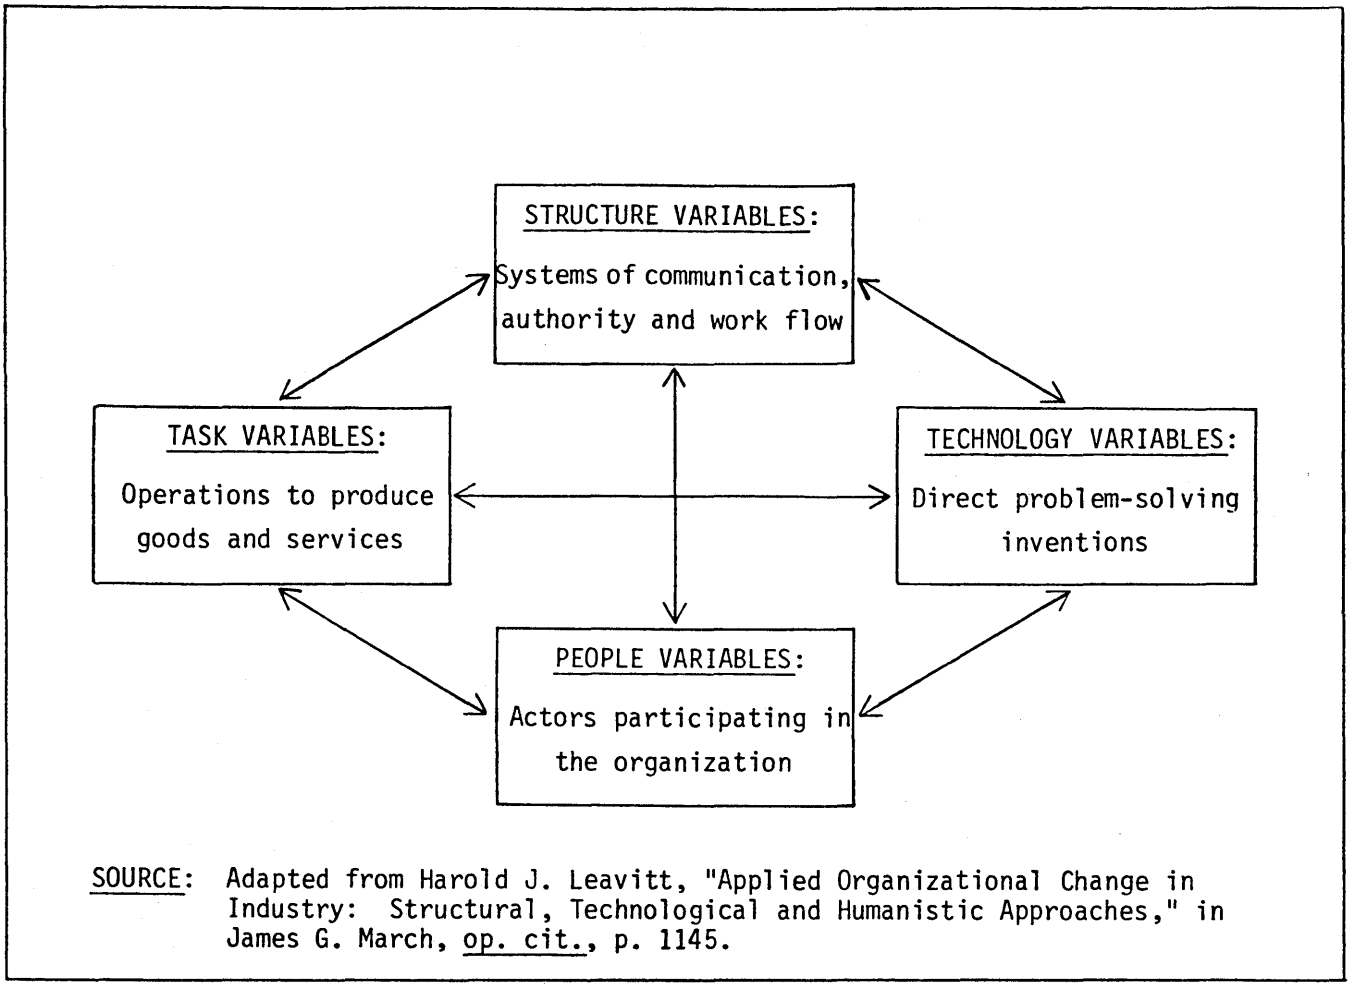

Figure 1—Leavitt organizational change framework

It should be noted that while data base technology is typically introduced during Stage III of computer technology assimilation, the degree of computer technology assimilation is only one of several factors affecting the timing of its introduction. Other factors affecting the timing are: (1) availability and maturity of the technology itself, (2) external knowledge of the technology, (3) business needs of the organization, (4) economic climate of the organization, and (5) competitive pressures for data-oriented customer services. Companies that are currently in Stage I or early Stage II of computer technology assimilation may well initiate data base technology in an earlier stage of maturity than has been typically observed in the past.

Nevertheless, the pattern of the data processing budget curve is a manifestation of the organizational learning. Stages I and II are predominately influenced by the assimilation of computer technology; Stages V and VI are predominately influenced by the assimilation of data base and data communication technologies. Stages III and IV are influenced by both types of technologies.

There are two key concepts that affect the rate and the way a company progresses through the six stages: (1) status of internal and external bodies of knowledge, and (2) balance between control and slack.

1. *Status of Internal and External Bodies of Knowledge*—At any point in time, there exists an external or professional body of knowledge and an internal, or company, body of knowledge on how to effectively manage information technology. The external body of knowledge is largely codified knowledge. It exists in books, seminars and courses. The internal body of knowledge is within the company and exists in documents and policies, as well as in the minds and behavior of the company's management. The internal body of knowledge is largely knowledge that is obtained through experience with information technology. It is also obtained through books, seminars and courses. But the critical point is that experiential knowledge within the company is the major factor in progression through the stages. Figure 3 illustrates the bodies of knowledge concept. The impact of external knowledge on the internal body of knowledge helps explain why companies that automated their first systems in 1970 move through the stages differently than companies

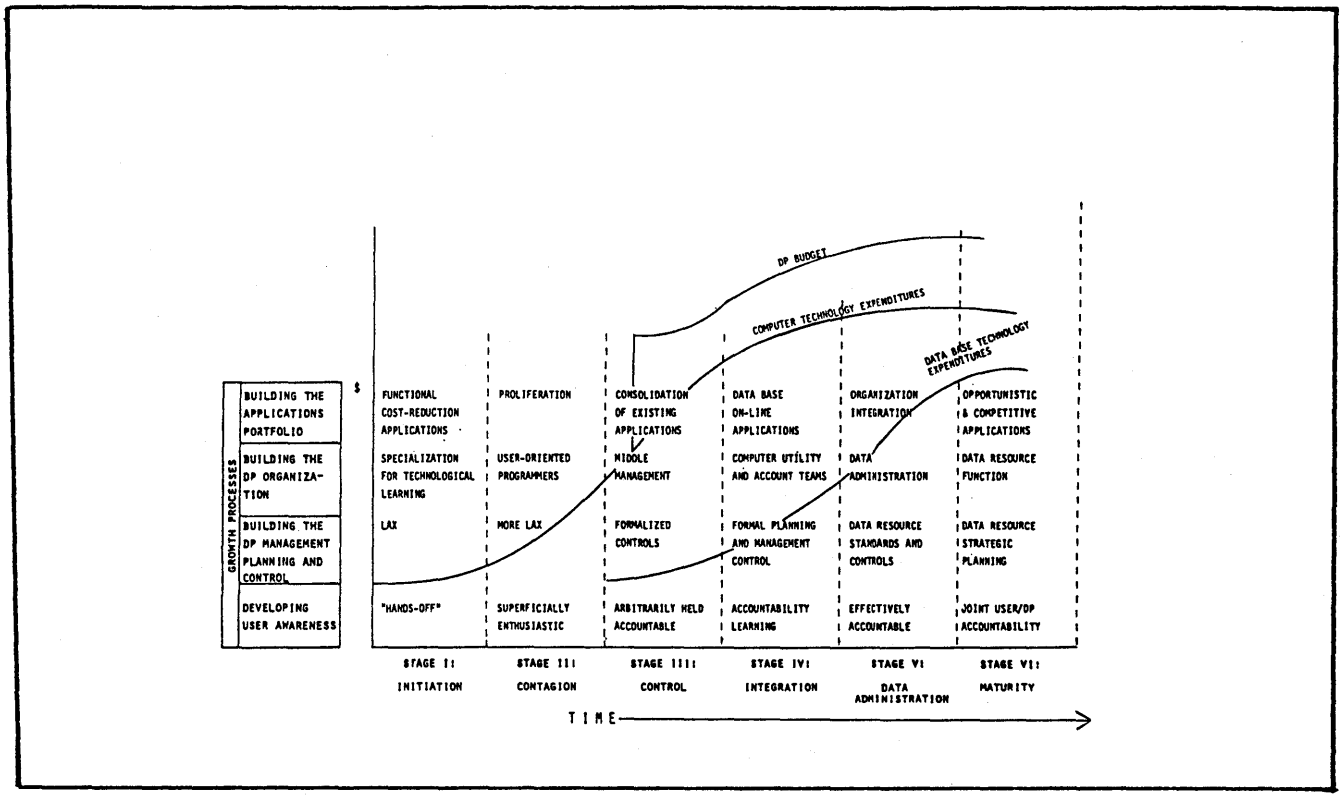

Figure 2—Six stages of data resource function

that automated their first systems in 1960. The relative permissiveness of an individual company to experiential learning is also important in understanding how a company moves through the stages.

2. *Balance Between Control and Slack*—When organizational learning is viewed as a managed process, two environments are balanced—control and slack.[2] In the control environment, all financial and performance management systems—including planning, budgeting, project management, personnel performance reviews and chargeout/cost accounting systems—are used to ensure that data processing activities are effective and efficient. In the slack environment, on the other hand, sophisticated controls are notably absent. Instead, incentives to use data processing in an experimental manner are present. The incentives come in the form of what Cyert and March call "organizational slack."[3] When management permits organizational slack in the data processing activities, they are committing more resources to data processing than are strictly necessary. The extra payment achieves another objective—nurturing innovation. When the objective is no longer present or when the benefits of overpayment are not apparent, slack is reduced. The balance between control and slack is important in analyzing the functions of each stage of organizational learning. Figure 4 shows this balance for the six stages.

In Stage I, a discretionary expenditure for data processing is made, and the objective is designated as the development of a particular application. The organization and staffing for data processing are focused on the narrow objective. Stage I is a period of primary learning about the technology and how to use it. It is also a "proving" period to demonstrate that the new technology has utility to the organization. Control is low because a high fixed-cost discretionary expenditure has been made, and there is little reason to monitor further low-level expenditures. Slack is low because the first applications are narrowly defined replacements for existing manual systems.

Once the first applications reach production status and demonstrate the utility of computer applications to the company, slack is increased to nurture widespread use of the computer, marking the transition into Stage II. Systems analysts and programmers are often recruited from user departments and trained. Formal control is kept low to promote extensive experimentation with applications in multiple functional areas. Having little experience with computer technology, management generally is unaware how fast applications proliferate. The data processing budget rises rapidly during this period because applications often are inefficient and because problems occur when attempts are made to integrate operationally-oriented applications with management's control and planning requirements.

The product of inexperienced programmers and virtually

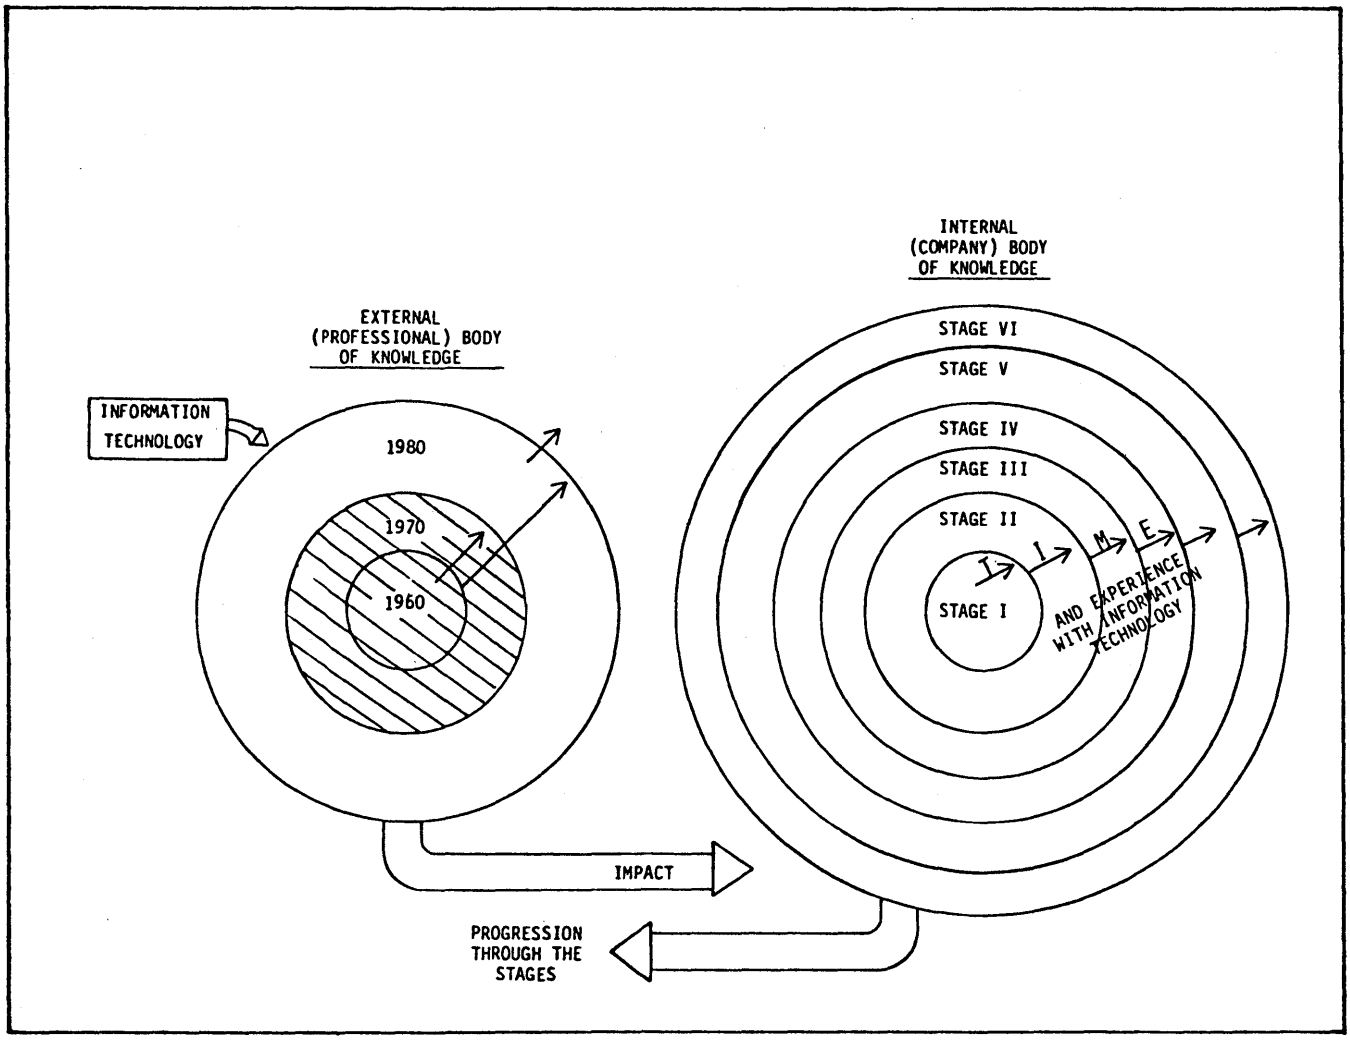

Figure 3—Development of DP bodies of knowledge and movement through stages

no standard for systems development is a portfolio of applications that are almost impossible to build upon. Thus, data processing expenses continue to rise while computer services fall off and stagnate.

When this happens, management initiates actions to increase formal control and reduce slack. The functions of Stage III are to develop appropriate management controls and to "professionalize" data processing personnel. Often management consolidates data processing activities and mandates either greatly reduced or zero budget growth. To appropriately restructure the applications portfolio, the data resource concept[4] is embraced and data-base technology is usually introduced to implement the data resource concept.

This has a confounding impact on the data processing budget as illustrated in Figure 2. Despite tight control and minimal slack in regard to computer technology, a discretionary expenditure is made for a data base application to test the viability of the technology. This is illustrated in Figure 4. Once the data processing staff is rebuilt and the data base technology is proven, the high control becomes a drawback to further progress. Low organizational slack impedes the experimentation and innovation needed to restructure the applications portfolio under the data resource concept.

In Stage IV, slack again becomes high, but control over the data processing department remains high. This is accomplished by fundamental reorganization of the data processing activities. The responsibility for applications that can be associated directly with functional users are assigned to the users and programmers and analysts are organized into Account Teams to assist users. This relieves the data processing department of the no longer logical responsibility for operating and maintaining low-level functional systems. The responsibility for multifunctional applications is vested in a user-represented steering committee. As shown in Figure 4, slack concerning data base technology is high, resulting in a rapid conversion of the existing applications portfolio to a data base structure, as well as a proliferation of integrated

STAGES	ORGANIZATIONAL SLACK		CONTROL	
	COMPUTER	DATA BASE	COMPUTER	DATA BASE
I	Low	NA (not applicable)	Low	NA
II	High	NA	Low	NA
III	Low	Low	High	Low
IV	High	High	High	Low
V	High	Low	High	High
VI	High	High	High	High

Figure 4—Balance of control and organizational slack through the six stages

applications. The architecture of these applications reflects user-orientation through the extensive use of on-line terminals in user departments.

The low control/high slack for data base technology in Stage IV leads to data processing budget growth at rates which lead to a second senior management intervention for control. Stage V is characterized by data administration and a sorting out of data processing department and user department responsibilities under the data resource concept. Slack is reduced and control is increased in order to implement the standards and policies required. The data base structure and specific technology employed are re-evaluated in light of current external and internal bodies of knowledge. Major restructuring of the data base is typically necessary in Stage V.

Once data resource management is accomplished in Stage V, slack can be increased in the specific areas of application development where it is required for innovation. The more stable and conventional data processing activities then can be subjected to a high level of control to ensure maximum efficiency. The result is a controlled data processing budget growth rate more consistent with the company's overall growth rate. These are the characteristics of Stage VI. They indicate organizational acceptance and a relative maturity in the Data Resource function.

Within the context of the two frameworks (i.e., organizational change and organizational learning about information technology), the organizational response to contemporary information technology developments can be probed.

ORGANIZATIONAL RESPONSE AND INFORMATION TECHNOLOGY DEVELOPMENTS

Among the organizational developments in companies' data processing departments that I have observed over the past five years or so, three stand out: (1) balancing centralization with decentralization, (2) data administration, and

(3) distributed processing. Each of these is associated with an initiating information technology and stage. Once initiated in a company, the organizational development or response to an underlying technology evolves through the stages. While there is a "natural" initiating stage, the organizational development may be initiated in other stages as well. Often, earlier initiation precedes a company's readiness for the organizational development and is dysfunctional to effective use and evolution of information technology. I call these stages "red flag" stages.

Organizational response #1: centralization versus decentralization

In the late 1950's and early 1960's, the initial high cost of computer processing and storage resulted in the centralized organization of most data processing departments. Then, as shown in Figure 5, the incredible cost/performance improvements in computer processing and storage and development of user-oriented programming languages gave rise to considerations for decentralizing parts of the data processing activity. Initial considerations were generally given to locating systems analysts in user departments followed by considerations to locate computers in the user departments as well.

The relative absence of planning and control of data processing activities in Stage II results in a recentralization of data processing in Stage III in order to implement the planning and control structures required to effectively manage the activity. Once the controls are implemented, the relative centralization/decentralization of the data processing activity tends to gravitate toward the overall centralization/decentralization philosophy of the company. This gravitation evolves through Stages IV, V and VI.

Stages I, II, and III are "red flag" stages because aggressive management action to effect centralization or decentralization which is contra to the natural forces of centralization in Stage I, decentralization in Stage II, and centralization in Stage III can have a disastrous impact on the data processing activity. The movement toward centralized MIS projects in the 1960's when many organizations trying such projects were in Stage II is an example of a disastrous impact. Many of these companies ended up writing off their MIS projects as total losses. The organizational learning on how to develop applications in multiple departments and manage large development had simply not developed sufficiently.

ORGANIZATIONAL RESPONSE	UNDERLYING INFORMATION TECHNOLOGY	INITIATING STAGE	RED FLAG STAGES	DEVELOPING STAGES
CENTRALIZATION VERSUS DECENTRALIZATION	PROCESSING, STORAGE, & HIGH LEVEL LANGUAGE DEVELOPMENTS	IV	I, II, III	V, VI

Figure 5—Organizational response #1: Centralization versus decentralization

ORGANIZATIONAL RESPONSE	UNDERLYING INFORMATION TECHNOLOGY	INITIATING STAGE	RED FLAG STAGES	DEVELOPING STAGES
DATA ADMINISTRATION	• DATA BASE • DATA COMMUNICATIONS	V	I, II, III, IV	VI
DP CONTROLLER		III	NONE	IV, V, VI
DP PLANNER		VI	I, II, III, IV, V	VI

Figure 6—Organizational response #2: Data administration

Organizational response #2: data administration

Data Administration receives a lot of attention in Stage III when data base technology is introduced. However, the phenomenon is not understood well enough to write appropriate job descriptions and staff it. As shown in Figure 6, the activities of data administration are usually incorporated into a DP Controller position. During Stage IV the applications portfolio is restructured using data base technology, and a critical mass of data base applications results. Data base applications, along with data communications technology, enable a user orientation.

Consequently, the experiential base that evolves by late Stage IV creates the need and appropriate organizational understanding for establishing data administration in Stage V. As the application portfolio continues to evolve with higher-level integrated applications, the opportunity for gaining competitive advantage through effective management and use of data resources emerges. This will lead to the position of Data Planner in Stage VI.

Stages I through IV are "red flag" stages for data administration because of the lack of critical experiential knowledge. However, Stages III and IV represent important opportunistic stages for laying the groundwork for effective data administration.

ORGANIZATIONAL RESPONSE	UNDERLYING INFORMATION TECHNOLOGY	INITIATING STAGE	RED FLAG STAGES	DEVELOPING STAGES
DISTRIBUTED PROCESSING	• MINI/MICRO-COMPUTER • TERMINALS	III	I, II	IV, V, VI
VICE PRESIDENT OF DATA RESOURCES		IV	I, II, III	V, VI

Figure 7—Organizational response #3: Distributed processing

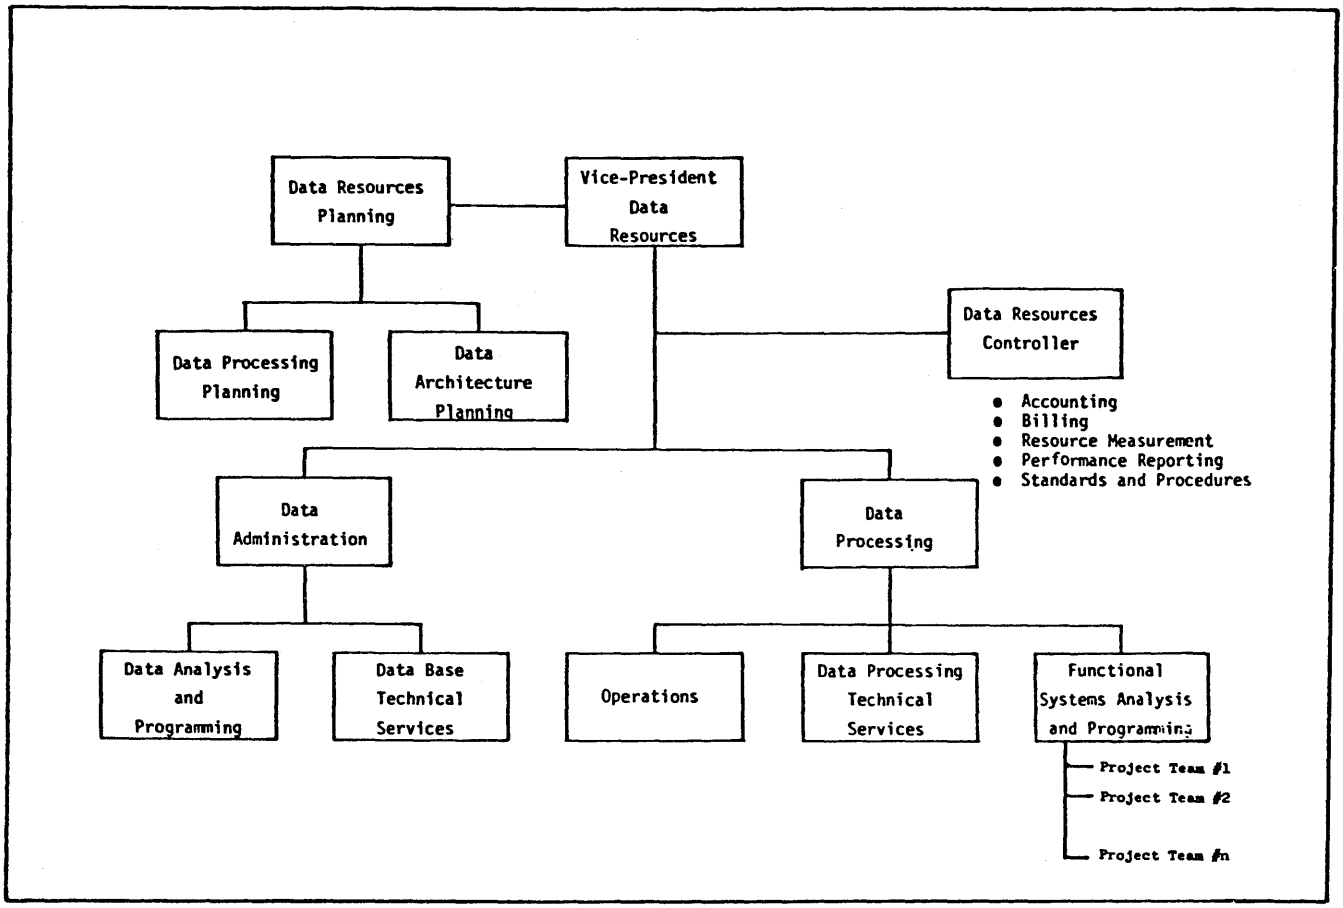

Figure 8—Stage VI data resource organization

Organizational Response #3: Distributed Processing

Distributed Processing is a direct result of technology developments in mini/micro computers, terminals, and data communications. As shown in Figure 7, distributed processing is usually initiated in Stage III. If initiated in Stages I or II, the technologies are usually overwhelming to the data processing department from both a technical standpoint and a management standpoint.

In Stage III the critical control structures are in place so as to enable a managed balancing of the relative centralization/decentralization of the data processing activity to correspond with the overall company philosophy.

The evolving complexity of distributed data processing within the context of an extensive applications portfolio that impacts every aspect of the business, leads to the need for the participation of a high-level data processing manager on the senior management team. In Stage VI, this is reflected in an organizational position such as a Vice President of Data Resources. Figure 8 illustrates the Stage VI organizational structure. Parts of the functions are distributed into the user departments dependent upon the company's overall organizational philosophy.

SUMMARY AND CONCLUSION

Organizations have been and are being remolded by developments in information technology. The advent of the computer has set off this remolding process, and the process has been quickening ever since.

The first remolding was initiated by breakthroughs in computer processing and storage technologies, and the innovation of higher level languages. The organizational response was search for the best balance between centralized and decentralized structures. The overall issue was never resolved because its resolution depended on the individual company's philosophy about centralization and decentralization.

Data base and data communications technologies set off another remolding process of organization structure. We are just beginning to witness the way that this remolding is shaping up. The six stages of the evolution of the data resource function is helpful to understanding current developments as well as future organizational developments.

Distributed processing has been set off by developments in mini-micro computer and terminal technologies. The main

effect of these technologies has been added complexity to the data resource function.

In conclusion, three points are important:

(1) Developments in information technology create organizational responses.
(2) Organizational responses of a company are dependent upon its data processing stage of maturity. The stage is a result of the organizational assimilation of external and internal bodies of knowledge. The rate of knowledge assimilation is greatly influenced by the balance of organizational slack and control.
(3) The current information technology and relative stage status of most companies has created an extremely complex data processing management environment that defies simple solutions. Organizational theories and frameworks are necessary to sort out the phenomena so that effective management action can be executed.

Are statistical data bases secure?*

by DOROTHY E. DENNING
Purdue University
West Lafayette, Indiana

INTRODUCTION

Statistical databases contain sensitive information about individuals. Their objective is providing access to summary statistics about groups of individuals, while denying access to the records pertaining to any particular individual. But this objective is difficult to meet, as seemingly innocuous summaries contain small vestiges of the original data. By correlating enough summaries, confidential data may be deduced and the privacy of some individual therefore compromised.

As more and more of these databases are put on-line, the problem of preventing their compromise is of growing concern. Several questions have been raised:

- How easy is it to compromise a statistical data base?
- Under what conditions are statistical data bases secure?
- Are these conditions usually met?
- Is it practical or even possible to impose these conditions on statistical data bases?

Recent studies reveal that the problem is even more difficult than at first believed. Methods once thought to significantly reduce the threat of compromise—e.g., refusing to issue summaries about small groups of individuals—are in fact easy to circumvent. This paper surveys some of these studies. We begin with a general model of a database.

DATABASE MODEL

Components

Consider a statistical database containing records of information about n individuals. Each record contains *category* and *data* fields. Categories are used to select subgroups of individuals having common characteristics; they need not be disjoint from the data values. There may also be a unique identifier field, which is neither category nor data. Statistical summaries are requested from the database with *queries* which apply to subgroups of individuals.

Table I shows a database of size n=12 containing information on customer accounts for a bank. Each individual belongs to exactly one category in each of these sets:

Sex:	M, F
Profession:	LAWYER, DOCTOR, JOURNALIST, PRESIDENT, SENATOR, BUDGET DIRECTOR
Board Member:	YES, NO
(Number of) Overdrafts:	any integer ≥0

Each individual also has data values for:

(Number of) Overdrafts:	any integer ≥0
Amount (of Overdrafts):	any integer ≥0

All examples will refer to this database.

Compromise

Compromise occurs whenever it is possible to deduce from the responses of one or more queries information not previously known about an individual. The compromise is *positive* if it reveals that the individual belongs to some category or has a particular data value. The compromise is *negative* if it reveals only that the individual does not belong to some category or have a particular data value. For example, learning that individual L had 50 overdrafts is a positive compromise; learning only that he had at least one overdraft is a negative compromise. *Partial compromise* occurs when information about at least one individual is deduced; *complete compromise* occurs when everything in the database is deduced. A database is *strongly secure* if both positive and negative compromise are impossible; it is *weakly secure* if only positive compromise is impossible.

Queries

Researchers have studied two basic forms of queries: characteristic-specified and key-specified. *Characteristic-specified queries* request statistics about all individuals in the data base satisfying a given characteristic; a *characteristic* is a logical formula using categories as operands and Boolean operators: and (·), or (+), and not (−). For a char-

* This work was supported in part by NSF Grant MCS75-21100.

acteristic C, the set of records satisfying C is called the *query set* X_C of C. For example, the characteristic C=M·(LAWYER+DOCTOR), specifying all male lawyers and doctors, has query set X_C consisting of the records for individuals A, D, E, and H. We shall use relations in the specification of characteristics, e.g., OVERDRAFTS≤2, since these are simply abbreviations for the "or" of several values, e.g., 0-OVERDRAFTS + 1-OVERDRAFTS + 2-OVERDRAFTS.

Studies of compromise of statistical data bases have considered characteristic-specified queries q(C) having one of three forms:

COUNT(C)=$|X_C|$, where $|X_C|$ is the size of X_C;

SUM(C;j)=$\sum_{i \in X_C} v_{ij}$, where v_{ij} is data field j of record i;

select(C;j)=select$_{i \in X_C}$ v_{ij}, where select is MEDIAN, SMALLEST, LARGEST, etc.

The query COUNT(C) simply returns the number of individuals satisfying characteristic C. The query SUM(C;j) returns the sum of the values in data field j for all individuals satisfying C. Note that the mean of these values can be computed from

MEAN(C;j)=SUM(C;j)/COUNT(C).

For select= MEDIAN, the query MEDIAN(C;j) returns the median value in data field j for all individuals satisfying C. Examples of queries are:

Formal Query	Answer	Informal Statement
COUNT(M·LAWYER)	3	number of male lawyers
COUNT(M·LAWYER·(OVERDRAFTS>10))	2	number of male lawyers having more than 10 overdrafts
SUM(LAWYER+DOCTOR; OVERDRAFTS)	58	total number of overdrafts of all lawyers and doctors
SUM(BUDGET DIRECTOR; AMOUNT)	$100,000	total amount of overdrafts of all budget directors
MEDIAN(LAWYER+DOCTOR; OVERDRAFTS)	1	median number of overdrafts of all lawyers and doctors

Key-specific queries request statistics for a set of k individuals identified by a list of keys I. The keys are typically the names of individuals. For a key set I, the set of records identified by the keys is the query set X_I of I. The query set size, m, is fixed for all queries. Queries for sums and selection queries are expressed as for characteristic-specified queries, with a key set I substituted for a characteristic C; e.g., SUM(I;j). Since the size of a query set is always m, queries for counts are not applicable.

Key-specified queries are of less practical interest than characteristic-specified queries, since statistical databases generally do not give out data about particular individuals. However, if each individual is identified by a unique set of categories, any key list can be expressed with characteristics. For example, the key list (A, B) can be expressed as the characteristic (M·LAWYER·$\overline{\text{BOARD MEMBER}}$+M·JOURNALIST). Thus, results which show that a database can be compromised with keys apply also to characteristics. However, caution must be taken in interpreting these results. Even though keys can be formulated as characteristics, it is not possible to do so without knowledge of the characteristics identifying the individuals named. Without this information, it is more difficult to control the composition of the query sets. For this reason, achieving compromise with characteristics may be more difficult than with keys. On the other hand, achieving compromise with characteristics may be easier than with keys since counts can be obtained for variable-size query sets.

METHODS OF COMPROMISE

Using small or large query sets

In one of the first published papers describing the problem of securing statistical databases, Hoffman and Miller described a simple algorithm for compromising a data base responding to COUNT queries.[1] Their algorithm is based on the principle of using queries which return small counts to isolate an individual. For example, consider these two queries and responses:

COUNT(M·BUDGET−DIRECTOR) =1
COUNT(M·BUDGET−DIRECTOR·(OVERDRAFTS>0))=1

If it is known that L is a male budget director, then the second query reveals that he had at least one overdraft. In general, if it is known that an individual belongs to categories $c_1, \ldots, c_k$ and if COUNT($c_1 \cdot c_2 \cdot \ldots \cdot c_k$)=1, then the query COUNT($c_1 \cdot c_2 \cdot \ldots \cdot c_k \cdot c_{k+1}$) reveals whether or not the individual also belongs to category c_{k+1} (according to whether or not the response is 1 or 0). Indeed, compromise may be possible even if the response to the first query is larger than 1, say 17, if the response to the second query is the same.

Hoffman and Millers' result is equally applicable to queries which return large counts of all but a few individuals in the data base. For example, L's overdrafts can also be determined from the queries:

COUNT($\overline{\text{M·BUDGET DIRECTOR}}$)=11
COUNT($\overline{\text{M·BUDGET DIRECTOR·(OVERDRAFTS>0)}}$) =11

These results have led researchers to consider databases which do not respond to queries q(C) when the query set size $|X_C|$ falls outside the range [k, n−k] for some k>0, where n is the size of the database. It was anticipated that k≥2 would significantly reduce the threat of compromise.

TABLE I.—Database Containing Information on Customer Accounts for a Bank

	keys	categories			data	
	Name	Sex	Profession	Board Member	Overdrafts	Amount ($)
1	A	M	LAWYER	NO	1	10
2	B	M	JOURNALIST	NO	0	0
3	C	M	PRESIDENT	NO	0	0
4	D	M	DOCTOR	NO	2	100
5	E	M	LAWYER	YES	30	50,000
6	F	F	LAWYER	NO	0	0
7	G	F	SENATOR	NO	3	50
8	H	M	LAWYER	YES	25	10,000
9	I	F	DOCTOR	NO	0	0
10	J	M	SENATOR	NO	0	0
11	K	F	JOURNALIST	NO	0	0
12	L	M	BUDGET DIRECTOR	YES	50	100,000

Trackers

Unfortunately, recent studies have shown this not to be the case. Schlörer showed that compromise may be possible even for large values of k using a "tracker" technique.[2] To illustrate his tracker, suppose k=3 for our database; i.e., no responses are given to queries which involve fewer than three or more than nine individuals. Consider these queries and responses, using as a tracker the characteristic $M \cdot \overline{\text{BUDGET DIRECTOR}}$:

$$\text{COUNT}(M \cdot \overline{\text{BUDGET DIRECTOR}}) = 7$$
$$\text{COUNT}(M \cdot \overline{\text{BUDGET DIRECTOR}} + M \cdot (\text{OVERDRAFTS}=0)) = 7$$

Because the responses to both queries are the same, it can be concluded that no male budget director had no overdrafts; therefore, L must have had an overdraft. Palme suggested a similar technique for queries that compute means.[3]

To construct a Schlörer tracker requires substantial knowledge of the characteristics identifying the individuals to be compromised. Denning, Denning, and Schwartz showed that general trackers may be found even without this knowledge.[4] Such trackers may be used to determine the answer to any COUNT or SUM query not answerable because the query set size is too small or too large. For example, if k=3, the characteristic T=LAWYER + DOCTOR is a general tracker. Let C=M·BUDGET DIRECTOR. Whereas the number of L's overdrafts cannot be determined directly from queries using only C (since $|X_c|=1$), it can be determined from queries using characteristics combining C with the tracker T as follows. First, the sum of the queries COUNT(T) and COUNT($\bar{T}$) can be used to determine the size n of the database; this gives n=12. Second, it can be deduced that L is the only male budget director from the queries COUNT(C+T) and COUNT(C+$\bar{T}$), since

$$\text{COUNT}(C) = \text{COUNT}(C+T) + \text{COUNT}(C+\bar{T}) - n$$
$$= 7 + 6 - 12$$
$$= 1$$

Third, the total number of overdrafts X can be determined by adding the responses to the queries SUM(T; OVERDRAFTS) and SUM($\bar{T}$; OVERDRAFTS), getting X=111. Finally, since L is the only budget director, the number of L's overdrafts can be determined from the queries SUM(C+T; OVERDRAFTS) and SUM(C+$\bar{T}$; OVERDRAFTS), as

$$\text{SUM}(C; \text{OVERDRAFTS}) = \text{SUM}(C+T; \text{OVERDRAFTS}) + \text{SUM}(C+\bar{T}; \text{OVERDRAFTS}) - X$$
$$= 108 + 53 - 111$$
$$= 50$$

We found further that for $k \leq n/4$ almost all data bases have general trackers (though finding them may not be easy). Trackers may also be applicable for larger values of k.

Adding dummy entries

Hoffman observed that data bases restricting the size of allowable query sets may also be subverted if records can be added to the database.[5] If query q(C) is not answerable because X_C is too small, individuals with the characteristic C are added to the data base; if X_C is too large, individuals with the characteristic $\bar{C}$ are added. This result, together with the tracker results, shows that limiting the size of allowable query sets is not an effective security measure.

Overlapping query sets

Another simple technique for compromising a data base is to construct query sets which have a high degree of overlap. For example, consider these queries and responses:

$$\text{SUM}(\text{LAWYER} + F \cdot \text{SENATOR}; \text{AMOUNT}) = \$60{,}000$$
$$\text{SUM}(\text{LAWYER}; \text{AMOUNT}) = \$60{,}010$$

Since G is the only female senator, the second query set

includes all individuals in the first query set except G. Thus, the amount of her overdrafts can be determined by subtracting the response of the second query from the first. This observation has led researchers to consider the effectiveness of methods which restrict the amount of overlap among query sets.

Linear systems

Dobkin, Jones, and Lipton considered compromising with key-specified SUM queries using query sets of size m.[6] They showed that, even if no two query sets can overlap by more than one record, compromise may be achievable in linear time (in m) without prior information, provided the data base is sufficiently large (roughly at least m^2 records). The method involves solving systems of equations for some particular data value. For example, suppose m=3 and let A_i denote the amount of overdrafts for the *ith* individual. Consider these 5 queries:

Q_1=SUM(A,B,C; AMOUNT)
Q_2=SUM(D,E,F; AMOUNT)
Q_3=SUM(A,D,G; AMOUNT)
Q_4=SUM(B,E,G; AMOUNT)
Q_5=SUM(C,F,G; AMOUNT)

$$\begin{aligned} &= A_1+A_2+A_3 && = \$\ 10 \\ &= A_4+A_5+A_6 && = \$50{,}100 \\ &= A_1+A_4+A_7 && = \$\ 160 \\ &= A_2+A_5+A_7 && = \$50{,}050 \\ &= A_3+A_6+A_7 && = \$\ 50 \end{aligned}$$

G's overdraft amount can be determined from

$$(Q_3+Q_4+Q_5-Q_1-Q_2)/3=\$50$$

Davida et al.[10] and Kam and Ullman[7] considered compromise under similar conditions.

Schwartz, Denning, and Denning extended these results to weighted summing queries.[8] We were surprised to learn that if the weights are unknown, complete compromise is possible (in linear time) provided one value in the data base is known. But compromise is impossible without initial information—even if overlap between queries is unrestricted.

Chin showed how achieving compromise with linear systems applies to characteristic-specified queries.[9] His model assumes only that no two individuals belong to the same categories.

Selection methods

Dobkin, Jones, and Lipton,[6] Davida et al.,[10] and Reiss[11] have considered key-specified queries which select some element from the query set; e.g., the median, largest, or smallest data value. Their results show that using combinatorics, compromise is generally achievable in linear time (or better) provided that no two individuals have the same data value. For example, consider these two queries involving records with distinct overdraft values:

MEDIAN(A,D,E; OVERDRAFTS)=2

MEDIAN(B,D,G; OVERDRAFTS)=2

Since D is the only individual common to both queries, the returned median value 2 must be the number of D's overdrafts. DeMillo, Dobkin, and Lipton also showed that this method of compromise applies even if the database "lies about the median value, provided it returns with some value in the query set."[12] For example, the previous example would result in a compromise of D's overdrafts even if 2 were not the true median of the query set values.

PRIVACY SAFEGUARDS

We have considered two measures—restricting the size of allowable query sets and restricting the amount of overlap between queries—which appear on the surface to reduce the threat of compromise. Yet on closer inspection, we observed that both of these measures fail to defend a system from even simple attacks. We shall now examine other privacy safeguards which will, hopefully, prove more effective.

Completely secure data bases

Several studies have reported conditions which, if imposed on the structure or contents of a database, guarantee its security.[6,7,9,13,14,15] In most cases, these conditions depend on the users having little or no supplementary knowledge about either the structure or the contents of the records. This generally rules out the users themselves (or their friends) being represented in the database. Since these conditions are seldom met, they seem to have little value in practice.

Random subfiles

Rather than making the entire Census available to statisticians, the Census Bureau distributes random subfiles of the data. The 1960 Census, for example, was distributed on tape as a $^1/_{1000}$ sample of the full Census with names and addresses removed. Also deleted was geographic information below the level of broad city-size class within the nine geographical divisions of the country.[16] As a result, the payoff from an attempted compromise of a particular individual's privacy from Census tapes is sufficiently small to not pose a serious threat. Unfortunately, this technique is applicable only to large databases; other methods are needed to prevent compromise of small databases.

Rounding schemes

Several studies have been made of rounding schemes for modifying the answers to queries.[3,16–21] One such approach is pseudo-random rounding. Truly random rounding is not

secure since the correct answer to any query can always be determined by averaging a sufficient number of responses to the same query. With pseudo-random rounding, the same query always returns the same response. This method appears to be reasonably effective, although any kind of "stochastic error" added to responses is subject to removal by methods from communication theory.

A second approach is to always round the actual response down to the nearest multiple of some integer or to report a range. For example, the database could respond to the query COUNT(LAWYER; OVERDRAFTS) with 50 (or the range 50-60) rather than the true value 56. However, as noted by Karpinski, this method is easily circumvented if records can be added to the database.[18] To determine the true value of the above query, an intruder could simply add records to the data base for fictitious lawyers having one overdraft each; after the *4th* record is added, the response becomes 60 (or the range 60-70), implying an original value of 56. Even if records cannot be added to the database, it may be possible to modify the characteristic of the query to include records of individuals for whom the number of overdrafts is known.

Partitioned databases

Another approach to preventing compromise partitions the database into groups. In the Yu and Chin scheme,[22] queries must be for characteristics involving entire groups, making it impossible to isolate a particular individual. For example, the sample database could be partitioned by profession into four groups:

Group	Identifying Characteristic	Members
1	LAWYER	A,E,F,H
2	DOCTOR	D,I
3	JOURNALIST+ BUDGET DIRECTOR	B,K,L
4	PRESIDENT+SENATOR	C,G,J

Whereas queries involving complete groups (e.g., all lawyers and doctors) are allowed; queries involving only part of a group (e.g., all male lawyers) are not. Clever query sequences can at best disclose information about an entire group. Yu and Chin show that the technique can be made effective even if the database is dynamically undergoing insertions, deletions, and updates.

The drawback is that the partitions may destroy the usefulness of the database. If the groups are not properly formed, users may not be able to obtain needed information. Whether or not a useful database can be partitioned in this way is open.

Threat monitoring

Threat monitoring techniques detect the possible occurrence of compromise. Felligi showed that it is at least theoretically possible to determine whether the response to a query, when correlated with the responses to earlier queries, could result in compromise.[23] However, the method is too cumbersome to apply in practice. Hoffman and Miller suggested that a log or audit trail of queries be kept and inspected for unusual bursts of activity or queries returning small counts.[1] Although certain compromises may go undetected, the presence of a log may provide a deterrent.

Schlörer suggested that frequency counts of categories be used to determine whether or not a given query might lead to compromise because of small counts.[21] Response is not made to any query involving categories $c_1, \ldots, c_k$ unless the product of the frequency counts $\text{COUNT}(c_i)/n$ (for $i=1, \ldots, k$) is above some threshold.

CONCLUSIONS

The "obvious" techniques for reducing the threat of compromise—e.g., limiting the range of allowable responses, restricting the amount of overlap between query sets, and certain rounding schemes—are easily circumvented. Other techniques—e.g., partitioning—may be robust, but at the price of limiting the usefulness of the data base. The conclusion is that complete privacy cannot be enforced without severely restricting the free flow of information. The questions of interest then become:

- Can we measure the relative security of a data base?
- What is an acceptable level of security?

ACKNOWLEDGMENTS

It is a pleasure to thank Mayer Schwartz and Peter Denning whose ideas and perceptions strongly influenced this paper.

INTRODUCTION

In the last several years, methods for controlling security in computer systems have become widely known. While in 1972 there were only one or two books and three bibliographies on computer security and privacy, in 1977 there were at least 15 books and six bibliographies on the topic. Expanding public concern with the problem is evidenced by a great deal of federal, state and local legislation.[1,2] Governmental agencies such as the National Bureau of Standards, the Defense Department, and the National Science Foundation are all sponsoring research efforts in the area, as have some private manufacturers.[3–5]

One consequence of this work is that a significant part of the computing community is now aware of techniques[6] for maintaining security in computer systems. Unfortunately, the question of how to measure the costs and effectiveness of the various security methods is still largely unexplored. Only recently has there been any reliable work done on costs of privacy transformations or authentication methods, and researchers have only scratched the surface in investigating metrics for security systems.[7] While some more formal work has begun,[8–13] there has so far been very little useful application of this theoretical work to practical security decisions. One exception is a privacy cost model which has been recently introduced.[14] This work assesses the impact of various privacy regulations upon data processing installations which handle personal information. Goldstein discusses conversion costs to meet privacy requirements and the "privacy increment" to installation operational costs. He does not, however, deal directly with the effectiveness of security techniques.

We will address the question of security effectiveness. We here describe SECURATE, a computer installation security evaluation and analysis system, which is based upon a model of a computer installation as a set of triples composed of objects, threats, and security features. SECURATE uses security rating functions based on fuzzy set theory to provide security ratings for an installation as a whole as well as for subsections. It helps to determine weak and strong points and facilitates the comparison of alternative security designs. SECURATE is not meant to be a substitute for a human decision maker.

The SECURATE user first supplies a set of object-threat-feature triples necessary to describe a computer system from a security point of view. OBJECTS are defined as the resources within a computing system, the loss of which would have a cost to the owner. THREATS are activities which a potential intruder may employ to gain unauthorized access to an object. This term also refers to chance events which may jeopardize an object. FEATURES are protective measures which present some degree of resistance to a threat. The second section describes this framework in more detail.

After the system description is complete, the user is asked to specify his or her outlook on security; some view total system security as an all-or-nothing thing, while others see it as dependent in various ways on a system's individual components. Based upon the user's outlook and the system description, SECURATE supplies evaluation functions which return natural-language security ratings of the system or its subsystems. The fifth section describes these evaluation functions.

After the system was implemented in APL, it was used at

* Work supported in part by Grant MCS76-09214 from the National Science Foundation and by the University Committee on Research, The George Washington University.

seven installations by students who were doing risk analyses of the installations. Feedback from this initial group of users is discussed in the seventh section.

TECHNICAL BASIS

The technical basis for SECURATE is in earlier work[15] which defines a security system as a set of objects, each with a loss value; a set of threats, each with a likelihood; and a set of features, each with a resistance. This work addresses the problem of imprecision in the approximation of values, likelihoods, and resistances by using linguistic variables[16] to combine the values of these variables into security ratings.

Clements' model groups resources within computing systems which are vulnerable to some security threat as the set O of security objects. Each object in the set possesses a loss value to its owner.

Associated with each security object O_j is a number of potential intrusion activities; all of these together form the set T of security threats. Each threat T_i has associated with it a likelihood of occurrence.

The object-threat relations form a bipartite directed graph (Figure 1) in which edge T_iO_j exists only if threat T_i is a viable means of compromising object O_j. The relations of threats to objects is not one to one; a threat may compromise any number of objects and an object may be vulnerable to more than one threat.

Finally, there is the set F of security features. A security feature performs a "firewall function" by presenting some degree of resistance to a penetration attempt. The set of security features transforms the bipartite graph of Figure 1 into the tripartite graph of Figure 2. In a "protected" system all edges are of the form T_iF_k and F_kO_j. Any edge of the form T_iO_j identifies an unprotected object. Each triplet (T_i, F_k, O_j) in $T\times F\times O$ contributes to the overall security rating of a system, as we shall see below.

In attempting to specify the object values, threat likelihoods, and feature resistances, one is confronted with the problem of imprecision. In evaluating a computer system's security, one generally relies on imprecise human judgment to provide approximate measures of the effectiveness of security features. The problem is aggravated when one attempts to produce security ratings for entire systems from these measures. The assignment of a numerical security rating is inconsistent with the complexity of data processing installations and the imprecision of the underlying measures. Stating that an installation is ".65 secure" has limited appeal for imparting a sense of how secure an installation is. In addition, the precision implied by such a rating should be viewed skeptically.

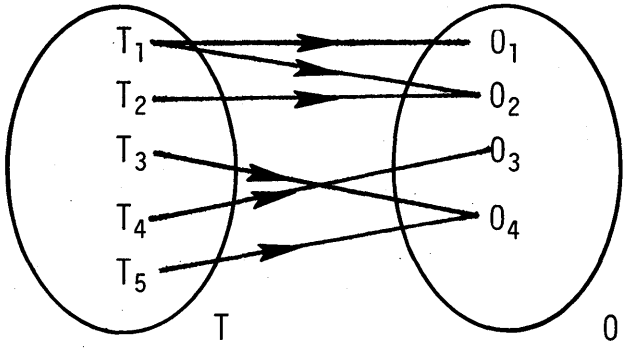

Figure 1—The threat-object relation

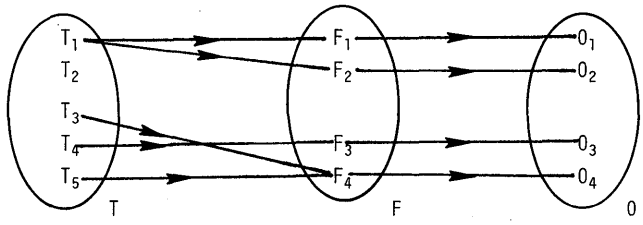

Figure 2—The basic security system

Clements suggested that it is possible to make meaningful measurements of the security of a computer system through the use of linguistic variables—variables which assume values which are words rather than numbers. Using this approach, the object values, threat likelihoods, and feature resistances (as well as the resultant security rating) are specified in terms such as *high, low,* and *medium.* Appropriate modifiers provide finer resolution by allowing terms such as *very high, somewhat low,* etc.

The user assigns linguistic values (*high, medium, very high,* etc.) to the component variables (loss value, likelihood, resistance) for each (object, threat, feature) triplet in the system. These measures determine the contribution of that particular triplet to total system security. How this is done is discussed in a later section.

Each linguistic variable is a fuzzy set whose members are real numbers in the interval [0,1]. These values comprise the *compatibility function,* μ_f, for the specific linguistic variable. For example, if $\mu_{\text{high}}(0.8)=0.9$, 0.9 represents the degree to which a non-fuzzy rating of 0.8 on a *base scale* agrees with a fuzzy rating of *high.* Figure 3 illustrates what the complete compatibility functions for typical *high* and *very high* terms might be. More detail on linguistic variables, base scales, and compatibility functions can be found in Reference 16.

OBJECT HIERARCHY AND LINGUISTIC TERMS

SECURATE provides a "default" hierarchical structure of objects commonly found in computer installations.[17] A small part of this object hierarchy and the corresponding threats and features are presented in the appendix.

There are two phases involved in using the system: (1) typing in a description of the installation and (2) using the security analysis functions.

Object value, threat likelihood, and feature resistance for each security point of interest are first specified by the user in terms of linguistic variables. The vocabulary and Backus-

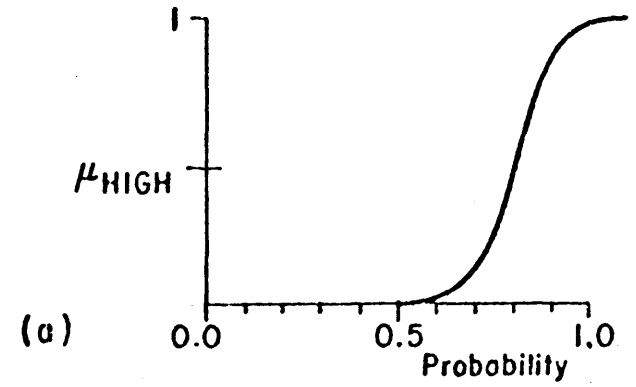

Figure 3a—Typical compatibility function of "high" probability

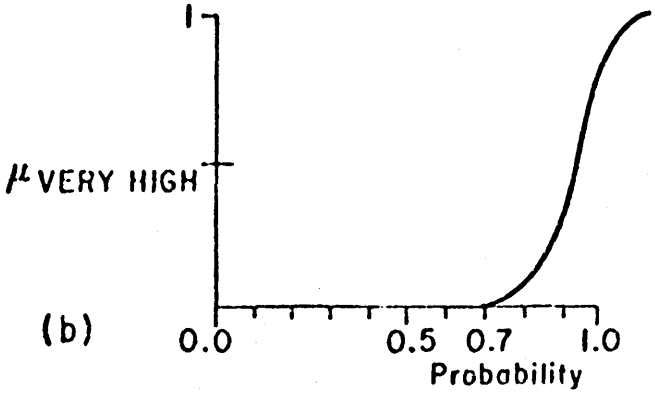

Figure 3b—Typical compatibility function of "very high" probability

Naur form syntax of the rating language, along with examples, are shown in Figure 4.

Once the installation to be analyzed is described in terms of these triples, the functions described in the fifth section are invoked by the user to evaluate and analyze its security.

THE USER INTERFACE

From the start of the SECURATE project, an important objective was to design and implement the system so that it would be as hospitable to the users as possible. Our goals concerning user-oriented features were primarily to keep the system simple, easy to use, and non-tedious. More specifically, we were concerned with the following points:

(a) User Understanding—for obvious reasons, achieving adequate user understanding is very important. Not only won't the system be useful if the user doesn't understand it, but it won't be used.

(b) Simple, Non-tedious Interface—a similar, much simpler system had been developed earlier by a student as a term project. A unanimous criticism of that system was that it took too long to use and the data entry was too tedious. As our system was to require considerably more information, it seemed important to keep the interaction as short, concise, and painless as possible.

(c) Useful Evaluation Functions—while it may seem that this is the most important point, it may actually be the least. A system which a user understands and is comfortable using is more likely to be used and be helpful than a system that doesn't possess these qualities, even if the evaluation functions provided by the first aren't quite as useful as those provided by the second.

Since the object hierarchy was used as a guide for collecting user data, it provided a convenient basis for structuring the input. We drew up forms which corresponded in format exactly to what appeared on the screen. The user wrote down on the forms only the necessary information and then transferred it easily to the system. These forms, by integrating the system commands with the input data in a coherent way, familiarized the users with the system's operation prior to their using it. Figures 5a and 5b show an example of the input form and the corresponding data entry. Further information concerning the user interface is given in Reference 18.

SECURATE assumes that the installation will be similar to that modeled by the hierarchy in Appendix A, although the user can modify the hierarchy appropriately as he or she supplies the triples information. SECURATE leads the user through the hierarchy (and any user modifications to it), providing the opportunity at each node to add offspring or specify triples. If a triple is specified for an object with offspring, it is assumed to refer to that object and each of its offspring. Objects, threats, and features appearing in more than one triple may have different values, likelihoods or resistances, respectively.

Figure 5b—Data entry information typed by the system is underlined

Once the triples are entered, they may be printed out using the DISPLAY function. For each triple this prints out: the triple number; the object name, number, and value; the threat name, number, and value; and the feature resistance. Figure 6 shows the DISPLAY output for a sample system. The information describing the installation is automatically saved and may be used later with repeated applications of the system.

EVALUATION FUNCTIONS

The general system structure is shown in Figure 7. There are several security evaluation functions implemented. Each produces an evaluation based upon the *section* of the system being considered *and* upon a given *outlook* on security.

The possible sections of a system which can be evaluated are the following:

(a) Overall System—This function returns a security rating for the entire installation. That is, it rates the entire set of triples.
(b) All subsections of a Section—with either the top level of the installation hierarchy or one of the subsections specified, this function returns an individual rating for each subsection at the next lower level. For example, if in our sample system, the top level of the hierarchy was specified for a sectional analysis, security ratings would be printed out for each of the following subsections: hardware, software, and the computer center (Figure 8).
(c) Individual Subsection—a security rating is returned for a specified subsection of the installation. Only triples for that subsection (including offspring) are considered (see Figure 9).

In choosing an outlook, the user in effect describes how he or she views security. Once an outlook is chosen, it stays in effect for all of the evaluation functions until it is respecified.

The *outlooks* are the following:

(a) Weakest Link—this will look for the weakest feature resistance and return that as the security rating. The theory here is that the system is only as secure as its weakest link (Figure 10).
(b) Selected Weakest Link—this produces a weakest link rating based on those triples which satisfy the condi-

tion that either the object value or the threat likelihood is greater than a user specified minimum. The theory here is that one would only want to consider triples where the object is of at least a certain value or the threat is of at least a certain likelihood (see Figure 8).

(c) Fuzzy Mean—this performs a fuzzy mean[15] on the feature resistances and returns the result as the rating. The theory here is that a system's security is the mean of the security of its components (Figure 11).

(d) Weighted Fuzzy Mean—this performs a fuzzy mean on the feature resistance weighted by the greater of the object value and threat likelihood for each triple. The theory is that of (c), with the additional assumption that the more valuable objects and those with more likely threats should receive greater weight in the security rating (see Figure 12).

Figure 12—Sample System Software Sectional Rating Using Fuzzy Mean Weighted by Value Outlook

by Maximum Object Value—for each major subsection of the object specified, this finds the fuzzy mean of the resistances. It then weights these fuzzy means by the maximum object value found in the triples for each major subsection and averages these weighted means. The theory is similar to (d), but with the assumption that the major subsections should be weighted by their relative values, irrespective of the number of triples they each have.

THE USE OF APL

APL is extremely well suited to applications involving linguistic variables and fuzzy set operations. Using appropriately named functions and variables, the linguistic variables can be easily converted into the corresponding base variables using the APL "execute" function. For example, HIGH might be a vector of (0 0 0 0 0 .1 .5 .9 1), representing the linguistic variable *high*. VERY might be a function which sharpens the curve given to it as its argument, perhaps squaring the argument. Then as shown in Figure 13, if VALUE were a variable containing the character string "VERY HIGH", executing it would return the vector (0 0 0 0 0 .01 .25 .81 1), representing the base variable for the linguistic variable *very high* (Figure 3 gives the curves representing *high* and *very high*). The important point here is that APL eliminates the need to do any parsing of the input values; the linguistic variables input are stored in character string format and used as input to the scoring functions at the appropriate time. Additionally, the built-in APL matrix operations are well suited to the fuzzy set operators, which use vectors and matrices extensively. These operators are described in detail in Reference 15.

```
      ∇VERY[□]∇
      ∇ OUT←VERY IN
[1]   OUT←IN×IN
      ∇

      HIGH
 0 0 0 0 0 0.1 0.5 0.9 1

      VALUE
VERY HIGH

      ⍎VALUE
 0 0 0 0 0 0.01 0.25 0.81 1
```

Figure 13—APL Execution of Linguistic Variables

On the negative side, APL is interpretive; this makes it significantly slower than compiled programs for repeated runs. In addition, it is poorly suited to applications not involving vectors or arrays. The latter point is important for the security evaluation system since most of the code deals with the user interface and the analysis functions. Not only were these awkward to program, but they run rather slowly (these two points not being unrelated). The rating functions, however, which make heavy use of the matrix capabilities while performing fuzzy set operations, are well suited to APL.

USER REACTIONS

Shortly after development started, we arranged to have the system (running on an IBM 370/145 system under the CP/CMS operating system) tested by students who were doing risk analyses of computer installations as term projects. SECURATE was used to analyze seven installations, including one at a large bank and one at a large utility company.

From written evaluations solicited from each of the users, as well as from conversations with them, it seems clear that the system achieved its goal of increasing understanding of installation security. In fact, a couple of users remarked that just filling out the forms made the strengths and weaknesses of an installation's security a lot clearer. Apparently focusing their thoughts into a logical, well-defined framework enabled them to view the situation more clearly and—even before using the system—to gain some of the insights we had hoped the system would provide.

The most interesting observations were those concerning the use of fuzzy variables. There appears to be definite tradeoff between user acceptance and ease of use. The concept of fuzzy variables was new to all of the users and was greeted with a certain amount of skepticism. While their acceptance of the idea grew as they continued to be exposed to it and had experience in using it, some of them remained skeptical. On the other hand, some of them commented, and we strongly feel this to be true, that the use of these words instead of numbers was a definite help in minimizing the

tedium involved in collecting the input data. The largest installation turned out to be represented by 136 triples, which cam to over 300 different measurements the user had to make. Pinpointing each one on a scale of 1 to 10 appears to us to be a lot more taxing than rating each one as a linguistic variable. Although we didn't do any comparative studies (which in retrospect would have been a good idea), many users seemed to agree with this in informal discussions.

SUMMARY

We have described an interactive security evaluation system which uses fuzzy metrics. The system models the installation to be analyzed as a set of object-threat-feature triples. The associated measures—object values, threat likelihoods, and feature resistances—are then used as input to security evaluation functions. The user specifies these features in terms of "fuzzy" linguistic variables. The system, implemented in APL, is currently operational on an Amdahl 470 computer.

APPENDIX—THE OBJECT HIERARCHY, THREATS, AND FEATURES

The structure of the *threats* is based on the *object hierarchy*, which is used as an outline. *Threats* are listed after the *objects* they refer to, the objects being specified by name and number from the object hierarchy. A threat listed after a non-terminal node of the object hierarchy refers to all objects descending from the node. Features which counter threats follow the listing of the threats.

A panel session—The contribution of planning to information systems productivity

SESSION CHAIRMAN—CHARLES C. TUCKER
Twentieth Century-Fox Film Corporation

Panel Members

John A. Zachman—International Business Machines
Daniel S. Appleton—Borg-Warner Corporation
Michael J. Kirrene—Avco Financial Services

PANEL OVERVIEW—Charles C. Tucker

The traditional approach to information systems development has been to plan at the project level. This leads to the development of independent systems, each with its own data, for each user. Most organizations suffer from the following shortfalls that results from this traditional approach:

1. Systems which are not supportive of business plans
2. Systems that are not easily adaptable to organizational changes
3. Data which is redundant and inconsistent
4. Systems that are difficult to interconnect
5. "Squeaky wheel" priority determination.

Management views this in terms of systems with short useful lives, which are expensive to operate and maintain, and support areas with little impact on the overall success of the company.

The Business Systems Planning methodology used at Fox overcomes these shortfalls by:

1. Tying information systems plans directly to business plans
2. Designing systems around business processes so they are organizationally independent
3. Treating data as a company resource so it can be shared and managed
4. Laying out the overall architecture or network first so the individual systems can be easily interfaced as they are developed
5. Providing a logical framework for determining implementation priorities.

Because of our investment in Business Systems Planning, we expect that the information systems we develop in the future will last longer, cost less to develop and operate, support business plans better, and address our most important information requirements first.

THE INFORMATION SYSTEMS MANAGEMENT SYSTEM: A FRAMEWORK FOR INFORMATION SYSTEMS PLANNING—John A. Zachman

Technology is precipitating a change in management's perception of the role of information systems (I/S) in the business environment. Business Systems Planning is an analytical methodology that has evolved in an attempt to better define this role and manage I/S more effectively in support of management.

As a result of a number of Business Systems Planning analyses, it is becoming apparent that the key to increasing I/S productivity in light of the new role being defined, is the recognition of several components of the overall I/S Management System that must be managed uniquely.

These components include:

1. A Strategic Plan and planning process that looks externally at the business, as well as integrating with the more typical Management Control and Operational Control plans and planning processes which look internally at I/S.
2. An Information Architecture that depicts the business and serves as the "preliminary design" of the integrated product that the I/S organization is in place to build.
3. A Data Architecture (and its attendant management facility) that protects the consistency of data for management's measurement purposes, as well as controls the project development activities to insure their conformance to the Information Architecture.

These components of the I/S Management System are over and above the traditional Development and Operations components, well recognized as requiring unique attention, supporting the role of I/S as it is perceived in today's typical environment. The recognition and management of the additional components will have a substantial impact in increasing productivity by minimizing systems redesign for data integration purposes, minimizing maintenance activity

caused by the interdependence of individual systems and files, and insuring that the systems developed more closely meet the expectations and requirements of management.

A DATA MODEL APPROACH TO BUSINESS SYSTEMS PLANNING AND CONTROL—Daniel S. Appleton

The management problem is to establish a viable Business Systems Plan based on the basic business mission. The MIS problem is to implement the Business System Plan. To do this, MIS must create a system structure in the business which will respond to constant changes. MIS must understand the fundamental structure and keep that structure flexible in response to the business.

At Byron Jackson Pump (BJP) we first developed a data model of our business structure.* Next, we tested this model conceptually to determine how it would respond to various changes: e.g., decentralization, product standardization, new product development, productivity improvement, cost reduction.

The data model of the business was then established as our basic Management Systems Technology and placed under control of what we call the Storage and Processing Control System (SPCS). The SPCS provides centralized, standardized control over all data elements, internal processing routines, minimum edits, security routines, and physical file structures. It defines the basic management technology which can be customized to the requirements of the various BJP manufacturing locations and DP Service Centers worldwide. It handles the basic spectrum of manufacturing systems, from process control through job shop control, including any hybrid mix of the two, and accommodates fluctuations based on product mix changes and strategic plans.

The level of management technology of the SPCS is controlled by the MIS Steering Committee, which funds major modifications. Minor modifications required to customize for efficiency or effectiveness at a given location are controlled by the location's System Management Team.

BJP's two other MIS control systems, i.e., the Input and Output Control Systems, provide the basic tools for distribution, implementation, and customization of the management technology of the SPCS at individual locations. The I/O Control Systems are managed by DP Service Centers in coordination with local Systems Management Teams in each location.

All three control systems taken together comprise BJP's Functional Network (FN) concept. FN is an approach to distributed data processing which concentrates on improving the efficiency and cost-effectiveness of the three basic DP functions: (1) Storage and Processing, (2) Input, and (3) Output. Its advantages over the traditional Applications Network concept include:

1. Lower DP marginal costs
2. Increased compatibility with business growth and dynamics
3. Better control over DP technology
4. More efficient use of DP overhead
5. More effective use of direct DP expenditures
6. Easier to customize
7. Reduced implementation time
8. Higher quality systems
9. Easier to maintain systems.

In summary, the data model describing BJP's management system technology provides a consistent, comprehensible foundation for development of the business system structure. Through BJP's Functional Network, the development, maintenance, implementation, customization and distribution of that management systems technology is controlled based on the specific needs of individual locations.

INFORMATION SYSTEMS PLANNING IN THE NON-PLANNING ENVIRONMENT—Michael J. Kirrene

Avco Financial Services (AFS) is the third largest consumer finance company in the U.S. with sizable operations in Canada and Australia and footholds in Puerto Rico, Great Britain, and Japan. The management team is young and aggressive, operations oriented, and determined to be number one. By any measures AFS is a successful company.

From a planning point of view, however, AFS represents the "typical" organization as defiend by John Zachman. Corporate planning and controlling efforts are focused upon individual projects. The formal Business Systems Plan as defined in the literature does not exist, and attempts to develop one would be viewed as bureaucratic endeavors designed to further delay addressing immediate data processing needs. While a company can obviously exist without a formal plan, the Information Systems Department must have a plan tied to the business goals in order to maximize its contribution to the welfare of the company it serves. It is even possible with todays operations support systems that data processings activities (or lack of activities) can be detrimental to the business.

The challenge is how to develop effective planning in a non-planning environment. Our Information Systems Department has taken a unilateral approach, including senior management whenever and wherever possible, but always taking the initiative. The results have been mixed. Although we do not have a Business Systems Plan, we at least have a projects plan reviewed by senior management on a quarterly basis and, more importantly, have taken that first crucial step of planning together with the company.

Intellectually, it is easy to accept the need for a Business Systems Plan properly derived from a careful analysis of the functional processes and information flow of the business. In the real world, however, it appears that rather than attempting to sell the typical company on Business Systems Planning, the Information Systems Department should be acting as a catalyst, developing business planning sponsors, aligning data processing more and more with the business objectives by learning more about the business it serves, and aggressively participating in the evolution from project planning to Business Systems Planning.

Einar Steffereud—Network Management Associates
J. A. Sutton—IBM Corporation

A POLITICAL PERSPECTIVE ON COMPUTERS IN LOCAL GOVERNMENT—William Dutton

Most people concerned with computing in complex organizations do not consider computers a subject for political analysis; but few people can maintain this view in the future. Social scientists define "politics" as the allocation of goods, services, values, and resources. Thus every organization is faced with "political" decisions when deciding whether to fund one program rather than another. From this point of view, "politics" is neither inherently "dirty" nor restricted to institutionalized procedures, such as voting, but is a common element of organizational life. Computing is a political technology because it can, and frequently is, used to effect the distribution of values among various interests. In any organization there are serious differences of opinion and interest over the adoption, support, use, and control of computer technology.

The political elements of computing can be addressed in three areas: (1) the allocation of computing resources as a means to control other related resources (e.g., staff); (2) the computer's use to effect the distribution of information, and therefore the distribution of power and control in an organization, and (3) the computer's use to reinforce an organization's political economy as reflected in the kinds of goods and services it provides. This talk draws upon data collected by the URBIS Group in several national surveys and case studies of computing in American local governments since 1974.

We have found computing to be a complex resource "package." And the allocation of the resources comprising the computing package is often a significant issue within organizations. Directly, computers constitute a resource because they bring with them differential control of their capabilities vis-a-vis other resource controllers. Indirectly, computers raise political issues because they frequently affect the relative distribution of other resources such as staff, money and status amongst organizational units.

Computing also raises political issues within organizations because of its instrumental value to different actors, particularly as a result of information that can be provided. Top decision-makers are interested in information that might help clarify choices and identify problems. Managers and supervisors are interested in operational data about those whose activities they guide and direct. In public agencies, data-dependent departments like planning seek some of their data from information-generating departments, which sometimes place propietary rights on their data. Since computers frequently alter the content, direction, and speed of information flows, they thereby affect the relative influence of these organizational actors.

Many problems with computing are not a function of inadequate or unavailable technical or managerial solutions. Rather, they are due to differences of interest or opinion regarding potential impacts. Beliefs about the best solution vary accordingly. However, solutions to computing problems which are solely technically-based or management-based may fail because they ignore the local politics of computing. Furthermore, some problems lack solutions, *even when politics is considered.* Technical and managerial solutions may create politically unacceptable impacts. Or, politically attractive solutions might not align with feasible technical and managerial solutions.

These observations will be illustrated with a variety of data drawn from the URBIS studies.

SERVICE PROVIDER OR SKILL BUREAUCRACY?—THE DATA PROCESSING FUNCTION IN LOCAL GOVERNMENT—James Danziger

A straightforward interpretation of the data processing unit's function is that is a *provider of services* to its clients. Increasingly, the formal information systems of many organizations is centered in EDP. Data processing is responsible for providing the local government with a set of service activities involving data: record-keeping, record-searching, printing and calculating, record restructuring, and analysis. The quality of the service hinges on the effective utilization

of hardware, software, and staff skills to the accurate, useful, and timely treatment of data. In this analytic sense, the EDP function is similar to the typing pool (although computing is far more technical): both EDP and typing involve the skillful organization of data, to facilitate their use by other organizational staff. If one were to provide a normative theory of organizational roles relating to EDP as a service provider, top managers would have the primary responsibility for deciding what EDP should do, the EDP unit would provide these data handling services, and the users of EDP services would organize them for effective utilization.

Alternatively, the EDP unit can be characterized as a "skill bureaucracy." The distinguishing feature of a skill bureaucracy is its relative monopoly on some area of technical expertise. While it does provide services, its behavior is driven by certain self-oriented values: (1) to preserve autonomy from outside control; (2) to dominate its relationship with its clients; (3) to expand its domain of activity; and (4) to be guided by its internal standards of professionalism. There is good evidence, for example, that skill bureaucracies in education and public-welfare achieve these values relative to policy-makers and to clients of their own services. Given the highly technical nature of computing and the professional concerns of computing specialists, EDP units seem particularly likely to manifest attributes of a skill bureaucracy.

The concepts of service-provider and skill bureaucracy are ideal-type characterizations, and actual EDP units display some aspects of each kind of orientation. However, data drawn from surveys of computing practices in local government under the URBIS project indicates that skill-bureaucratic features are common in many American local government EDP organizations. This talk will address these alternative models of the EDP function based upon both survey data and case studies.

USEFUL APPLICATION OF POLITICS IN COMPUTING—Einar Steffereud

THE ORGANIZATIONAL ENVIRONMENT

In many large organizations computing allocations are made either by committee or by a "computing czar." While these choices seem to span the range of centralized authority through participatory decision-making, in fact they often fail to achieve the intended effects. This talk provides a framework for understanding how committees can be effectively organized to deal with different computing rationales used by operating units, and thus to act so as to sensibly distribute resources rather than simply diffuse responsibility.

Computing has assumed a central role as a major engine of production and is shared by large portions of many organizations. Despite the deployment of mimicomputers, many organizational units are becoming increasingly dependent upon shared or common computing systems (including networks). While it is common for different organizational units to develop their own rationales for action, shared data and computing resources tends to lead to smaller differences of rationale at the operating levels of large organizations.

PROBLEMS OF COMPUTER GOVERNANCE

As computing becomes more pervasive, it becomes more essential to find workable compromises between value system differences between operating departments in an organization. These negotiated compromises are essentially "political" rather than "technical" solutions. (Conflicting values cannot be forced by the authority of a computing "czar." The half-life of a computing "czar" is inversely proportional to the extent to which he assumes control of other people's resources.)

So how can the problems of computing governance by effectively resolved? An effective governance structure must aggregate the required power from operating departments. This differs from a responsibility diffusion committee which includes "representatives" from operating department who have little power to commit their departments to authoritative policies. Observations in several diverse computer using organizations indicate that user committees which fail to mirror the de facto power structure of the organization tend to be ineffective in dealing with conflicts over computing use, and fail to make "sensible" allocation decisions. With a power aggregation committee, substantial political issues can be resolved, which otherwise tend to be analyzed, debated, and avoided.

This talk illustrates several different strategies of computing governance with examples drawn from a variety of computer-using organizations.

ORGANIZATIONAL CONSIDERATIONS IN D.P. RESOURCE ALLOCATION—J. A. Sutton

Data processing resources frequently are in great demand by "user-departments" who would like to utilize those resources. When the allocation of these resources is perceived as unfair, members of user-departments may become dissatisfied with the data processing department. The frequency with which articles appear pointing out user-D.P. problems and suggesting solutions to these problems suggests dissatisfaction is widespread.

This discussion focusses on organizational mechanisms intended to provide the necessary communication and resource allocation between the Data Processing Department and departments wishing to utilize data processing services. Several mechanisms frequently proposed to facilitate interdepartmental transactions will be discussed, research results on their effectiveness will be reported, and recommendations will be made for the management of the interdepartmental interface.

Mechanisms for the management of the interface between

D.P. and user departments generally fall into two categories: (1) formalization of interfaces (e.g., establishment of a D.P. Steering Committee), and (2) decentralization of some function to the user department (e.g., location of systems analysts in the user department). Mechanisms from both of these categories are frequently intended to "increase user involvement."

Organizational behavior theory suggests that the potential for conflict at the D.P.-user department interface is great and that substantial benefits might accrue from improved integration between departments. Recent research suggests that some of the mechanisms proposed to enhance D.P.-user relations have little impact (e.g., whether the D.P. manager reports to a department head or is himeslf a department head has little impact on user satisfaction with D.P.). We observe that as D.P. departments grow in size, they exhibit a tendency to increase the number of formal mechanisms in place, yet evidence suggests that simply adding mechanisms has little effect on user satisfaction. However, the perceived effectiveness of many mechanisms is closely related to user satisfaction with D.P.

These results suggest that adding mechanisms intended to enhance the perception of "fair" resource allocation and to improve user satisfaction with D.P. may not serve the intended purpose. Rather, the results suggest that the *quality* (or perceived effectiveness) of interdepartmental integration mechanisms may be the critical issue. Hence, the efforts of the D.P. manager (and others) may be better spent at improving the effectiveness of existing mechanisms rather than putting new mechanisms in place.

Software development methodology

OVERVIEW

Beginning in the late 1960s with an interest in programming methodology, researchers and practitioners alike have begun to pay increased attention to the methods used to develop software. This interest in technique is driven by two major concerns: productivity and quality.

As the cost of software has soared, both in absolute terms and as a fraction of the budget of many organizations, managers have realized that the productivity of the software development group was a critical factor. The call has gone out for improvement and this in turn has caused many people to take a new look at the methods they are using.

The vastly expanded role of software-intensive systems in the operation of most organizations has also caused managers and users alike to look critically at the quality of the software produced. The most obvious quality factor is reliability, but there are many other factors such as security, efficiency, and maintainability. As with productivity, those responsible for building software have realized that one of the variables in building quality software is the method used.

This increased emphasis on methodology has rapidly expanded beyond the original concern with programming alone. Today, we realize that the entire life-cycle of software—from initial need through years of repair and enhancement—must be considered when we start to address issues of quality and productivity.

Matching this life-cycle awareness, we have organized five sessions for NCC '78 that address methodological questions in different phases of software development:

Software Design and Analysis includes papers that address questions of overall system definition and organization.

Programming Methodology will focus on several topics that are relevant to the way in which we create individual programs.

Software Verification, Validation, and Testing samples several new and important concepts in the still-critical area of demonstrating system correctness.

Software Maintenance has been organized especially to address this phase that is often neglected in technical meetings. Although no papers appear in the Proceedings, the panelists represent a large amount of experience with maintenance activity, making this an especially interesting session.

User Experience with New Software Methods is an attempt to redress an imbalance inherent in technical meetings. A panel of six experts with personal and corporate experience using many of the new methods has been assembled. They will share their experience as users—not creators—of the new methods and discuss some of the problems encountered and benefits gained in implementing them. This should be an especially valuable session to attend, in addition to reading the position papers from the panelists that appear in the Proceedings.

All of the paper sessions include a discussant to provide balance and perspective on the presentations. We hope that these sessions will contribute to your understanding of new software methodologies and, in turn, help you and your organization to improve both the quality and productivity of your software development.

A description scheme to aid the design of collections of concurrent processes*

INTRODUCTION

Abstract data types have recently emerged as an important facility for the specification of sequential programs. Originally defined in the language SIMULA,[1] abstract data types were soon recognized as useful in structured programming.[2] Their recent refinement has taken three directions. First, they have been developed to support top-down design methods.[3] Second, they have been extended so as to provide a basis for formal verification.[4] Finally, they have been used as the basis for a tool to aid program development[5] which admits rigorous, but perhaps incomplete, analysis.[6] The variety of these uses indicates the breadth of the benefits which accrue from facilities for high-level, abstract description.

While abstract data types are convenient for the description of a software system's data storage components, they are not convenient for the succinct description of those system components which are more for the processing than the storage of data. This is particularly true when the components operate concurrently.** The major problem is that abstract data types are oriented towards describing components as structures of data which are operated upon via procedure calls. Many components—e.g., a text editor in an operating system or a file system in a multiprocessor computing facility—are not naturally described in this manner.

Extensions and modifications to abstract data types could be developed to increase their effectiveness in describing processing components in software systems—this has been done in the Gypsy system[7] and the Modula programming language.[8] In this paper, however, we develop a description scheme that retains many of the concepts of abstract data types but builds upon the concept of a sequential process. Further, the description scheme developed in this paper focuses upon the succinct *modelling* of a system's processing components rather than their detailed programming.

The modelling scheme presented here is an extension of a scheme for describing sequential process interaction[9] that was developed as a basis for software system analysis.[10] It has been prepared for use in the Design Realization, Evaluation And Modelling (DREAM) system[11] which provides bookkeeping and analysis aid to the designers of large-scale software systems. The scheme is part of the DREAM Design Notation (DDN) which has been developed to permit the incremental development of a system's design as a series of design description fragments, called *textual units*.

In the next section, the basis for the modelling scheme is established by developing an abstract view of sequential process interaction as occurring through message interchange. The following sections then develop the model of

* This work was supported by a grant from Sycor, Inc.

** By *concurrent* we mean parallelism which may be actually achieved by executing the system in a multiprocessing environment or which may be only apparent at abstract levels of system description and never achieved during system execution.

a *subsystem,* i.e., a collection of concurrent sequential processes. Subsystem interfaces and interaction are described first. Then a scheme for the non-procedural description of a subsystem's behavior is presented. The paper concludes with a brief discussion of the ways in which the modelling scheme may be beneficially used during the development of large-scale software systems.

The focus of this paper is upon DDN constructs for describing collections of concurrent sequential processes. More complete treatment of this material and discussions of other aspects of DREAM may be found in References 12 through 16. Also, the focus is upon the use of the constructs—their syntax is covered in Reference 17. Some justification for the constructs are given; others lie in the DREAM system's general philosophy which is discussed in Reference 18.

AN ABSTRACT VIEW OF SOFTWARE SYSTEMS

A software system may be viewed as composed of parts, *subsystems,* which operate concurrently and asynchronously and which interact either through shared data objects or by the sending and receiving of messages. This is a natural way in which to view multiprocessor systems, since these systems actually have components which interact by message transmission. But this view is also appropriate when it is merely a logical one and the system actually runs in a uniprocessor environment. In this case, the view facilitates the decomposition of the system (and thereby the mastery of its complexity[19]) and message transmission is used only to model the actual interactions.

As an example of this view of software systems, consider the HEARSAY speech recognition system[20] developed at Carnegie-Mellon University. One subsystem within the HEARSAY system is a data base, called the blackboard, which contains all the information about the utterance being recognized and the hypotheses which have been made as to its linguistic structure. The other subsystems within the HEARSAY system are processing components called knowledge sources. Each knowledge source inspects the information in the data base and augments or modifies it according to the rules which the knowledge source is programmed to enforce.

The interactions among these subsystems are as follows. Since it would be wasteful to have each knowledge source constantly inspect the data base to determine whether it should perform any processing, the data base is programmed to know which data base entries are of interest to each knowledge source and to send a signal to a knowledge source whenever one of the data base entries of interest to it changes value. Each knowledge source is reentrant and this (conceptually) means that each knowledge source has several internal servicer subsystems, each of which can perform the processing to be done by the knowledge source. When a knowledge source is signalled by the data base, one of these servicer subsystems is activated and it inspects the data base and makes any appropriate modifications. The interactions between a servicer and the data base consist of a sequence of message transmissions, with the data base returning messages in response to the requests sent by the servicer.

THE MODELLING SCHEME

A modelling scheme based upon this abstract view of software systems must have facilities for describing subsystems and their interactions. In this paper, we focus upon those subsystem interactions which occur through message transfer. We assume, therefore, the existence of a scheme for describing data objects that may be shared by a community of concurrent subsystems.* Such a scheme must be able to describe many aspects of shared data objects, but for the present discussion it is only important that the scheme allow the specification of the possible values of the data objects.

A subsystem model must describe three aspects of the subsystem. First, it must specify the interfaces to the subsystem not only in terms of the format of the information flowing through each interface but also in terms of what information may legally flow through each interface. Second, it must specify the legal sequences of message flow through the interfaces. Finally, it must relate the subsystem's operation at one point in time to its operation at a previous point in time—i.e., it must specify the more global aspects of the subsystem's operation.

In the following sections, each of these aspects is discussed and illustrated by examples which, taken together, comprise a description of the knowledge source subsystems of HEARSAY.** Since all of the knowledge source subsystems are similar with respect to their interactions with the data base, the description developed in the examples is of the *class* of knowledge source subsystems. To reflect that different instances of this class vary with respect to their details, such as the number of entries in the data base that are of interest to the knowledge source, we define a parameterized class. This means that part of the definition of the class is a specification of *qualifiers* which may be assigned values when an instance of the class is created. Class definitions and qualifiers are discussed more fully in Reference 12.

SUBSYSTEM INTERFACES

A subsystem's interface consists of a set of *ports* through which messages may flow. Conceptually, a port is a communication line along which messages flow, one at a time, and which does not have any storage capabilities. Ports correspond to uni-directional communication lines and therefore have a direction *in* or *out.*

---

* A scheme that was developed in conjunction with the work reported here is discussed in Reference 13.

** The description is an approximation of the actual structure and operation of the knowledge sources in HEARSAY. It reflects our understanding of the description which appears in Reference 20, but has also been constructed so as to provide examples of the facilities in DDN.

```
[knowledge_source] : SUBSYSTEM CLASS;

  QUALIFIERS;
     DOCUMENTATION;
        #_values is the number of data base entries
        monitored for this knowledge source; #_servers
        is the number of parallel servers in this
        knowledge source
        END DOCUMENTATION;
     #_values, #_servers
     END QUALIFIERS;

  await: ARRAY [1::#_values] OF IN PORT;
     BUFFER SUBCOMPONENTS;
        signal OF [on_off_switch]
        END BUFFER SUBCOMPONENTS;
     END IN PORT;

  make_request: ARRAY [1::#_servers] OF OUT PORT;
     BUFFER SUBCOMPONENTS;
        request OF [data_base_operation]
        END BUFFER SUBCOMPONENTS;
     BUFFER CONDITIONS;
        request=inspect,
        request=modify
        END BUFFER CONDITIONS;
     END OUT PORT;

  get_answer: ARRAY [1::#_servers] OF IN PORT;
     BUFFER SUBCOMPONENTS;
        answer OF [data_base_response]
        END BUFFER SUBCOMPONENTS;
     END IN PORT;

  END SUBSYSTEM CLASS;
```

Figure 1

The messages which flow through a port are (ordered) sets of data objects. Each port therefore has associated with it a set of *buffers,* each able to store one data object. The set of buffers indicates the types of data objects which comprise a message and the order in which the data objects are composed to form a message.

The messages which may legally flow through a port are specified by giving *buffer conditions* for the port. A buffer condition is a predicate over the buffer data objects, indicating the set of legal values for the buffer data objects as well as the legal correlations among the values. OR'ed together, the buffer conditions associated with an in-port (out-port) are analogous to a pre-condition (post-condition).[21]

In DDN, a port is defined by a textual unit which specifies the port's name and direction and which has nested textual units which specify the buffers and the buffer conditions associated with the port. A set of ports is defined in Figure 1 for objects in the class [knowledge_source].* If an object of this class were created with #_values having the value 4 and #_servers having the value 3, then the object would appear as pictured in Figure 2. Notice that defining an array of ports implies that there is an array of buffers, one for each port. The condition associated with the make_request ports indicates that messages flowing out through these ports should have only the value *inspect* or *modify*.

* It is a convention in DDN to enclose an identifier in square brackets when it is used to name a class.

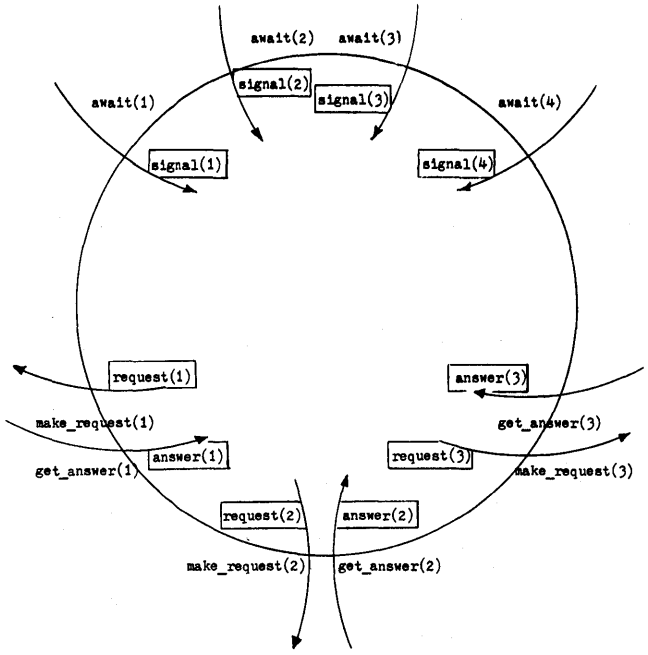

Figure 2

A port definition is comparable to a heading for a procedure stated in a programming language. It is similar in that it specifies a name by which the port (procedure) may be referenced and the number, type and order of the data objects (parameters) in messages (parameter lists) processed by the internal components (procedure body). It differs because ports allow only one-way communication whereas procedures provide two-way communication. The buffer conditions of DDN are similar to the *entry* and *exit* specifications of Alphard[4] with the additional aspect that they are required to be valid whenever a message flows through the port.

MESSAGE FLOW THROUGH A SUBSYSTEM

The role that a subsystem plays within a community of subsystems is specified by a definition of the correlations among the messages flowing into and out of the subsystem. When this defines the injection of messages into the subsystem's environment as a result of the reception of messages, then it serves to specify the facilities provided by the subsystem. When it defines the reception of messages subsequent to the injection of messages into the environment, then it serves to specify the subsystem's utilization of other subsystems in its environment.

A subsystem's message flow characteristics may primarily be defined in terms of sequences of message transmissions through the subsystem's ports. This is analogous to defining a procedure in terms of a set of parameter/result pairs. More complex characteristics, called *global characteristics,* concern the correlations between transmissions occurring in different message transmission sequences. For example, in manipulating a stack, a pop operation must be preceded, at

some point in time, by a push operation. In this section, the concern is with the more easily specified sequential message transmission characteristics. The specification of global message flow characteristics is treated in the next section.

Sequential message transmission characteristics are specified by giving a set of programs, each of which is a model of a sequential process, called a *control process*. Each control process model specifies a set of sequences of message flow through the subsystem. A control process is defined by a nondeterministic, procedural model which specifies the control process' message reception and transmission activity. Nondeterminism is allowed because it contributes to the clarity of the model, allowing succinct definition of the control process. A procedural specification is also used to enhance the clarity of the description.

Messages flow in and out through a subsystem's ports as a result of *receive* and *send* operations. For a send operation, a message is first composed using the values of the buffers associated with the port that is specified in the send operation. Then, the message is sent out through the port to be placed in the link to which the port is attached* and thereby made available for reception by some subsystem. The control process which invoked the operation is suspended while the message is constructed and placed in the link. Since links have infinite storage capacity, this suspension is relatively short and the send operation can therefore be considered to be a non-blocking operation.

When a receive operation is performed, the control process invoking the operation is suspended until a message is retrieved from the link to which the port specified in the receive operation is attached. The message is then decomposed and distributed among the buffers associated with the port. Since it is possible to request a message when none is available, the receive operation can block the control process which invoked it for relatively long periods.

Prior to a send operation, the subsystem will compute the values of the data objects which compose the message and place these values in the buffers. This computation may be lengthy and complicated, but neither its time consumption nor its detail are of interest in defining sequential message

```
'[knowledge_source]: SUBSYSTEM CLASS'
  listener: ARRAY [1::#_values] OF CONTROL PROCESS;
     MODEL;  ITERATE
                RECEIVE await(MY_INDEX);
                END ITERATE;
             END MODEL;
     END CONTROL PROCESS;
```

Figure 3

* Communication among asynchronous message transmitters and receivers requires a transmission controller that is able to store messages that have been sent but not yet received and requests for messages which have been lodged but not yet satisfied. In DDN, an idealized controller, called a *link*, is provided. Links hold messages and requests in (unbounded) bag data structures. Thus they do not necessarily pass messages on in the order the messages were sent, nor do they necessarily service requests for messages in the order the requests were lodged. Ports may be attached to links by a process described in Reference 14.

```
'[knowledge_source]: SUBSYSTEM CLASS'
  servicer: ARRAY [1::#_servers] OF CONTROL PROCESS;
     MODEL;  ITERATE
                request(MY_INDEX) SET TO modify OR inspect;
                SEND make_request(MY_INDEX);
                RECEIVE get_answer(MY_INDEX);
                END ITERATE;
             END MODEL;
     END CONTROL PROCESS;
```

Figure 4

transmission characteristics. Thus, in a control process, computational detail is suppressed by modelling it with a *set-to* operation which may be applied to a buffer data object and causes the buffer to assume a value prescribed in the set-to operation.

To describe the sequential message transmission characteristics of [knowledge_source] subsystems, two control process types are needed. The first, specified in Figure 3,* models the consumption of messages which arrive at the await port from the data base. This models the subsystem's operation with respect to signals sent to indicate a change of some data base entry of interest to the knowledge source. The variable MY_INDEX has a value in the range declared as the bounds of the array of control processes and is used to make each control process model distinct with respect to the buffers and ports to which it refers.

The second type of control process is specified in Figure 4. These control processes model the operation of the servicers of the incoming signals, indicating that they present requests to the data base through one of the make_request ports and wait for answers to the requests through one of the get_answer ports. Note that nondeterminism may be specified in the set-to operation by giving a logical expression which specifies the set of values which could possibly be assigned to the data object as a result of the computation modelled by the set-to operation. The control process structure of a [knowledge_source] subsystem in which #_servers is 3 and #_values is 4 is graphically represented in Figure 5.

Each model is a control program over send and receive operations on ports and set-to operations upon buffers. The control constructs are Algol-like. There are constructs for definite iteration: an "ITERATE n TIMES" construct and a "FOR ALL i IN set_of_values" construct. WHILE and UNTIL constructs are available for indefinite iteration. Since many subsystems are designed to never terminate, there is also an ITERATE construct for infinite iteration. Conditional control may be specified by the usual forms of the IF construct. There is also a generalized CASE construct which allows "labelling" of the cases with logical expressions. All of the control constructs have a nondeterministic version. For example, the construct "ITERATE n OR MORE TIMES" may be used to indicate that the number

* The quoted prefix attached to the control process textual unit in Figure 3 indicates that this textual unit is intended to be an additional part of the definition of the [knowledge_source] subsystem class. This prefixing construction allows selective modification of a DREAM design description, thereby permitting incremental elaboration of a software system's design.

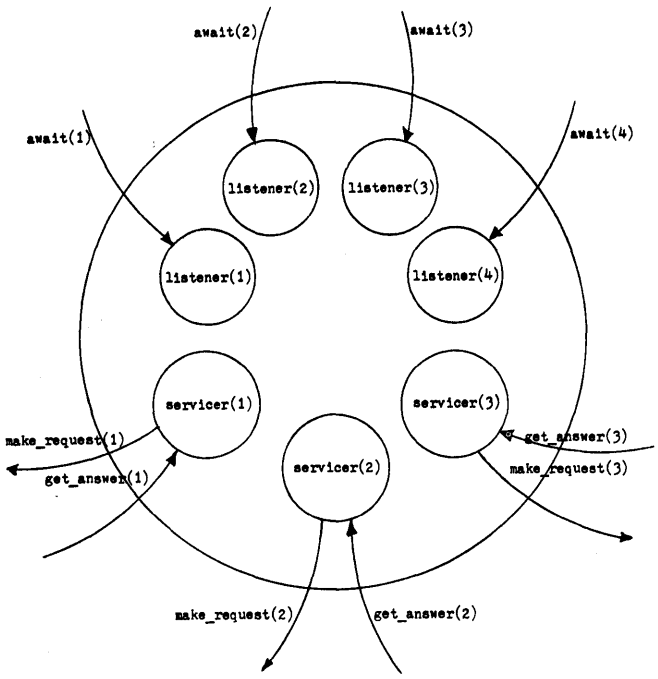

Figure 5

of times, while known before iteration begins, can be any number greater than or equal to n.

GLOBAL BEHAVIOR

The facilities provided by a subsystem generally cannot be used in a totally arbitrary order. For example, the facility which a file system provides for opening a file must be used prior to the facilities for reading and writing the file. Thus there are correlations between what happens in one sequential message transmission and what may happen in another sequential message transmission.

This global behavior may be specified in terms of *events*, activities that may be observed external to the subsystem. Usually an event is the transmission of a message through a port, and thus may be identified as the execution of a send or receive operation in one of the control process models. In general, an event may be associated with the execution of any one of the instructions in a control process model. (Since control process models are used as part of the behavior description of a subsystem, they are known to an external observer.)

```
'[knowledge_source]: SUBSYSTEM CLASS'
   listener: ARRAY [1::#_values] OF CONTROL PROCESS;
      MODEL; ITERATE
         hear:   RECEIVE await(MY_INDEX);
                 END ITERATE;
             END MODEL;
      END CONTROL PROCESS;

   servicer: ARRAY [1::#_servers] OF CONTROL PROCESS;
      MODEL; ITERATE
         start:  NULL;
                 ITERATE WHILE PERHAPS
                    request(MY_INDEX) SET TO modify OR inspect;
         ask:       SEND make_request(MY_INDEX);
         get:       RECEIVE get_answer(MY_INDEX);
                    END ITERATE;
                 END ITERATE;
             END MODEL;
      END CONTROL PROCESS;
```

Figure 6

```
'[knowledge_source]: SUBSYSTEM CLASS'
   EVENT DEFINITIONS;
      consult: SEQUENCE(ask, get),
      hear_and_do_something:
            SEQUENCE(hear, start, REPEAT(consult))
      END EVENT DEFINITIONS;
```

Figure 7

Global behavior is specified by defining a set of sequences of events. Note that this is what was accomplished procedurally via the control process models—each model defines a set of sequences of message transmissions where each sequence corresponds to an execution of the model. For the non-procedural specification of behavior, formal language theory provides several techniques since the set of events may be considered to be an alphabet and a behavior is then a language over this alphabet.[10]

Two aspects of global behavior—one being required for correct operation and the other corresponding to a design decision—need to be specified for [knowledge_source] subsystems. First, a servicer must not interact with the data base until after it has been activated by a signal indicating that an entry in the data base has changed. Second, the interactions with the data base must be ordered such that no request from any of the servicers is lodged until the previous request has been answered—the servicers must coordinate their interactions with the data base so that they utilize its facilities in a subroutine fashion.

To describe this behavior, we first define some events as indicated in Figure 6. The statement labels define names for events which correspond to the execution of the labelled statement. Note the use of the NULL instruction to allow denotation of the event "a servicer starts a sequence of interactions with the data base."

More macroscopic events are needed to conveniently define the global behavior. These are defined by the textual unit shown in Figure 7. The REPEAT operator denotes that the consult event may be repeated zero or more times. The SEQUENCE operator denotes that the events which are its arguments are sequenced in the specified order. Thus, the hear_and_do_something event corresponds to a signal ar-

      MUTUALLY EXCLUSIVE
         (consult, [knowledge_source]|consult)
      END DESIRED BEHAVIOR;
```

Figure 8

riving from the data base and the subsequent interactions of a servicer with the data base.

Using these events, the global behavior may be specified as in Figure 8. The first part of the specification indicates that hear_and_do_something events may proceed in parallel up to the limit imposed by having only #_servers servicers. The second part indicates that interactions with the data base are mutually exclusive, i.e., ordered in time.

This example has used only a portion of the facilities available in DDN for behavior specification. Events may be associated with other aspects of a subsystem's operation, more complex relationships among events may be defined, relationships between events defined for different subsystems may be established, and events which are not associated with any computational part of the system may be defined. A complete description of DDN facilities for behavior specification is given in Reference 15.

CONCLUSION

The modelling scheme presented in this paper allows the abstract description of a collection of concurrent processes (a subsystem). Models in this scheme describe the interactions which may take place between a subsystem and other subsystems. A model therefore provides a specification for a subsystem which describes its behavior in relation to its environment but hides the subsystem's operational detail. A model consists of a definition of the subsystem's interface, a procedural description of legal usage of the interface and a non-procedural description of the legal usage of the subsystem over time.

Models in the scheme are rigorous, unambiguous specifications of the components within a software system. At the very least, the models serve to record the facilities which each component is to exhibit and the manner in which these facilities are to relate. The models provide, therefore, specifications which may be used to guide the eventual implementation of the components.

The models may also be used in the formulation of arguments as to the appropriateness of a system's design. While general techniques for formal verification cannot be defined, both simulation and analytic techniques can be used to derive information concerning the dynamic characteristics of the interactions among the subsystems.[22] The designer may then use this information to determine whether or not the specified desired behavior is actually achieved or to uncover situations in which the desired behavior is not achieved. This allows the designer to make corrections before proceeding and to proceed with increased confidence in the validity of the design.

We have found the modelling scheme to be convenient for the description of a variety of software systems.[23-27] We feel that it demarcates an important set of facilities which are required for the specification of software systems and that it will prove to be valuable as a basis for a variety of tools to aid designers of large-scale software systems.

INTRODUCTION

Computer-based systems that perform sophisticated tasks in the face of challenging and variable environments are being developed in increasing numbers. Among the examples that can be cited are space exploration modules, highly automated weapon systems, and data-base management systems. The design and development of systems of this class involve many difficulties, and no generally accepted, successful methodology for the task is available.

This paper proposes a contribution to such a methodology in the form of a model that is believed to be generally applicable to the construction of interactive systems. The model is based on the identification of key features common to such systems. These features will be described first. To illustrate the concepts involved, running examples of a large timesharing operating system, and a robot driving an automobile in traffic will be used. Later, applications of the model to the design of microprocessor systems and multilanguage processing systems will be discussed.

INTERACTIVE SYSTEMS

Interactive systems are complexes of people, hardware, and software, performing a set of well-defined *tasks*. These tasks are subject to, or initiated by, conditions met in the *environment,* and are carried out under general *performance objectives*. A timesharing operating system has an environment consisting of user-manned terminals and other peripheral devices, and its tasks are the standard types of user requests. A robot chauffeur has an environment consisting of its passengers and the world outside the car, including roads, other cars, traffic signals, parking areas, and so on. Some of its tasks are starting, entering and leaving traffic lanes, parking, and obtaining fuel. Performance objectives for the robot include safety, comfort of passengers, and obedience to traffic regulations while for the timesharing system they include response time, throughput, and reliability.

As these examples show, tasks are the standard components of system activity. Tasks are refined by breaking them down into common *subtasks,* which are further decomposed until they result in relatively low-level units called *actions*. For example, the robot chauffeur's activity is expressed in terms of actions such as turning the ignition on or off, accelerating, steering and braking. These actions are the elements of the subtasks of turning a corner, obeying a traffic signal, occupying a parking place, and so on. Actions in the case of the timesharing operating system include compiling a program, searching a directory, or moving a block of data to permanent storage. Actions require *resources* for their execution. For example, an action for the operating system may be programmed as a machine language subroutine, but a processor and some core memory must be assigned in order that the action can be performed.

An interactive system may also receive assignments of unfamiliar tasks which must be carried out by *plans*—combinations of standard tasks which are formulated during the operation of the system. A plan will require a decision as each task is completed about the next task to be undertaken. A plan is needed by the robot chauffeur for an auto trip to an unfamiliar destination, while the operating system needs a plan for a large job, involving a number of tasks which must be completed quickly with minimum disruption to other system users.

An interactive system has *input* from, and *output* to, its

* The research reported here was supported by the National Science Foundation under grant MCS 76-07682.
** On leave from the American University.

environment. Input may include tasks, as well as data about the conditions in the environment that are involved in executing tasks. For example, users of the timesharing system can input requests, while the robot chauffeur may sense traffic conditions. Output may modify the environment or provide information related to tasks. The operating system may output an error message; the robot chauffeur may turn on the automobile's headlights.

Finally, an interactive system must store and maintain access to a considerable amount of *information*. Some of this information is general, concerned with the set of tasks and their translation into actions the system can execute. Another part of this information is environmental data—e.g., automobile traffic conditions for the chauffeur and job mix for the operating system. Yet another part is information which must be maintained about the states of the various parts of the system as well as planning information. The former might refer to the status of a task for a particular user of an operating system, while the latter might refer to information to be used to determine how well the chauffeur is performing an unfamiliar task assigned to it.

METHODOLOGY

In constructing a complex interactive system, one must find adequate solutions for three major aspects of system organization. First, the execution of system tasks must be controlled. The actual course taken in completing a task depends on the particular conditions met in the environment; and it can be recognized that the control problem is a substantial one. Second, the information needed by the system must be managed so as to be available when needed. And third, system resources (such as memory and processor time for an operating system) must be managed.

A complex interactive system must be organized into logical parts, and this must be done so as to meet two conflicting constraints. For economy, costly resources must be shared by system elements wherever possible, and functions that are the same should not be duplicated. But for effective performance, the parts should be as independent as possible, so as to avoid unnecessary communication and to keep down competition for resources, both of which add to the cost of overhead. A good trade-off between independence and sharing must be found if the design is to achieve performance objectives at reasonable cost.

One approach that has been used in constructing complex systems may be called *bottom-up*. Development begins with small elements that handle critical details of the system's operation. Larger aggregates are formed using these parts, and the process is continued. The resulting system is structured in layers, each with a particular capability; the top layer handles the tasks in the form that the system receives them. In the case of an operating system; this type of layered structure has been called a *hierarchy of virtual machines*.[1] This type of hierarchy can also be realized by an approach called *top-down* which starts with a gross description of the system and calls for successive refinement until the small critical elements of the system are reached.[2] The difficulty with the former approach is that considerations of performance and economy do not enter in the early stages of the development, and the early decisions may well make it impossible later on to achieve performance objectives economically. While this difficulty is removed in the latter approach, it is hard to apply unless one has a good understanding of how the system operates.

Another approach to construction is to dissect the system into *modules*, which operate independently except for well-defined controls and intercommunication; see e.g., Parnas.[3] The problem of the designer using this approach is to specify modules that require little duplication of information and low-level functions, and that can share resources to an appropriate degree. Useful guides to the choice of such modules do not seem to be available.

The proposed approach to modularization is intended to provide a guide or model of general applicability. Called *structural decomposition*, it derives from work on artificial intelligence.[4–7] It leads to breaking up the system into modules that either directly execute some action, or else support its execution. Support may take the form of control, allocation of resources, or management of information.

An important feature of the model is its separation of the short-range, intermediate-range, and long-range aspects of control. Short-range control is involved in executing and supporting individual actions. Intermediate control relates to the determination of the next action to be called when the outcome of the current action occurs. Long-range control arises in planning how to carry out assignments of unfamiliar tasks in terms of known tasks, in adapting the system to changes in the environment, or in otherwise modifying the system. Separation of control in this way reduces the average frequency of communication without restricting the kinds of communication that can take place, and can therefore lead to lower overhead.

Handling input and output in interactive systems often presents technical difficulties. Thus, the model places communication with the environment in a separate module.

STRUCTURAL DECOMPOSITION

An interactive system is constructed out of numerous components, with well-defined interfaces. Some parts are hardware, others are software; they are likely to be human components also. Hardware is usually specific to the particular type of system, but the other aspects of the modules that make up the system are being discussed. For the purposes of this exposition, it is irrelevant whether they are realized in software, firmware, or people.

The proposed approach to the design of such systems is to break them down into elements in a particular way. *Structural decomposition* implies that each module corresponds directly to some aspect of executing the task as a series of actions. The decomposition proceeds in stages, each stage refining the parts identified in the preceding one, until the system has been expressed as off-the-shelf elements.

The first two stages of this decomposition are general enough to serve as a model for a wide class of interactive systems. The description of these stages will emphasize the role played by each part in carrying out tasks, and also the communications between parts.

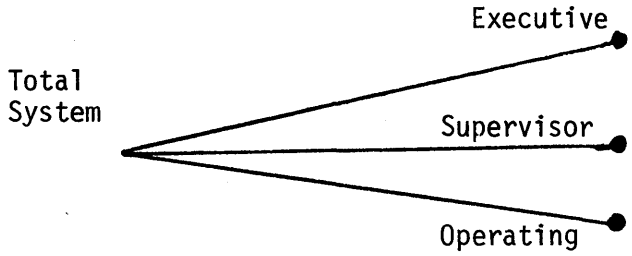

Figure 1—The first stage decomposition

At each stage, a specification for each part, the communications it receives and the communications it issues is determined. This specification guides the further refinement of the part, considered as a finite-state machine.

The first stage

The initial decomposition of the system is into parts that deal respectively with the long-range, mid-range and short-range aspects of activity. These parts are known as the *Executive, Supervisory,* and *Operating* components (see Figure 1).

The Executive is responsible for changes to the system, including both structural modifications and adjustments to adapt to variation in the environment. (This component usually is realized at least partly by a human administrator, but since changes to the system as initially put together are inevitable, the design should make explicit provision for them.) The Executive plans the expression of new tasks, if any, in terms of simpler tasks already known to the system. It also handles system start-up.

The Supervisor's job is to translate tasks into sequences of actions. It does this by initiating the next action on the basis of the outcome of the action just completed. The Supervisor also maintains knowledge of the current status of the system's tasks.

The Operator handles input from and output to the environment. Also, it carries out the actions called for by the Supervisor, making available resources and supporting functions as required. It keeps information pertaining to the environment and to the status of resources.

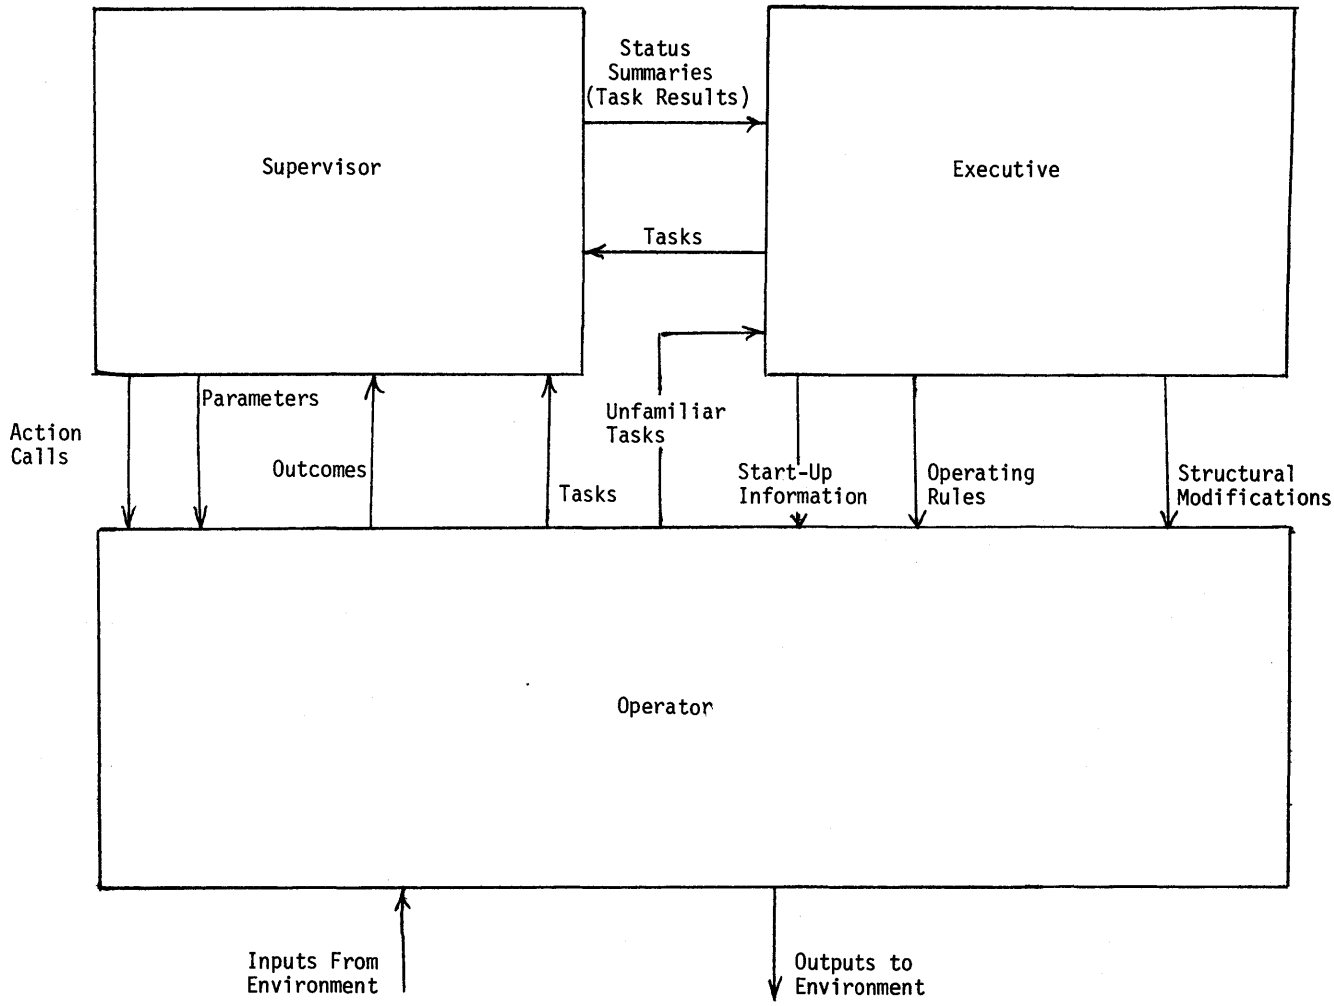

Figure 2—Communication in the model

Communications between these components must take place (see Figure 2). The Operator transmits to the Supervisor any tasks that it recognizes among the inputs from the environment. It also reports the outcome of each completed action, including any status information needed for specifying subsequent actions.

The Supervisor calls on the Operator for each action as appropriate, and provides the parameters that particularize the action to the current situation. Also, it provides to the Executive status summaries needed for the decisions the Executive makes.

The Executive supplies the Operator with start-up information, adjustments in operating rules, and structural modifications, as these become appropriate. If necessary, it passes to the Supervisor the task knowledge for handling a new task.

The second stage

Each of the components of the first stage is itself decomposed into parts. Among those parts are certain active elements that perform special functions. Such elements are known as *processors,* and indeed they may be realized by microprocessors; on the other hand, their functions may be supplied by programs that share general processing units. At the level of this discussion, it does not matter which way the element will be implemented. Also, it is possible that a processor is busy when a new call for its function arises. In such a case, the processor is assumed to have its own queue.

The "knowledge" or "information" used by the components has already been mentioned. The data structures that embody the knowledge are identified elements of the components in the second stage.

The Supervisor consists of a *task processor,* an *action sequencer,* and two data structures—the *task knowledge* and the *task status.* When a task is received from the Executive or the Operator, or when the latter reports the outcome of an action, the task processor updates the task status and determines the next action to be called. The task knowledge is used in this process. If the new action must wait for attention along with others already called, the action sequencer decides its place in the line. The task processor passes the results of tasks to the Executive.

The Operator contains an *input/output processor,* a set of *action processors, support units,* and *environmental data.* The input/output processor handles inputs from the environment, in the light of task status information received from the Supervisor, and recognizes tasks, as well as task-related data to be added to the store of environmental data. The processor also issues output to the environment as directed by the Supervisor. The action processors execute actions, using environmental data and task status information; outcomes are reported back to the Supervisor. The support units make their resources available to the processors, manage the environmental data, and do low-level scheduling when necessary.

The Executive has a *planning unit* and *decision information.* The planning unit can express a novel job in terms of

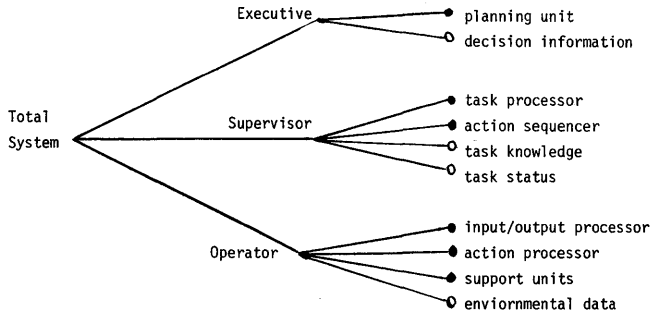

Figure 3—The structural decomposition

tasks that the Supervisor is able to manage, and it directs the sequence of such tasks, calling each new one in light of the result obtained in the current one. In the process it uses its decision information, which includes measures of performance objectives and summaries of past experience. A task result may also indicate that rules in use by the Operator need modification, or even that some Operator element should be replaced, and the Executive will then issue the necessary change.

The diagram in Figure 3 summarizes the structural decomposition arrived at in the second stage. Solid dots represent active modules, and open circles represent information elements. Active modules may themselves be constructed by applying structural decompositions to them.

Actions

As mentioned earlier, the concept of action is central to the approach being discussed. An action is an atomic unit of activity that occurs in many tasks. It is executed when it has been supplied with the resources and information it requires, and it continues until it reaches some appropriate termination point. (This is in contrast to the notion of process, used in many software systems. A process can be interrupted at arbitrary points, and resumed later. The interruption incurs an overhead cost in storing the process state and restoring it when it resumes.)

In effect, actions are the operations in terms of which tasks are programmed. The choice of the set of actions for a system is a fundamental part of the effort of constructing the system. An action should take a reasonable number of the basic clock cycles of the system. This is because each action initiation involves the Supervisor, and also requires that resources and information be supplied; the longer the duration of the action, the smaller is the ratio of system overhead to task execution. On the other hand, no action should be allowed to hold on to its resources so long that other requirements of the system are affected adversely, and this condition will set a limit to the duration of any action.

Actions should be general, so that they can respond to the variations in the environment. The Supervisor, when it calls for an action, supplies the parameters that specialize the action to the current situation.

The example in Table I, representing a very small part of the task knowledge needed by a robot chauffeur, serves to

TABLE I.—Subtask: ENTER AT (entry point) AND STOP AT (type of stopping place)

Action	Parameters	Outcome	Next Action
seek	entry point type	not yet found	seek (entry point)
		found	enter
		blocked	(terminate)
	stopping place type	not yet found	seek (stopping place)
		found	park
		not available	(terminate)
enter	entry point	not yet done	enter
		done	park
		accident	(terminate)
park	stopping place	not yet done	park
		done	(terminate)

show how a subtask might be expressed in terms of actions; and how the actions are particularized by parameters. The subtask calls for the robot to enter some specified type of location—parking lot, service station, driveway and so forth—arrived at in a previous subtask; after entering, it is to park in an appropriate spot.

The action *seek* requires that some place in the immediate environment be found that matches the type description given in the task knowledge. Therefore, the action is executed by the I/O module rather than some other processor. If the time allocated for the action is insufficient for it to find the place, the action *seek* may be continued. The subtask is terminated when the car has been parked, or when completion has become impossible. In either case, a new subtask will be determined by the Supervisor.

EXAMPLES

The application of the interactive system model to the design of a robot chauffeur has been outlined above in general terms; for further details, see Reference 7. The model has also been applied to the development of a timesharing operating system,[8] and a brief description of this application will be given.

An operating system

The environment of the operating system, as mentioned earlier, are users at terminals, and other peripheral devices. The tasks are job requests issued by users. The environmental data are user program and data files—both temporary and permanent. Examples of actions, in addition to those given earlier, are running as much of a user program as can be completed within an allowed time quantum, and inputting and outputting lines of text at terminals.

System functions are handled by the support units of the Operating component (called the Interface in the reference cited). These functions include managing core memory; allocating I/O channels, buffers, and similar resources to actions that require them; and scheduling processors to execute actions.

The Supervisor at any time is controlling the carrying out of each user's current request. When it calls an action, the call is placed on an action queue, according to its priority, by an action sequencer. The action call waits until it has received the processor, core memory, and other resources needed for its execution. The action program then carries out the action, reports the outcome to the Supervisor, and releases resources that are no longer needed. The Executive (called the Policy component in this application) can modify scheduling and other system rules to adjust to workload changes. The system administrator, who is treated as part of the Executive, can plan the handling of unusual jobs.

To illustrate the task knowledge for such a system, consider the subtask *Open* (file, access) which can be used to open a file. The following actions comprise the subtask:

transfer (file part, buffer)—transfers the next portion of the indicated file into a buffer allocated by the system.
search (buffer, file descriptor, access)—searches the buffer area to find a file descriptor. If present it determines whether the user has the indicated access right.
output (message)—prints the indicated message on user's terminal.

A representation of a simplified version of the subtask in terms of the above actions is described in Table II; the initial action is *transfer*.

TABLE II.—Subtask Open (file, access)

Current Action	Parameters	Outcome	Next Action
transfer	next portion of directory, buffer	transferred	search (file, access, buffer)
search	file, access, buffer	found and access okay	output ('OPENED')
		found and access not okay	output ('ILLEGAL ACCESS')
		not found	transfer (next portion of directory, buffer)
		EOF	output ('FILE NOT PRESENT')
output	message	outputted	—

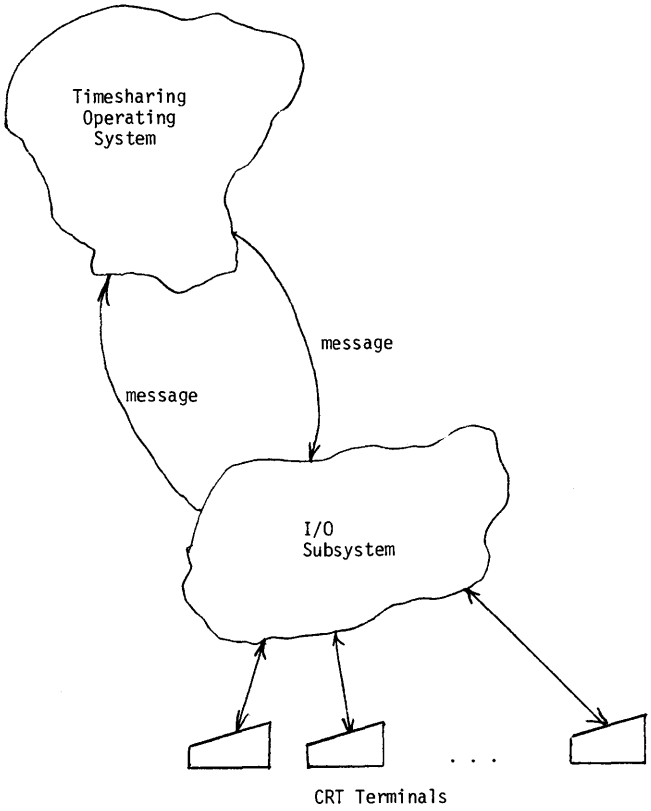

Figure 4—The I/O subsystem

A microprocessor system

As another example of the use of the model, a microprocessor system will be discussed (a more general microprocessor system is described in Reference 9). It is believed that the proposed model with its attendant concept of actions allows a methodology for the integration of hardware and software in a natural way. One example of this is in the realization of actions—an action may be dedicated to one microprocessor (or specialized piece of hardware), or several similar actions may be assigned to one microprocessor.

Consider the I/O terminal subsystem in Figure 4 that has been factored from a timesharing operating system in order to meet certain performance objectives (e.g., efficiency). Lines of input from CRT terminals are considered as messages to be transmitted between the operating system and the I/O subsystem. The subsystem itself can be decomposed applying the model. The Supervisor for such a system would take signals from the terminal, considering them as tasks, and would translate them into actions which would be executed by the Operator component. An Executive component could conceivably be used to regulate I/O traffic.

Many designs and implementations exist for such a subsystem along with their attendant opportunities for parallelism. A simplified hardware/software realization of the I/O subsystem using microprocessors is given in Figure 5. It has been assumed that the number of terminals is so large that it is infeasible to have the I/O subsystem share a processor with other parts of the system. Here there are only two components of the model—the Supervisor and the Operator. The Supervisor has a dedicated microprocessor since it must handle requests from terminals as well as outcomes of action executions. Each action has a dedicated microprocessor since many terminals may be requesting service at the same time. Thus at any given time each action microprocessor can be handling different parts of tasks issued from several terminals and the operating system. Other elements of the configuration include a decoder/router for routing action calls from the Supervisor to their respective action queues, an I/O bus and a random access memory.

The I/O bus requires two message formats—the I/O Supervisor format (see Figure 6) and the random access memory format. There is one sub-format for tasks and one sub-format for outcomes. Tasks are issued by the timesharing operating system or by a CRT terminal, while outcomes are the results of action executions.

During regular operation, terminals signal the system by placing an *Input* task on the I/O bus in Supervisor format. The task is recognized and placed on the Supervisor queue. When the task gets to the head of the queue, the Supervisor issues the first action call in the action sequence that comprises the task (see Table III).

In this case, the first action is *transfer* which transfers a message (synchronously) from the specified terminal to an internal buffer. The next action *check* determines whether the message is a command or a data item. If it is a legal command, it is *sent* to the operating system for execution, if not *transfer* outputs an error message to the appropriate terminal. If a data item is encountered, then *add* makes it the next line of the user's workspace.

The Supervisor determines the next action for a task on the basis of the outcome of the present action for this task. At any point in time an action microprocessor can be processing an action call obtained from the head of its action queue. When finished, the outcome is placed on the I/O bus

TABLE III.—Input (terminal)

Current Action	Parameters	Outcome	Next Action
transfer	terminal, action	transferred	check (buffer)
check	buffer	command	send (buffer)
		illegal command	transfer ('ILLEGAL COMMAND', terminal)
		data	add (buffer, workspace)
send	buffer	sent	
transfer	buffer, workspace	added	
		overflow	transfer ('WORKSPACE OVERFLOW', terminal)

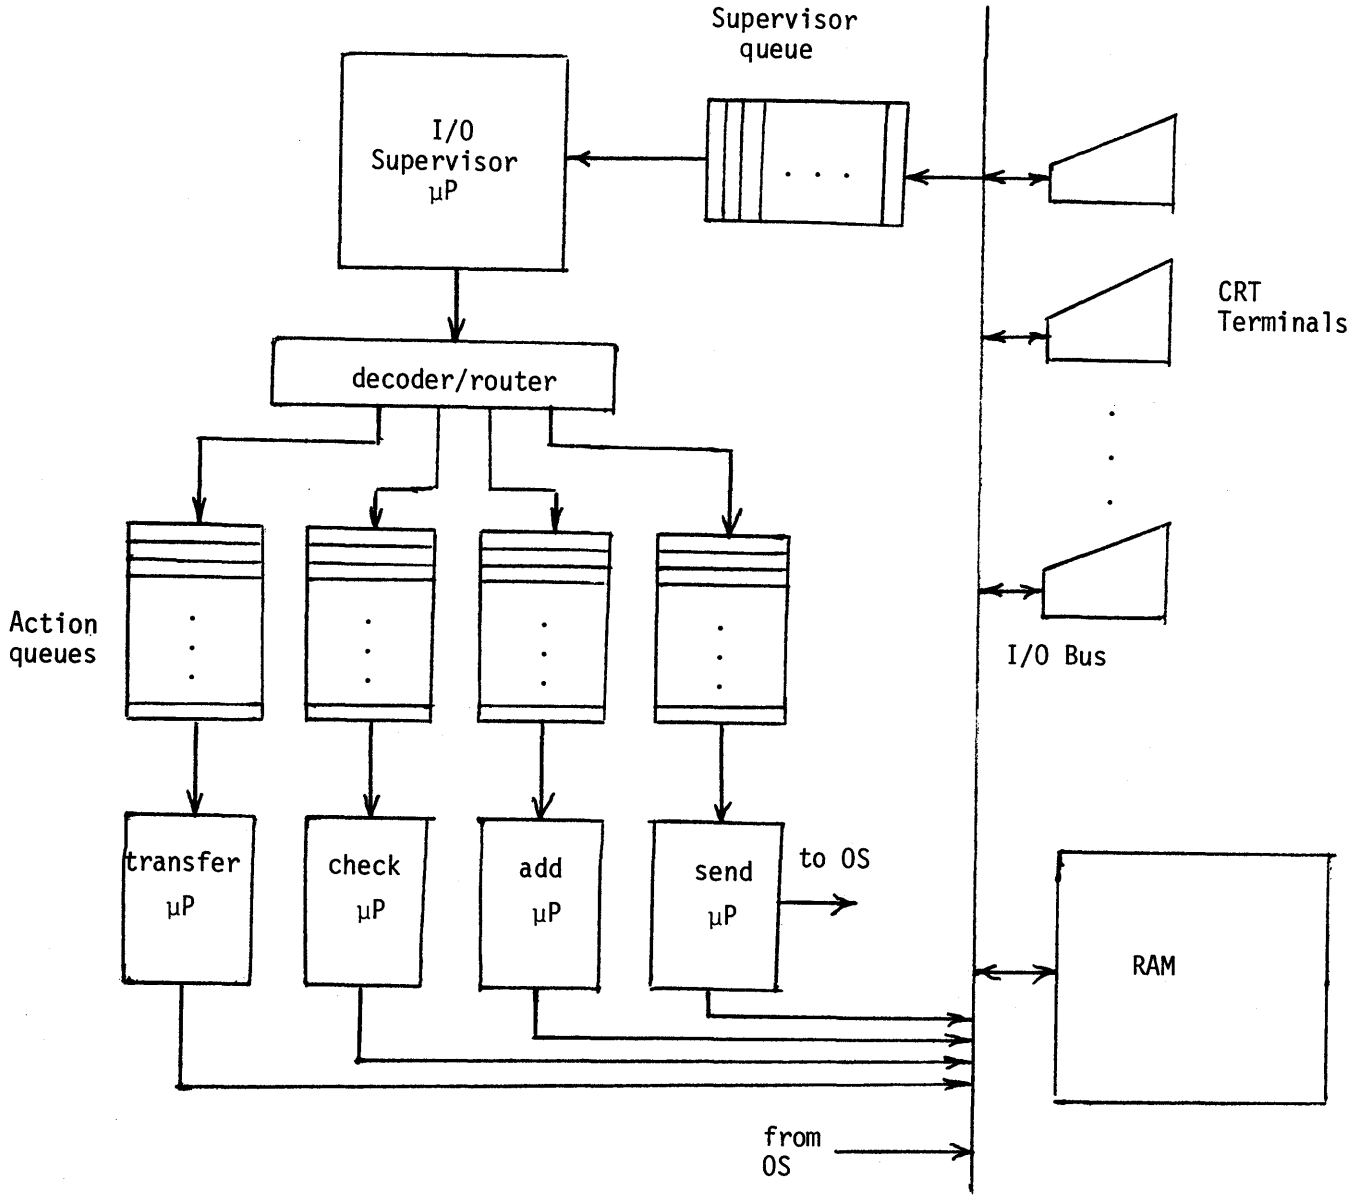

Figure 5—A hardware/software realization

and a new action call is obtained from the associated action queue. The system recognizing that the information on the bus is an outcome, puts it on the Supervisor queue. Eventually the Supervisor removes this outcome from its queue, and examines the associated task data structure to determine which action call to issue next.

0	task code	terminal no.

1	outcome code	terminal no.

Figure 6—I/O bus sub-formats

The action *transfer* is a bit different from the others. It essentially initiates an I/O operation; when the operation is complete, the associated terminal places the outcome on the I/O bus. The Supervisor of the operating system can forward a task to the I/O subsystem in an analogous way by placing a call on the I/O bus. The outcome can be returned to the Supervisor of the operating system through the *send* action.

A multi-language processor

As a final example, the application of the model to the design of a processor which executes a user's program written in an arbitrary combination of programming languages will be discussed. The model provides a natural framework

in which to realize such a processor. As a prelude, the utility of a multi-language system will be elaborated on.

Being able to write a program in a programming language suitable to expressing the solution of a problem in a straightforward manner is very desirable. String processing algorithms are easily written in SNOBOL, algebraic and vector computations are easily represented in APL, and input/output operations are most effectively specified in PL/I. Since a universal programming language which can do all of these things well is impractical at this time, it is desirable to be able to use statements from a variety of languages to express a given algorithm.

The usefulness of this approach is particularly evident in the following program segment which contains PL/I and APL statements:

```
IF x¬=0 THEN Y←+/Z1×W;
        ELSE Y←+/Z2×W;
PUT DATA (Y);
```

When Z_1, Z_2 and W are conformable matrices, even this simple two line segment is difficult to program in either PL/I or APL. It is difficult in PL/I because (1) vector operations are not available, (2) PL/I subroutines for APL operations require a different syntax, and (3) PL/I subroutines do not return arrays as values. It is difficult in APL because the equivalent of PUT DATA naming each element would require the user to generate the names of each element.

The proposed model offers a means to realize such an approach in a natural way. Consider an interactive timesharing system with a subsystem able to handle interpretively user programs written in arbitrary combinations of programming languages. Here the operating system is used to create programs, store and retrieve files, provide I/O capabilities, etc. The subsystem is invoked as an action *interpret* applied to a user program.

The subsystem consists of a Supervisor and an Operator. The Supervisor calls upon actions executed by the Operator which (1) provide a generalized fetch-execute cycle for several language processors, and (2) directly execute [10] statements in these languages. Here, then, operations such as add and compare are no longer the basic units of computation; statements in specific languages are the basic units of computation. Thus, given an assignment statement

```
X=A*B+C/D
```

in a program file which is tagged with some language specific information (e.g., language type), an action sequence controlled by the Supervisor gets the statement from the program file, identifies the indicated language, computes the expression and performs the assignment.

Variables and data structures must be specified in such a way that the meaning of each statement is unambiguous, even if it may be interpreted in more than one language. Each action can have more than one outcome. If an action associated with a statement in a particular language executes properly, it may, for example, assign a value to a variable or indicate the next statement to be executed. Otherwise, it may fail to parse or encounter execution difficulty; either of these will cause a return to the operating system.

CONCLUSION

This paper has presented a model and methodology for the construction of interactive systems. Its usefulness has been shown in its application to realizing timesharing operating systems, robot-chauffeured automobiles, microprocessor systems and multi-language processor systems. It is felt that a structural approach of this nature is necessary in managing the complexity of the decomposition of large interactive systems.

Software fault-tolerance in the Pluribus

by JOHN G. ROBINSON and ERIC S. ROBERTS
Bolt Beranek and Newman Inc.
Cambridge, Massachusetts

INTRODUCTION

Over the past decade, the decreasing cost of minicomputer components has encouraged the use of multiprocessor techniques in the design of high-speed, cost-effective computer systems. Multiprocessor architectures have two principal advantages over conventional single-processor designs. First, a multiprocessor system can achieve greater computational speed through parallelism in its task structure. A second advantage is that multiprocessors realize greater reliability through redundancy of processing elements. This paper discusses several aspects of multiprocessor reliability as it applies to the Bolt Beranek and Newman (BBN) Pluribus system.[1]

Recent advances in processor technology, including the development of inexpensive LSI-based microprocessors, have further increased the cost advantages of multiprocessor systems and have led to the consideration of multiprocessor architectures involving very large numbers of processors. Early examples of multiprocessor systems designed around minicomputers include the C.mmp system at Carnegie-Mellon[2,3] and the BBN Pluribus. Each of these early systems has prompted the development of larger microprocessor-based systems, such as the Carnegie-Mellon Cm* project[4] and the BBN "Butterfly" machine.

THE BBN PLURIBUS

The BBN Pluribus system has been described in detail in a number of previous papers.[1,6] The Pluribus was originally designed as a reliable, modular, high-speed Interface Message Processor (IMP) for use with the ARPANET.[7] To date, eight such systems have been delivered. The Pluribus has also been used to support a real-time processing and display system for seismic data[8] and a terminal handler connecting a large number of terminals to several host computers.[9] Future applications include a high-speed version of the Satellite IMP.[10] On the whole, our experience with building Pluribus systems has been favorable, and we are currently trying to attract a more general market.

The basic organization of a typical Pluribus system is illustrated in Figure 1. Each processor bus contains a number of processing units (usually two) and associated local memory for each processor. The processors are SUE minicomputers produced by the Lockheed Electronics Corporation. Common memory (that which is accessible to all processors) is distributed among the system memory busses. The I/O bus units provide an interface to a variety of input/output devices, such as communication lines and modems in conventional Pluribus applications. In addition, each I/O bus includes a real-time clock used to coordinate processor activity and a special hardware device called a PID (Pseudo Interrupt Device) used for process scheduling. The individual busses are connected to each other via bus couplers which are indicated by the solid lines in Figure 1.

The hardware organization of the Pluribus makes it possible to achieve system reliability through the redundancy of hardware components and interconnection paths. For example, if a processor bus becomes unusable through hardware failure, the remaining processor bus(ses) will generally be able to provide sufficient computational power to run the system. Similarly, if the connection between a processor and common memory bus is lost, the system can proceed normally by removing either of the two busses from the operational system.

RELIABILITY IN THE PLURIBUS

Fault-tolerant computer techniques originally arose in response to the unreliability of early digital hardware.[11] Historically, the principal concern of fault-tolerant system design has been with completely error-free system operation. The classical technique used to provide reliability at this level is to include three or more instances of each system component; each component performs each calculation simultaneously. Additional hardware is then used to check the individual results for correctness, relying on a majority decision in the case of a discrepancy.

The notion of relaxed reliability

Most of the past research in reliable computer system architecture has been directed toward applications in which completely fault-free operation has been necessary. In designing the Pluribus, we have been concerned with applications whose reliability requirements are much less stringent. We have found that these applications suggest a

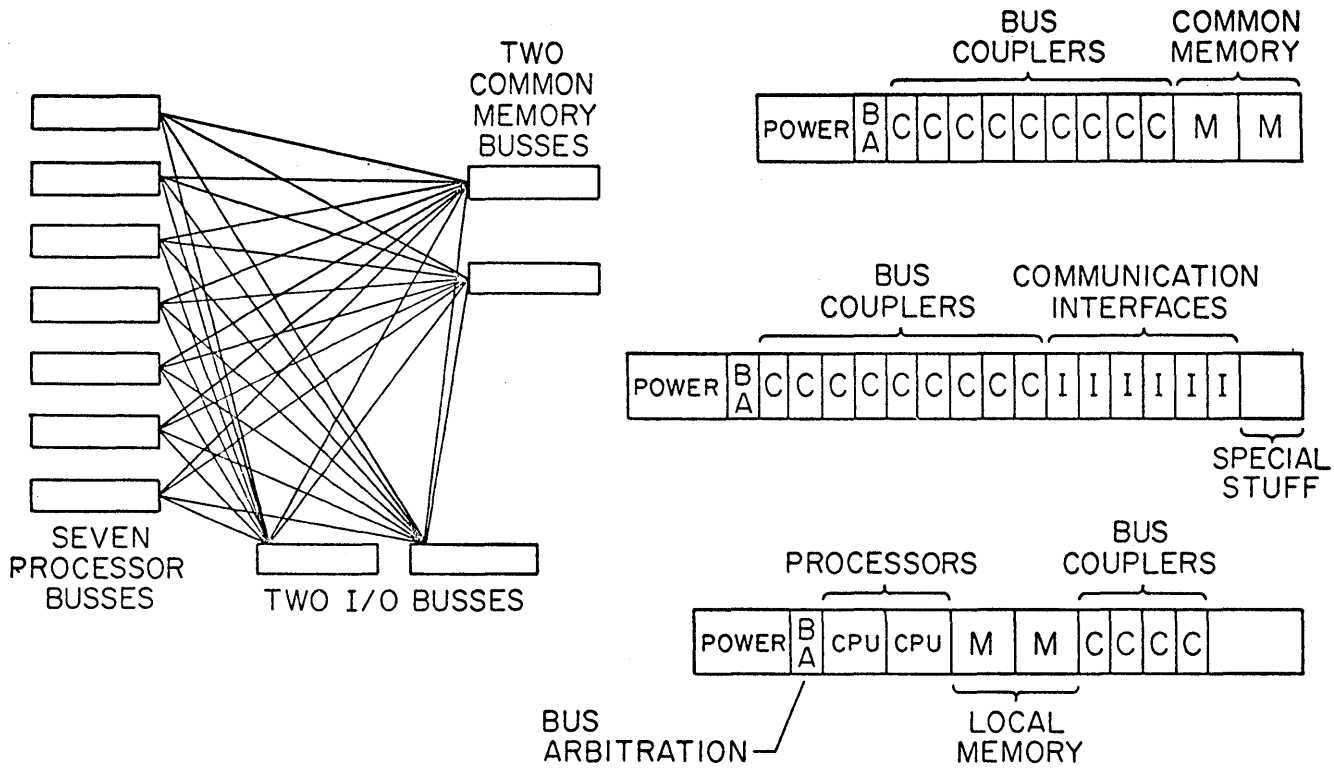

Figure 1—Typical Pluribus System Configuration

relatively new set of techniques and that many of the classical approaches to fault-free reliability do not directly apply.

In the Pluribus, we have not been as concerned with continual error-free operation as with providing maximum system availability. In the environment of a communications network, for example, it is desirable to keep each node functioning even if data is lost during a failure-induced transient. A communications network is characterized by a relatively steady-state operation which is largely independent of all but the most recent network activity. If a node in the network is forced to reinitialize, some active message traffic will generally be lost, but the node will very quickly be able to handle new messages in a normal fashion. This property of the communications network makes a relaxed reliability mechanism very attractive in that the continuity of system operation can be insured without incurring the cost of a more elaborate hardware reliability scheme.

We feel that the relaxed reliability model is widely applicable in other areas. For example, by enhancing a general-purpose operating system with checkpointing facilities, it should be possible to create an environment where such approaches to fault-tolerance may be used to advantage. The techniques used in the Pluribus should permit such a system to reconfigure following a failure and automatically resume normal operation from the previous checkpoint. In the network environment, checkpointing is not necessary since there is no long-term context to be saved. A system with checkpointing approximates the network environment by providing a clean state (the previous checkpoint) at which operation can resume.

Relaxed reliability in the Pluribus

Unlike most conventional systems, the principal responsibility for maintaining reliability in the Pluribus is placed on the system software rather than in the hardware structure. The Pluribus hardware was designed to provide an appropriate vehicle for the software reliability mechanism. When hardware errors are detected, the software exploits the redundancy of the hardware by constructing a new logical system configuration which excludes the failing resource, using redundant counterparts in its place.

Pluribus systems make use of redundancy in their software structures for much the same reason. Redundant information is intentionally introduced into the data structures at various points and checked by processes operating upon those structures. An example of this technique applied to buffer structures is described later. In addition, periodic background processes are used to recompute certain variables which are maintained by the operational system. If the recomputation uncovers a discrepancy, the variables are fixed or a more drastic recovery is attempted.

In many cases, a failure is not detected at the exact time of occurrence but at the time that the software encounters some failure-induced discrepancy. By this time, the effects of the failure may be more widespread and the actual cause of the failure may be difficult to detect. In such cases, the system is not able to perform instantaneous recovery and seeks instead to restore normal operation as quickly as possible.

The value of software reliability

Our experience with the Pluribus has convinced us that fault-tolerance need not be expensive, provided complete fault-free operation is not the goal. Pluribus hardware can be configured for redundancy by including one extra copy of each critical system resource (i.e., one extra processor bus, one extra memory bus, and so forth). In general, software reliability mechanisms are highly flexible and are largely independent of the application routines.

As a result of placing the responsibility for system recovery on the software, Pluribus systems are capable of surviving (or isolating the effects of) a wide variety of intermittent failures and design errors in either hardware or software. Diagnosis of the failures can often be accomplished while normal operations continue.

THE PLURIBUS OPERATING SYSTEM

This section discusses the organization of the Pluribus operating system and some of the techniques used for achieving coordination of multiple processors. These techniques are further explored in later sections, which provide two examples of Pluribus fault-tolerant software strategies. One of these examines the Pluribus IMP buffer system in detail, and the other covers strategies for understanding failures when they occur and effecting necessary repairs.

General responsibility of the operating system

The software reliability mechanisms for a Pluribus system are coordinated by a small operating system (called "Stage") which performs the management of the system configuration and the recovery functions. The overall goal of the operating system is to maintain a reliable, current map of the available hardware and software resources. The map must include accurate information not only about the hardware structure of the machine, but also about variables and data structures associated with the processes that use that hardware. Moreover, the operating system must function correctly even after parts of the system hardware have ceased to be operational. New resources, as they are discovered (e.g., because hardware has been added or repaired), should be incorporated as part of the ongoing operation of the application system.

Since any component of the system may fail at any time, the operating system must monitor its own behavior as well as that of the application system. It may not assume that any element of hardware or software is working properly—each must be tested before it is used and retested periodically to ensure that it continues to function correctly. The operating system must be skeptical of its current picture of the system configuration and continually check to see if the environment has changed.

The Pluribus operating system builds the map of its environment step by step. Each step tests and certifies the proper operation of some aspect of the environment, relying on those resources certified by previous steps as primitives. Early steps examine the operation of the local processor and its associated private resources. Subsequent steps look outward and begin to discover and test more global resources of the system, giving the checking process a layered appearance. In the Pluribus operating system, each processor begins by checking its own operation and by finding a clock for use as a time base. Once these resources have been verified, the processor can begin to coordinate with the other active processors to develop an accurate picture of the system.

At the same time, the system must balance the need for reliable primitives with the need to accomplish normal operation efficiently. When all the environment has been certified, the system should spend most of its processing power on advancing the operational algorithms and return only occasionally to the task of reverifying its primitives. When failures of the environment have been detected, however, the power of the system must be brought to bear on the task of reconfiguring to isolate the failure.

Hierarchical structure of the stage system

The Pluribus operating system is organized as a sequence of stages which are pooled by a central dispatcher. A processor starts with only the first stage enabled. As each stage succeeds in establishing a proper map of its segment of the system state, it enables the next stage to run. Each stage may use information guaranteed by earlier stages and thus may run only if the previous stage has successfully completed its checks. Once enabled, a stage will be polled periodically to verify that the conditions for successful completion of that stage continue to apply. The system applies most of its processing power to the last stage that is enabled but returns periodically to poll each earlier stage. The application system is the final stage in the sequence and may run only after the earlier stages have verified all the config-

TABLE I.—Pluribus Operating System Stages

STAGE	FUNCTION
0	Checksum local memory code (for stages 0, 1, 2). Initialize local interrupt vectors, and enable interrupts. Discover Processor bus I/O. Find some real-time clock for system timing.
1	Discover all usable common memory pages. Establish page for communication between processors.
2	Find and checksum common memory code (for stages 3, 4, 5). Checksum whole page ("reliability page").
3	Discover all common busses, PIDs, and real-time clocks.
4	Discover all processor bus couplers and processors.
5	Verify checksum (from stage 2) of reliability page code (for rest of stages plus perhaps some application routines). External reloading of missing code pages is possible once this stage is running.
6	Checksum all of local code.
7	Checksum common memory code. Maintain page allocation map.
8	Discover common I/O interfaces.
9	Poll application-dependent reliability and initialization routines. Periodically trigger restarts of halted processors.
10	Application system.

uration information of the application and the validity of the data structures.

Table I lists each stage of the Pluribus operating system, together with the aspects of the environment it guarantees. Many of the functions listed will not be discussed further but are provided to illustrate the layering of stages.

Since processors continue to perform each of the stages periodically, changes in the environment will eventually be noted. Any stage detecting a discrepancy in the configuration map will disable all later stages until the discrepancy is repaired. Then, all the later stages, which might depend on data verified by the disabling stage, will be forced to run all their checks, guaranteeing that they will make any further modifications to the configuration map necessitated by the first change. A serious failure, such as a non-existent memory interrupt, disables all but the first stage. In these cases, some reconfiguration might be needed, and all stages should perform all their checks before the application system is resumed.

Establishing communication

So far, we have described the progress of one processor through the staged checking procedures of the operating system. All processors in the Pluribus perform the same checks, since it is important that they agree about the state of the system resources. Coordination of multiple processors with potentially different views of the hardware configuration requires two mechanisms: the processors must agree on an area of common memory in which to record the machine configuration map, and they must cooperate in their decisions to modify the map.

The first step in coordinating the multiple processors of a Pluribus is to agree on a page of memory through which to communicate. The procedure for initially establishing the page for communication is clearly delicate. Prior to establishing the page, the processors have no way to communicate about where it will be. The procedure must operate correctly in the face of failures which might leave some of the processors seeing a different set of common memory pages from the rest. Processors which are unable to see the communication area will attempt to use another memory page and must be prevented from interfering with the unaffected processors.

Any processor that is first starting up (or restarting after some massive failure) can assume nothing about the location of the communication page. Any page may be used, and therefore a small area for communication control variables is reserved on each page of common memory. Part of this area is used for a brief memory test, which must succeed before the page may be used at all. Every processor attempts to establish the lowest-numbered (lowest address in memory space) page that it sees as the page through which to communicate. To be valid, any page must have a pointer to the current communication page, and the communication page must point to itself.
